

# 2022

## ANNUAL MEETING

**ABSTRACT BOOK**

**MAY 11-14**  
**AUSTIN, TEXAS**

[WWW.AUTISM-INSAR.ORG](http://WWW.AUTISM-INSAR.ORG)

## Invited, Keynote Speakers, Awards

### KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

#### 101 - Keynote Talk - Damien Fair

( *Keynote*) Developmental Cognitive Neuroscience in the Era of Big Data

*D. Fair, Masonic Institute for the Developing Brain, Minneapolis, MN*

Developmental cognitive neuroscience is being pulled in new directions by network science and big data. Brain imaging (e.g. functional MRI, functional connectivity MRI), analytical advances (e.g. graph theory, machine learning), and access to large computing resources have empowered us to collect and process neuro-behavioral data faster and in larger populations than ever before. The translational potential from these advances is unparalleled, as a better understanding of complex human brain function is best grounded in the onset of these functions during human development. However, the maturation of the developmental cognitive neuroscience has seen the emergence of new challenges and pitfalls, which have significantly slowed progress and need to be overcome to maintain momentum. Here I examine the state of developmental cognitive neuroscience in the era of networks and 'big data' and highlight the solid footing we can take forward into the future.

### KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

#### 103 - Keynote Address - Liz Pellicano

( *Keynote*) The Foundations of Autistic Flourishing

*E. Pellicano, University College London, London, United Kingdom*

At the core of all decent societies is an effort to enable all people to live full and flourishing lives. But what does a flourishing life look like for Autistic people? And how can we all help to build a foundation for such lives? In this talk, Liz Pellicano contends that answering these questions requires us to step away from key assumptions that have structured autism science for decades now. She explains the ways in which both hidden biases and methodological errors too often obscure understanding the nature of Autistic flourishing. She also traces the contours of a new scientific process, one that breaks down the distinction between 'lab' and 'life' and places Autistic people and their families and allies right at the heart of research decision-making itself.

### KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

#### 104 - Keynote Address - Joseph Buxbaum

( *Keynote*) Precision Medicine in Autism

*J. D. Buxbaum, Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY*

That autism has multiple, distinct biological causes is a concept that has existed since the earliest descriptions of autism. For more than a decade, beginning with the advent of affordable high-throughput sequencing, genome-wide studies of rare coding and non-coding genetic variation in autism have been ongoing, and have completely transformed our knowledge of the biological bases of autism. With hundreds of strong-effect autism genes identified, we are now able to translate these genetic findings into valid model systems for neuroscience. More importantly, these etiological discoveries provide a path towards precision medicine in autism. In this talk, I will summarize progress in gene discovery in autism, and give examples of, and approaches to, precision medicine that can arise from such etiological insights.

### KEYNOTE — INVITED, KEYNOTE SPEAKERS, AWARDS

#### 105 - Keynote Address - Evdokia Anagnostou

( *Keynote*) Exploring Heterogeneity in ASD: From Bench to Clinic to Stakeholder Priorities

*E. Anagnostou, Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada*

The past decade in ASD research is characterized by a concerted effort to describe and understand its heterogeneity. We will use Canadian multimodal data (structural and functional imaging, phenotypic, and potentially genomic data) from our POND network (<https://pond-network.ca/>) and others, to highlight advances in this area, within ASD and across neurodevelopmental conditions. Stakeholder experience and perspectives will be discussed to illuminate and challenge our common interpretations of such work.

## PANEL — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

### 210 - Chronic Physical Health Problems in Autistic Adults

**Panel Chair: Sander Begeer, VU University Amsterdam, Amsterdam, Netherlands**

**210.001 (Panel)** Autism and Chronic Ill Health: An Observational Study of Symptoms and Diagnoses of Central Sensitivity Syndromes in Autistic Adults

**S. L. Grant<sup>1</sup>, S. Norton<sup>2</sup>, R. F. Weiland<sup>3</sup>, A. M. Scheeren<sup>1</sup>, S. Begeer<sup>4</sup> and R. A. Hoekstra<sup>1</sup>,** (1)Department of Psychology, King's College London, London, United Kingdom, (2)Department of Health Psychology, King's College London, London, United Kingdom, (3)Vrije Universiteit, Amsterdam, Netherlands, (4)VU University Amsterdam, Amsterdam, Netherlands

**Background:** Autistic adults, particularly women, are more likely to experience chronic ill health than the general population. Central sensitivity syndromes (CSS) are a group of related health conditions, including fibromyalgia, migraine and temporomandibular disorders, that are all thought to include an underlying sensitisation of the central nervous system. Autism and CSS have substantial crossovers in their expression, including physical symptoms such as sensory sensitivity and fatigue, and psychosocial factors including anxiety, stress and trauma. Research indicates that symptomatic joint hypermobility and related conditions appear to be more common in the autistic population, and these are also related to chronic and centralised pain. However, a direct link between autism and central sensitisation has not yet been investigated.

**Objectives:** This study aimed to investigate the occurrence of CSS diagnoses and symptoms in autistic adults, and to explore whether CSS symptoms were related to autistic traits, mental health, sensory sensitivity, or gender.

**Methods:** Participants included 973 autistic adults (410 men, 563 women, mean age = 44.6y) registered at the Netherlands Autism Register, who completed questionnaires assessing autistic traits, sensory sensitivity, CSS symptoms and diagnoses, physical and mental health symptoms. The reliability and validity of using the Central Sensitization Inventory (CSI) in an autistic sample was established with exploratory and confirmatory factor analyses. Chi<sup>2</sup> analyses, independent t-tests, hierarchical regression and path analysis were used to analyse relationships between measures, age and gender.

**Results:** Factor analysis of the CSI indicated that the total CSI score provided a valid and reliable assessment of CSS symptoms in autistic adults, with a bifactor model comprising one general factor and four orthogonal factors generating the best model fit. Multigroup factor analysis indicated that the CSI was capturing the same construct in men and women, although there were some indications of differential item functioning. 21% of participants reported one or more CSS diagnosis, compared to CSS rates varying from 0.2% to 20% in the general population. 60% scored at or above the clinical cut-off for a CSS. Autistic women were more likely to report a CSS diagnosis,  $X^2(2, N = 973) = 33.68, p < .001$ , and experienced more CSS symptoms than autistic men,  $t(971) = -11.774, p < .001$ . Women also reported greater anxiety,  $t(634) = -5.809, p < .001$ , more sensory sensitivity,  $t(391) = 3.539, p < .001$ , poorer physical health,  $t(971) = 4.228, p < .001$  and lower subjective wellbeing,  $t(416) = 3.289, p = .001$ . Exploratory hierarchical regression analysis showed that sensory sensitivity, anxiety, age and gender were significant predictors of CSS symptoms,  $F(5,353) = 75.09, p < .001$ , together accounting for 50.9% of the variance in CSI scores. A path analysis indicated that sensory sensitivity and anxiety mediated the relationship between autistic traits and CSS symptoms (see Fig 1).

**Conclusions:** CSS diagnoses and symptoms appear to be very common in the autistic population. Awareness of an association between autism and central sensitisation should inform clinicians and guide diagnostic practice, particularly for women where CSS are common and autism under-recognised.

**210.002 (Panel)** Chronic Physical Health Disorders in Adults with Autism Spectrum Disorder

**J. H. Ward<sup>1</sup>, E. M. Weir<sup>2</sup>, C. Allison<sup>3</sup> and S. Baron-Cohen<sup>3</sup>,** (1)Department of Gastroenterology, Royal Devon & Exeter NHS Foundation Trust, Exeter, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, Autism Research Centre - University of Cambridge, Cambridge, United Kingdom, (3)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

**Background:**

Research has shown that autistic adults are at increased risk of chronic physical health conditions (e.g. epilepsy, gastrointestinal disorders, bone and joint disorders, arrhythmias). It is unclear whether this is due to covariance between genes for autism and physical health conditions, demographic factors (e.g., biological sex, ethnicity, age), or environmental factors (e.g., smoking, alcohol, body mass index (BMI)).

**Objectives:**

To investigate the relationship between autism and chronic physical health conditions and the influence of demographic factors, family history, and environmental factors.

## Methods:

We employed a cross-sectional observational study design via an anonymous, online survey of autistic and non-autistic adults (n=2,395, mean age=41.7, 50.8% female, 49.2% autistic). The survey asked participants to self-report information about their demographics, autism status, diet, exercise, sleep, sexual health, substance use, personal medical history, and family medical history (for first-degree, biological relatives). When answering questions about medical history, participants could select common conditions from a provided list or could self-disclose rarer conditions using free text. Results were analysed using binomial logistic regression across four models of increasing complexity (shown in Figure 1). Only conditions that achieved 1% endorsement within the sample (n=24) were included in analysis. We employed multiple comparison correction using the Benjamini-Hochberg Correction. For conditions where perfect separation issues arose that were unavoidable, we have presented only the unadjusted odds ratios.

## Results:

Autistic people are significantly more likely to report having a physical health condition across all of the organ systems tested in this analysis. The most significant finding was for gastrointestinal conditions, where the p value remained at 0 even after controlling for demographics, family history, and lifestyle factors. Disorders of the neurological, dermatological, rheumatological and visual system also remained highly significant after covariates were accounted for.

Compared to non-autistic people, we found highly significant increases in rates of irritable bowel syndrome, hernias of the gastrointestinal tract, gastric reflux, migraine, epilepsy, chronic fatigue syndrome, endometriosis, and premenstrual syndrome among autistic adults. Full results have been provided in Table 1 below. Interestingly, we find that the association between Coeliac's disease and autism becomes non-significant when controlling for family history, suggesting shared variance between family history and autism in this relationship and thus presenting a new avenue for investigation. Further, despite not being an option for selection on the list of medical conditions on the survey, Ehler-Danlos Syndrome was frequently reported by female autistic participants, and when compared with non-autistic females, the odds ratio was estimated at 4.60 (2.29-9.25 95% CI,  $p=5.75 \times 10^{-5}$ ), even when controlling for family history.

## Conclusions:

This study provides evidence of widespread, physical health comorbidity that spans nearly all major organ systems among autistic adults compared to non-autistic adults. Our findings underline the importance of a greater awareness in clinical settings of the potential physical health comorbidities for autistic patients. However, they also point towards potential avenues requiring further exploration, such as the association of autism with disorders with known genetic components such as Ehler-Danlos Syndrome and Coeliac's Disease.

## **210.003 (Panel) Do Insured Adults with Autism Experience Increased Odds of Hospitalizations and Mortality in the U.S. after a COVID-19 Diagnosis?**

**A. M. Davis<sup>1</sup> and H. Belcher<sup>2</sup>, (1)Johns Hopkins Univ, Baltimore, MD, (2)Johns Hopkins University, Baltimore, MD**

---

## Background:

The risk of hospitalization and death from the coronavirus disease 2019 (COVID-19) is increased in individuals with comorbid medical conditions, such as obesity, diabetes, chronic obstructive pulmonary disease, chronic renal failure, cardiovascular disease, and pregnancy. Individuals with autism spectrum disorder (ASD) often have comorbid conditions with the potential for increased vulnerability during the coronavirus pandemic. Increased COVID-19-related mortality and morbidity among populations with developmental disabilities has been reported; however, health outcomes attributable to COVID-19 in autistic people are largely unknown. Socioeconomic factors and region-specific health policies may increase the risk for COVID-19-related poor health outcomes and shorter lifespans among individuals with ASD.

## Objectives:

It was hypothesized that individuals with ASD would be at increased odds of COVID-19 mortality adjusted for demographic characteristics and the number of comorbidities.

## Methods:

An analysis was conducted of aggregated, de-identified data representing claims of 752,237 privately insured individuals in the U.S. with a COVID-19 diagnosis, drawn from the FAIR Health, Inc.<sup>[1]</sup> National Private Insurance Claims (FH NPIC<sup>®</sup>) repository database. The data were analyzed using hierarchical multivariate logistic regression models to assess the odds of hospitalization and death among COVID-19 patients with autism.

## Results:

The odds of COVID-19 hospitalizations were 3.04 times higher (95% CI: 2.63-3.51) among individuals with an ASD diagnosis compared to those without, adjusted for demographic characteristics, Health Resources Services Administration (HRSA) region and states with Affordable Care Act (ACA). The odds of COVID-19 hospitalization adjusted for comorbidities demonstrated a dose-response with significant increases for each additional comorbidity, from 2.74 (95% CI: 2.65-2.83) times the odds of mortality for one comorbidity to 23.71 (95% CI: 23.05-24.36) times the

odds of hospitalization for five or more comorbidities. Following adjustment for comorbidities, odds of hospitalization for autistic individuals were not significantly different from individuals without ASD. Odds of COVID-19 death were 3.87 times higher (95% CI: 2.10-7.12) among individuals with an ASD diagnosis than those without, adjusted for demographic characteristics, HRSA region, and states with ACA. The odds of COVID-19 mortality adjusted for comorbidities demonstrated a dose-response with significant increases for each additional comorbidity, from 4.98 (95% CI: 3.74-6.63) times the odds of mortality for one comorbidity to 52.50 (95% CI: 40.91-67.37) times the odds of mortality for five or more comorbidities. Following adjustment for comorbidities, the odds of mortality for autistic individuals decreased to 1.81 (95% CI: 1.00-3.28).

#### Conclusions:

Study results supported the hypothesis of increased odds of hospitalization and mortality for patients with ASD and COVID-19. The more co-occurring disorders a person has, the increased the odds of death. Adjusting for demographics and comorbidities, autistic individuals face a significantly higher mortality risk, but not hospitalization admission. Public health policies should identify those with ASD and COVID-19 as a high-risk population that requires early identification and careful monitoring.

**210.004** (Panel) Tailored Healthcare Adjustments for Older Autistic People: An Evaluation of an Intervention to Improve Healthcare  
**B. Ingham<sup>1</sup>, P. Rob<sup>2</sup>, T. Brown<sup>3</sup>, I. A. James<sup>4</sup>, D. Mason<sup>5</sup>, C. Scarlett<sup>6</sup>, E. Walton<sup>7</sup>, M. Woodbury-Smith<sup>8</sup> and J. R. Parr<sup>9</sup>**, (1)Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne, United Kingdom, (2)Population Health Sciences Institute, Newcastle University, Newcastle Upon Tyne, United Kingdom, (3)Cumbria, Northumberland Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne, United Kingdom, (4)University of Bradford, Bradford, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)North Tyneside CCG, Newcastle-upon-Tyne, United Kingdom, (7)Newcastle University, Newcastle upon Tyne, United Kingdom, (8)Newcastle University, Institute of Neuroscience, Newcastle upon Tyne, United Kingdom of Great Britain and Northern Ireland, (9)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom

---

#### Background:

Improved services that meet the health and wellbeing needs of older autistic people are needed to address autistic people's health conditions (Croen et al., 2015), premature mortality (Hirivkoski et al., 2015) and barriers to effective healthcare (Mason et al., 2019). We consulted with older autistic adults and clinicians to develop the 'Tailored Healthcare Adjustments' (THA) intervention, a structured and personalised approach to using reasonable adjustments to improve healthcare access.

#### Objectives:

To explore outcomes following the 6 week THA intervention for older autistic people: Acceptability (including trial measures and recruitment processes), feasibility (including recruitment and retention) and utility (change in attitudes, improving healthcare access, identifying unmet clinical needs).

#### Methods:

A single arm feasibility study was undertaken with clinically diagnosed autistic people aged  $\geq 50$  years who had at least two health conditions. The THA intervention consists of up to 4 sessions with a participant to explore tailored health adjustments and subsequent sessions with healthcare providers to implement these adjustments. Quantitative data about quality of life, and physical health conditions experienced was collected pre and post intervention. Feasibility was measured through recruitment and retention rates. Acceptability was measured through semi-structured interviews to elicit views on the intervention and trial, including reasons for participation, clarity of the processes, and whether the intervention was helpful (change in attitudes, better access to healthcare, identified unmet clinical needs).

#### Results:

24 older clinically diagnosed autistic adults consented; 21 participants undertook the intervention (16 male, 5 female, aged between 53 and 69 years, mean= 58.8). 17 people completed follow-up measures and interviews. Reasons for attrition were predominantly physical health related (e.g. in palliative care). Thematic analysis on the interviews revealed 3 themes and 8 subthemes on the feasibility and acceptability of the intervention. Themes identified included: (A) reasons for participation (helping themselves and/or other autistic people through developing the evidence base, raising awareness of autism); (B) feasibility and acceptability (ease of completing assessment measures, importance of adapting the assessment environment and the potentially therapeutic benefit of completing assessments); and (C) attitudes and approaches to healthcare (importance of clinician communication and changes in participants' own approach to healthcare).

Participants reported they needed to get used to completing assessments, and they wanted to increase health professional's awareness and knowledge on autism. Importantly, participants reported feeling more confident knowing that their GPs are aware of their adjustments: *"I can explain myself better to him if he's asking the questions, and he's more understanding towards me as well, because he's more aware of what I need"*. Within this,

participants reported that new health conditions and unmet needs were identified through the THA intervention, which were then treated, adjustments introduced or onward referrals made (e.g. referral to falls clinic, investigation of potential hernia).

Conclusions:

The THA intervention was found to be feasible and acceptable for autistic adults to engage with. THA increased access to healthcare for older autistic adults with long-term health conditions. The THA intervention is appropriate for use in a future trial.

## PANEL — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

### 226 - Interventions to Promote Skill Development As Autistic Youth Transition to Adulthood

**Panel Chair:** Julie Taylor, *Vanderbilt University Medical Center, Nashville, TN*

**Discussant:** Reid Caplan, *Brandeis University, Waltham, MA*

**226.001 (Panel)** Surviving and Thriving in the Real World: A Randomized Clinical Trial of a Daily Living Skills Intervention for Adolescents with Autism Spectrum Disorder

**A. Duncan<sup>1,2</sup>, J. Meinzen-Derr<sup>1,2</sup>, C. Fassler<sup>1</sup> and L. J. Stark<sup>1,2</sup>, (1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)College of Medicine, University of Cincinnati, Cincinnati, OH**

**Background:** Autistic adolescents without an intellectual disability (ID) have daily living skills (DLS) that typically fall 6-8 years below their same-aged peers. DLS include activities in areas such as Personal (self-care, health), Domestic (cleaning, cooking), and Community (money management, transportation), and have been linked to a more positive adult outcome in employment and independent living. However, there are currently no interventions that target DLS. Surviving and Thriving in the Real World (STRW) is a 14-week group intervention for autistic adolescents and their parents that was developed to fill this gap by targeting critical DLS (personal hygiene, laundry, cooking, and money management) using evidence-based strategies (behavior contract, modeling, technology). Initial efficacy studies have shown that STRW participants acquire and maintain DLS and begin to close the gap between age and DLS.

**Objectives:** To test the preliminary effectiveness of STRW in adolescents (14-21 years) with ASD as compared to a control group (PEERS social skills intervention).

**Methods:** Participants included 112 youth with ASD (age M = 16.3, SD = 1.1, 71.4% male, 79.5% White, IQ M = 98.5, SD = 11.0). All participants had DLS deficits as defined as a 15-point difference between their IQ and scores on the DLS domain or subdomains on the Vineland Adaptive Behavior Skills, 3<sup>rd</sup> Edition (VABS-3). Eligible adolescents were randomized to receive either STRW or PEERS, which are similar in duration, frequency, and delivery. Due to COVID-19, approximately 26% of the sample received the interventions in-person and 74% received it via telehealth. Primary outcome measures were the VABS-3 DLS domain and subdomains and goal attainment scaling (GAS), which allows for assessment of individual DLS goals in the 4 areas targeted in STRW.

**Results:** Data collection at post-treatment for all cohorts was just recently completed and only data on the parent/caregiver interview form of the VABS-3 is available for analysis. Prior to the conference, we will have all data collected including all outcome measures for the 6-month follow-up timepoint. Preliminary results indicated that youth in the STRW intervention made significant gains on the VABS-3 DLS domain ( $p = .04$ ) and Domestic subdomain ( $p = .02$ ) as compared to the control group (see Table 1). An examination of change within the STRW group revealed that participants showed significant gains from pre- to post-treatment (all  $p$ 's < .001) on all VABS-3 DLS areas and large effect sizes were obtained. The PEERS group also showed significant gains for pre- to post-treatment (all  $p$ 's < .001).

**Conclusions:** STRW participants demonstrated improved DLS as compared to the control group such that they gained 2-3 years of DLS over the course of a 14-week intervention. The most gains were made in the VABS-3 Domestic subdomain, which is core content in the STRW intervention (e.g., cooking on the stove, laundry). Interestingly, the control group also made DLS gains, though not to the same degree as those in STRW. Future analyses that will be presented include changes in individualized GAS from pre- to post-treatment, and whether DLS gains were maintained at 6-month follow-up.

**226.002 (Panel)** Development, Efficacy, and Community-Based Optimization of a Transition Support Program for Young Adults with Autism  
**A. M. Brewe and S. W. White, Psychology, The University of Alabama, Tuscaloosa, AL**

**Background:** Emerging adulthood is a period of heightened risk for people with autism spectrum disorder (ASD). In fact, people with ASD experience lower rates of employment and postsecondary school enrollment compared to their age- and ability-matched peers. These low rates are partially due to the limited availability of evidence-based services that support transition into adulthood.

**Objectives:** We present results on the feasibility, acceptability, and efficacy of a comprehensive transition support and intervention program (STEPS: Stepped Transition in Education Program for Students with ASD), compared to a transition-as-usual (TAU) control. We also describe a current study to optimize STEPS for use in the community using a qualitative examination of implementation barriers and facilitators.

**Methods:** An iterative approach involving focus groups and surveys with stakeholders was taken to develop and refine STEPS, resulting in two levels (STEP 1 and STEP 2) designed to meet students' specific developmental needs at the secondary and postsecondary levels, respectively. Both levels were developed with the goal of improving self-determination, self-knowledge, and self-regulation. In STEP 1, 24 cognitively able adolescents with ASD ( $M$  age: 17.09, 95.80% male, 100% White) were randomized to receive STEPS ( $n=15$ ) or TAU ( $n=9$ ). In STEP 2, 35 cognitively able young adults with ASD ( $M$  age: 19.71, 71.43% male, 80% White) were randomized to receive STEPS ( $n=17$ ) or TAU ( $n=18$ ). Following the trial, stakeholders (i.e., people with ASD, caregivers, and professionals involved in community-based transition support;  $n=45$ ) were engaged in semi-structured interviews to identify barriers and facilitators of providing STEPS in the community, by community providers. This stakeholder feedback is being used in an ongoing study to optimize STEPS for community implementation.

**Results:** STEPS demonstrated sufficient feasibility, measured by  $<15\%$  attrition and  $>90\%$  average therapist fidelity. Participants and caregivers also reported sufficient acceptability, with  $>75\%$  of participants and caregivers rating STEPS as "somewhat" or "very helpful" and offering "good" or "great" benefit. Two two-level hierarchical linear models, one each for STEP 1 and STEP 2, examined efficacy. STEP 1 participants demonstrated significant improvement in transition readiness to postsecondary school, compared to their TAU peers ( $\chi^2(1)=4.52$ ,  $p=.03$ ; see Figure 1). STEP 2 participants did not demonstrate statistically significant improvement in adjustment to college compared to their TAU peers ( $\chi^2(1)=3.37$ ,  $p=.06$ ; see Figure 2). Treatment effect size estimates indicate that STEPS produces moderate-to-large effects at endpoint (STEP 1  $d=.881$ , STEP 2  $d=.644$ ). Data from qualitative interviews are currently being examined using thematic analysis and will be available before the presentation.

**Conclusions:** Discussion of STEPS development is framed within the ORBIT model of intervention research. Given participation in STEPS was feasible and acceptable by families and led to improvement in transition readiness, additional research on the effectiveness of STEPS with a larger, more diversified sample is warranted. Additionally, preliminary data from an ongoing study to prepare STEPS for community implementation will be discussed.

**226.003 (Panel) Healthy Relationships on the Autism Spectrum (HEARTS): A Feasibility Test of an Online Class Co-Designed and Co-Taught with Autistic People**

**E. F. Rothman<sup>1</sup> and L. Graham Holmes<sup>2</sup>,** (1)Community Health Sciences, Boston University, Sargent College, Boston, MA, (2)Hunter College, CUNY, New York, NY

**Background:** Autistic people, like all people, need and deserve education about how to have healthy relationships. Healthy relationships skills are not the same as social skills. Healthy relationship skills tend to be less task-oriented, amorphous, and generally improve relationship quality for both people. They include, for example, effective interpersonal communication, conflict resolution, obtaining consent, establishing boundaries, rapport building, and expressing intimacy (Wood et al., 2012). In 2020, our team collected formative data from 25 autistic individuals about what they would like to learn from a healthy relationships class, and how such a class would ideally be delivered. Building upon these findings, in 2021, our team—which includes seven autistic self-advocates—collaboratively developed a six-session healthy relationships class to be delivered online by a team of one autistic and one non-autistic teacher. The class, called Healthy Relationships on the Autism Spectrum (HEARTS), was delivered five times during 2021.

**Objectives:** The purpose of this study was to test the feasibility and preliminary efficacy of the HEARTS program.

**Methods:** Fifty-five individuals 20–43 years old participated in a one-arm pre/post-test evaluation study of HEARTS. Individuals were eligible if they were: (1) 18–44 years old; (2) English-speakers; (3) Either diagnosed with autism by a professional or self-diagnosed; (4) Had  $\geq 1$  relationships that they wanted to improve; and (5) Demonstrated ability to communicate (via chat, AAC or verbally) with a researcher. Participants completed an online pre-test survey (40 min duration) the week prior to HEARTS' first session. Four weeks after the final session they completed the post-test. Participants received up to \$200 for participation. Of the 84 screened for eligibility, 90% ( $n=76$ ) were eligible for research. Of the 76 eligible, 95% ( $n=72$ ) consented to participate. Of the 72 who consented to participate, 76% completed both baseline and post-test surveys. Of the 55 participating, 31% were male, 55% female, and 11% non-binary gender. Eighty percent identified as White. Twenty-five percent ( $n=14$ ) were self-diagnosed autistic (Table 1).

**Results:** Participants decreased hostile automatic thoughts ( $p<.05$ ), dating abuse ( $p<.05$ ), fight-or-flight response ( $p<.05$ ), and rejection sensitivity ( $p<.001$ ) (Table 2). Participants experienced improved flourishing ( $p<.001$ ), coping with rejection and jealousy ( $p<.001$ ), motivation to engage with others for socializing ( $p<.05$ ), self compassion ( $p<.05$ ), and positive thinking ( $p<.05$ ) (Table 2). Interpersonal competence did not improve, and loneliness did not decrease significantly. In addition, the percentage of participants who agreed that they knew how to call the national domestic violence hotline increased from 42% to 69% ( $p<.001$ ), the percentage who knew how to call a sexual assault crisis organization increased from 40% to 66% ( $p<.001$ ), and the percentage that totally agreed with the statement "I know the warning signs of abuse in dating relationships" increased from 73% to 91% ( $p<.01$ )(Table 2).

**Conclusions:** It was feasible to deliver HEARTS online. Pairing an autistic and non-autistic person to team teach HEARTS was well-received. Comparison of pre- to post-test survey responses indicated that participants may have benefited from participating in HEARTS.

**226.004 (Panel) Teaching Parents How to Effectively Navigate Adult Services on Behalf of Their Autistic Transition-Aged Youth: A Multi-Site Randomized-Controlled Trial**

**J. L. Taylor<sup>1</sup>, M. M. Burke<sup>2</sup> and L. E. Smith DaWalt<sup>3</sup>,** (1)Vanderbilt University Medical Center, Nashville, TN, (2)University of Illinois Urbana-Champaign, Champaign, IL, (3)University of Wisconsin-Madison Waisman Center, Madison, WI

Background: Accessing needed services and supports is a challenge for many autistic youth as they transition from adolescence to adulthood. Not only is the adult service system underfunded, but it is also difficult to navigate. Increasing the ability of families to navigate adult service systems may be one avenue to improve service access and ultimately transition outcomes. To address this issue, we developed ASSIST (Advocating for Supports to Improve Service Transitions) – a group-based intervention that teaches parents how to advocate for adult services and supports on behalf of their transition-aged youth on the autism spectrum. The present study reports on findings from a randomized-controlled trial of ASSIST in three states in the US.

Objectives: Does participating in ASSIST increase parents’ ability to advocate for adult services and supports, as evidenced by increased: knowledge about the adult service system; confidence navigating adult services; and empowerment?

Methods: 185 caregivers of autistic youth were recruited from study sites in three states in the US (Illinois, Tennessee, Wisconsin). Caregivers were primarily mothers (89.7%) and white, non-Hispanic (84.3%). Youth with ASD ranged from 16 to 26 years of age ( $M = 20.1$ ), 75.1% identified as male, 40% had an intellectual disability, and 60.5% were enrolled in high school.

Participants were randomized to either treatment or control conditions. The treatment group participated in ASSIST, meeting weekly (2 hours/week) for 12 weeks. Topics included services and supports related to employment, education, independent living, community participation, and health insurance. Control group participants received all written materials shared with the treatment group. Outcomes were collected prior to randomization and after the treatment group finished ASSIST. Knowledge of adult service systems was measured using a multiple-choice test developed for this study. Confidence navigating adult services was assessed via a 10-item measure (Taylor et al., 2017). Parental empowerment was measured using the Family Empowerment Scale (Koren et al., 1996). Regression analyses were used to examine whether there was an effect of treatment group on outcomes after controlling for baseline scores and study site.

Results: 174 participants (94%) completed the post-test questionnaire and thus have data on outcomes. Controlling for baseline scores and study site, treatment group participants knew more than the control group about adult services and felt more confident navigating the adult service system after taking ASSIST,  $\beta_s = .28$  and  $.15$ , respectively,  $ps < .05$  (see Figure). There were no significant group differences in parental empowerment. Analyses are ongoing: further analyses will examine aspects of the parent (e.g., stress, education) and youth (e.g., high school or intellectual disability status) that moderate these treatment effects.

Conclusions: Providing comprehensive information about adult services and supports is effective in increasing parents’ knowledge about the adult service system and their confidence advocating for services. The multi-site nature of this study suggests that ASSIST may be useful in many service system contexts. Increasing parents’ advocacy ability is likely to lead to better service access (Lee et al., in press); data to test this hypothesis in the context of ASSIST is currently being collected.

## PANEL — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

### 227 - Quality of Life

**Panel Chair:** Elizabeth Pellicano, *Macquarie School of Education, Macquarie University, Sydney, NSW, Australia*

**Discussant:** Zachary Williams, *Medical Scientist Training Program, Vanderbilt University School of Medicine, Nashville, TN*

**227.001** (Panel) Trajectories of Positive Affect, Well-Being, and Quality of Life during the Transition to Adulthood

**J. B. McCauley<sup>1</sup>, E. B. Clarke<sup>2</sup>, H. K. Schiltz<sup>3</sup> and C. Lord<sup>4</sup>,** (1)*Saint Mary's College of California, Moraga, CA*, (2)*University of California, Los Angeles, Los Angeles, CA*, (3)*Psychology, Marquette University, Milwaukee, WI*, (4)*UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA*

Background: Recent research has highlighted challenges faced by autistic individuals as they transition into adulthood, including difficulties establishing relationships (Sosnowy et al., 2019), employment/post-secondary education (Taylor & Seltzer, 2011), and stagnation in adaptive behavior growth (Clarke et al., 2021). Though trajectories of mental health concerns in this population have been documented (McCauley et al., 2020; Stringer et al., 2020), few reports have examined positive aspects of socioemotional functioning to better understand growth or decline in well-being, quality of life, and positive emotions during this transition.

Objectives: The current study explored longitudinal trajectories of happiness metrics from ages 14 to 26, and whether patterns of change in happiness constructs relate to adult outcomes.

Methods: Participants ( $n = 157$ ) were drawn from a longitudinal cohort ( $n = 253$ ) first assessed for ASD diagnosis at age 2 with frequent follow-up assessments into adulthood. Starting in adolescence, participant caregivers completed assessments on mental health and well-being. Composite scores from the Positive and Negative Affect Scale positive scale (PANAS; Watson, Clark, & Tellegen, 1988), Well-Being Questionnaire (WBQ; Ryff, 1989) and Quality of Life Questionnaire (QLQ; Schalock & Keith, 1993) were each used to model happiness from ages 14 to 26. Adult outcomes for social relationships, autonomy, and engagement were defined specific to ability status.

Results:

Group-based trajectory modeling was used to determine latent classes of change in three metrics of happiness - PANAS, WBQ, and QLQ - using the traj procedure in Stata (Jones & Nagin, 2007).

Results for the PANAS revealed three distinct classes: “1 - Low Declining”, “2 - Mid-Stable” and “3 - High Stable” (Figure 1). Results for the WBQ revealed three distinct classes: “1 - Growing”, “2 - High-Stable” and “3 - Declining” (Figure 2). Results for the QLQ estimated one trajectory class with cubic growth - stable until age 17, then fluctuating upwards into adulthood.

No significant link emerged between PANAS and WBQ classes ( $p=.163$ ). PANAS class membership was significantly associated with social ( $p<.001$ ), work/daily activities ( $p<.001$ ), and autonomy ( $p=.013$ ) outcomes. Participants in the High-Stable PANAS class were significantly more likely to have: one friend/social contact, a job/activities outside the home, and greater autonomy compared to participants in the Low-Declining class; the Mid-Stable and High-Stable PANAS classes did not significantly differ on these outcomes. WBQ trajectory classes and social, work, and living status outcomes were not significantly related ( $p>.05$ ).

Conclusions: Characterizing trajectories of happiness metrics as autistic individuals enter adulthood is an essential pursuit for understanding how to promote positive transitions. Findings revealed different patterns of growth for each happiness measure, which may reflect developmental differences in how the measures function. The longitudinal course of positive affect (e.g., enthusiastic, proud, inspired) was most closely related to living, social, and work experiences of both more and less able autistic adults, while well-being (e.g., positive feelings about purpose/self) was not. This novel finding, to be compared with self-reported measures, highlights that transient emotional experiences (e.g., excitement) are likely intertwined with the broader social and community contexts within which each autistic adult resides.

#### **227.002 (Panel) “Money Is like This Secret Thing That No One Talks about”: Understanding the Determinants of Autistic Adults' Financial Wellbeing**

**E. Pellicano**<sup>1,2</sup>, **R. Y. Cai**<sup>2,3,4</sup> and **G. Hall**<sup>1,2</sup>, (1)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, QLD, Australia, (3)Aspect Research Centre for Autism Practice, Autism Spectrum Australia, Melbourne, VIC, Australia, (4)School of Psychological Sciences, Monash University, Melbourne, VIC, Australia

Background: Financial wellbeing is an important component of people's overall wellbeing, reflecting the capacity to live a comfortable and fulfilling life. Despite many autistic people having a desire to work, the majority are not employed full-time or are under-employed and have low levels of income. Such circumstances present serious constraints to achieving financial wellbeing – yet virtually nothing is known about this topic.

Objectives: We sought to understand the ways in which Australian autistic adults understand financial wellbeing, and the structural, intermediary and individual factors that support autistic people to achieve good financial wellbeing.

Methods: This study followed a two-phase explanatory sequential mixed-methods design (participant selection model). In Phase 1, 191 adults took part in an online survey designed to assess financial wellbeing in autistic people. In Phase 2, 21 participants were purposively selected based on the quantitative data (subjective financial wellbeing; Kempson et al., 2017) they provided in Phase 1, including 12 people with high financial wellbeing and nine with low financial wellbeing. We report on Phase 2 data here. We followed Braun and Clarke's method for reflexive thematic analysis to analyse the data using an inductive (bottom-up) approach to identify patterned meanings within the dataset. We also adopted a participatory approach, such that one autistic researcher, who was a paid member of the team, interviewed all participants and was integral to the interpretation of the results.

Results: We identified four themes (see Figure 1). Having access to a stable income made an enormous difference to people's financial wellbeing (Theme 1). It allowed them to have enough money to cover their expensive/meet their needs, and it removed some uncertainty by allowing them to put some money aside, to have a buffer and build some financial resilience (in terms of savings). Participants also emphasised how their broader social supports shaped their financial wellbeing (Theme 2), particularly support from family either through financial assistance or guidance at various times in their lives. Nevertheless, planning – for the present and the future – was reported to be a challenge (Theme 3), especially for people in the low financial wellbeing group, who often did not have enough money to meet their basic needs (housing, clothes, food): “Sometimes tomorrow is a pie-in-the-sky concept”. Despite all these challenges, our participants reported a strong drive to stay in control and avoid unnecessary risk (Theme 4).

Conclusions: Our findings revealed how crucial a reliable income is for autistic people's financial wellbeing. Low incomes meant that our interviewees did not feel they had enough to cover day-to-day expenses and a savings safety net for the unexpected. They felt this ultimately limited their life opportunities. These difficulties came despite the fact that many were extremely disciplined in their accounting and budgeting strategies, and that people worked hard to find financial security. Future research should investigate the ways in which autistic people could secure more reliable incomes and identify what is needed to help support autistic people to achieve financial resilience in often demanding and unpredictable personal and societal circumstances.

#### **227.003 (Panel) A Living Environment Adapted to the Needs of Autistic Adults: What Does Literature Offer?**

**A. M. Nader**<sup>1</sup>, **M. Charette**<sup>2</sup>, **E. St-Jean**<sup>3</sup>, **V. Lasalle**<sup>2</sup>, **N. Jeanneret**<sup>4</sup>, **B. Forgeot d'Arc**<sup>5</sup>, **I. Courcy**<sup>4</sup> and **R. Godbout**<sup>1</sup>, (1)University of Quebec in Montreal, Montreal, QC, Canada, (2)Faculty of Design, Université de Montréal, Montréal, QC, Canada, (3)Psychiatry, Université de Montréal, Montréal, QC, Canada, (4)CIUSSS Nord-de-l'Île-de-Montréal, Montréal, QC, Canada, (5)Département de Psychiatrie, Université de Montréal, Montréal, QC, CANADA

**Background:** A majority of autistic adults live in one form of residential care (adapted apartment, group-home, etc.) while the majority wish to live independently (Sosnowy et al, 2018). Associated conditions (e.g. Intellectual disability, mental health issues) are common in autism, resulting in further challenges for long-term housing. What is a good living environment and what should be consider when conceiving home for autistic adults?

**Objectives:** To identify the scientific literature on best practices in the conception of living environments for autistic adults. This literature review aimed to 1) describe the variables studied (population, types of home, outcome measures associated to quality of life (QoL), etc.); 2) identify environmental factors associated with the QoL of autistic adults in residential living, especially with regard to the built and the social environments.

**Methods:** A transdisciplinary systematic literature search was performed combining information from health, human, social sciences as well as architecture fields (e.g. PubMed, PsycINFO, CINAHL, ERIC, Wiley, Design and Applied Arts Index, Sociological Abstracts; 2011-2021). Key word included ["autism", "Asperger", "PDD"] AND ["residential", "house", "home", "facilities", "accommodation"]. A total of 69 900 citations were identified. After duplicate removal, 17991 studies were screened by titles/abstracts for eligibility; documents that were relevant underwent full text review. Two investigators independently screened studies according to predetermined criteria, focusing on finding informative articles on conditions related to residential care. 35 studies met the inclusion criteria (participants aged  $\geq 18$ ; residential care (excluding family home); empirical studies, French or English). Descriptive qualitative analysis of the content was done following a systemic model (factors related to the a. individual; b. immediate physical and relational environment; c. community).

**Results:** Objective 1: A majority of studies focus on autistic adults with intellectual disability and behavioral challenges living in group-home. Current literature suggests that behavioral problems and comorbidities are two components adding complexity of designing adapted residential facilities. Overall, the most assessed primary outcome across studies was behavior, followed by QoL measures through questionnaires completed by proxy (parents, staff). Only two studies addressed the subjective perception of autistic people on what they consider a good living environment for them. Most studies were conducted with small samples and only two assessed the impact of residential care model on QoL. Objective 2: 5 relevant key themes were identified including 1) sensory issues; 2) social regulation; 3) communication; 4) security 5) social participation. Those themes were mainly addressed in the context of architectural design principles and much less in the context of relational environment (other residents or staff), nor the role of community.

**Conclusions:** This systematic review reveals that little is known on the impact of residential facilities on the QoL of autistic individuals, and on factors associated with their wellbeing in the context of living facilities. A better understanding of conditions associated to QoL when designing living environment is a starting point to a profound change in how clinician, administrators and researchers conceive housing for adults with complex conditions. Including autism communities in priority-setting is imperative for designing home *with* and *for* autistic adults.

**227.004 (Panel)** Later Age of Autism Diagnosis Is Associated with Poorer Mental Health and Subjective Quality of Life in Autistic Adults  
**G. A. McQuaid<sup>1</sup>, N. R. Lee<sup>2</sup> and G. L. Wallace<sup>3</sup>,** (1)George Mason University, Fairfax, VA, (2)Department of Psychological and Brain Sciences, Drexel University, Philadelphia, PA, (3)The George Washington University, Washington, DC

---

**Background:** Earlier diagnosis of autism spectrum disorder (ASD) is associated with better outcomes; conversely, later diagnosis can be detrimental to outcomes, including poorer mental health and subjective quality of life (QoL). Existing studies have primarily examined associations between age of ASD diagnosis and mental health in pediatric samples or in samples which include both youth and adults, thereby not capturing or potentially missing impacts of diagnosis in late adolescence and adulthood. To date few quantitative studies have directly examined effects of diagnostic timing on mental health and QoL in autistic adults. Further, extant studies that have examined QoL have primarily examined only social QoL, and have not controlled for effects of factors that may impact diagnostic timing among individuals without intellectual disability (e.g., female birth-sex).

**Objectives:** Examine effects of diagnostic timing on mental health and on a comprehensive measure of QoL in a large sample of autistic adults while controlling for key, potentially confounding variables.

**Methods:** 609 autistic adults aged 18.2-50.0 years [y] (62.1% female; age:  $M=34.01y$ ,  $SD=8.91$ ; diagnosis age:  $M=22.3y$ ,  $SD=13.2$ , range 0.5-49.08y) were recruited via Simons Powering Autism Research Knowledge (SPARK) Research Match to complete an online battery of surveys. Participants self-reported on a) anxious (Generalized Anxiety Disorder-7 [GAD-7]) and depressive (Patient Health Questionnaire-9 [PHQ-9]) symptoms, b) global perceived stress (Perceived Stress Scale [PSS]), c) four domains of subjective of QoL measured by the World Health Organization Quality of Life (WHOQOL-BREF) and d) autism-specific QoL (Autism Spectrum Quality of Life [ASQOL]). Eight hierarchical linear regressions were conducted in which the mental health and QOL measures served as dependent variables of interest. These models included birth-sex and interview-age in the first step as control variables; age at autism diagnosis, the primary independent variable of interest, was entered in the second step. Results were corrected using the false-discovery-rate method, and a corrected  $q$  value of  $<.05$  was considered significant.

**Results:** Regression models (Table 1) revealed that, after controlling for birth-sex and age of survey completion, age of autism diagnosis contributed additional variance to mental health (depression:  $\Delta R^2=.01$ ; anxiety:  $\Delta R^2=.01$ ; perceived stress:  $\Delta R^2=.04$ ). Further, diagnosis age explained additional variance in autism-specific QoL ( $\Delta R^2=.02$ ), and in WHOQOL-BREF Psychological ( $\Delta R^2=.02$ ), Social Relationships ( $\Delta R^2=.007$ ), and Physical Health ( $\Delta R^2=.01$ ) domains.

**Conclusions:** For the first time, to our knowledge, this study shows that later age of autism diagnosis is associated with detrimental impacts on both mental health and on multiple domains of subjective QoL. Importantly, these effects of age at autism diagnosis are robust and remain after controlling for birth-sex, which as Table 1 shows, has a significant impact on all mental health measures, and all QoL measures except Social Relationships. These results in a large sample with a wide range in age of autism diagnosis point to the importance of timely diagnosis, and also to the critical need to provide supports to later diagnosed individuals that will decrease the burden of mental health symptoms and improve all aspects

## POSTER SESSION — ADULT OUTCOME: MEDICAL, COGNITIVE, BEHAVIORAL

### 415 - Adult Outcome: Medical, Cognitive, Behavioral

**415.001** (Poster) Sex Differences in Rates of Coping Self-Efficacy, Depression, and Suicidal Ideation Among Autistic Adolescents and Young Adults

**T. D. Marsh<sup>1</sup>**, **B. Tomaszewski<sup>2</sup>**, **M. L. Cook<sup>3</sup>** and **L. G. Klinger<sup>4</sup>**, (1)TEACCH Autism Program, TEACCH Autism Program, UNC Chapel Hill, Chapel Hill, NC, (2)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, TEACCH Autism Program, Chapel Hill, NC, (3)TEACCH Autism Program; Psychology & Neuroscience, University of North Carolina, Chapel Hill, NC, (4)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

#### Background:

Autistic adolescents are reported to have elevated rates of suicidality and depression (De-la-Iglesia & Olivar, 2015; Hedley & Uljarevic, 2018). In non-autistic populations, transitional periods like that from adolescence to adulthood are often marked by increased rates of depression, lower rates of self-efficacy, and higher rates of suicidal ideation in females compared to males (Garrison et al., 1991). Given the increased rates of autism in males compared to females, little is known about the specific experiences of adolescent females and whether they show the same elevations in depression and suicidality that is seen in non-autistic female adolescents.

#### Objectives:

The purpose of this study is to examine the possible differences in rates of suicidal ideation, coping self-efficacy, and depression between male and female autistic adolescents and young adults. Similar to non-autistic populations, we predicted elevated rates of depression, suicidality, and lower coping skills in adolescent autistic females.

#### Methods:

Participants (N=184, 72% male, 27% female) were individuals with a prior diagnosis of autism, ages 16-21, who participated in a transition to adulthood intervention program (TEACCH School Transition to Employment and Post-Secondary Education Program; T-STEP). Prior to the intervention, participants were asked to complete questionnaires assessing suicidality (P4 Suicidality Screener), emotion coping (Coping Self-Efficacy Scale Revised; CSES-R) and depression (Center of Epidemiologic Studies Depression Scale Revised; CESD-R).

#### Results:

A structural equations model was performed to examine relationships among sex, suicidal ideation, depression, and coping self-efficacy. The results indicated there to be no significant relationship between sex and suicidal ideation ( $p=0.88$ ) with equal suicidal ideation among both males (37.69%) and females (36.00 %). Females had higher rates of depression ( $B=0.254$ ,  $p=0.012$ ) and lower coping self-efficacy scores ( $B=-0.354$ ,  $p<0.001$ ) than males. Across males and females, depression and coping self-efficacy had a significant negative relationship with higher depression associated with lower coping self-efficacy ( $B=-0.541$ ,  $p<0.001$ ). Across both males and females, higher rates of suicidal ideation were related to higher rates of depression ( $B=0.564$ ,  $p<0.001$ ) and lower coping self-efficacy scores ( $B=-0.325$ ,  $p=0.001$ ).

#### Conclusions:

As is true for non-autistic adolescents and young adults, transition-aged autistic females were more likely to be depressed and more likely to struggle with coping self-efficacy than autistic males. Despite autistic males having lower rates of depression than autistic females, they did not differ in their rates of suicidal ideation. Future research is needed to examine whether intervention programs targeting depression, coping, and suicidal ideation are differentially effective for autistic females compared to autistic males.

**415.002** (Poster) Affective Responses Predictive of College Students' Attitudes and Willingness to Interact with Peers with ASD

**A. M. Birnschein<sup>1</sup>**, **A. B. McClain<sup>1</sup>**, **R. L. Harmon<sup>1</sup>**, **C. A. Paisley<sup>2</sup>** and **T. S. Tomeny<sup>1</sup>**, (1)Psychology, The University of Alabama, Tuscaloosa, AL, (2)The University of Alabama, Tuscaloosa, AL

Background: Typically developing (TD) peers generally demonstrate negative attitudes toward (Butler & Gillis, 2011) and low willingness to interact with peers with autism spectrum disorder (ASD; Sasson et al., 2017). Few researchers have investigated which affective mechanisms underlie these findings (e.g., Ling et al., 2010). Researchers investigating peer responses toward individuals with a variety of mental health conditions have found that positive affect is positively associated with a greater willingness to interact (O'Connor et al., 2020). Additionally, anger is negatively correlated with willingness to interact (Griffin, 2018) and to help (Ling et al., 2010) and positively associated with punitive intentions; sympathy is positively associated with willingness to interact (Angermeyer et al., 1997; Dolphin & Hennessey, 2014); and pity is positively associated with helping behaviors (Corrigan et al., 2013; Dolphin & Hennessey, 2014).

**Objectives:** This study aimed to test whether an expanded range of affective responses would be significantly predictive of TD peers' attitudes toward and willingness to interact with a hypothetical peer with ASD. It was hypothesized that fear, guilt, hostility, and shyness would be negatively associated with peers' attitudes and behavioral willingness to interact while self-assurance would be positively associated.

**Methods:** 469 male and female college students (79.3% female), ages 18-24 ( $M = 18.62$ ,  $SD = .94$ ), read a vignette depicting a character demonstrating characteristics of ASD. Participants were told to consider that the character asked them to be partners on a class project. Participants then responded to questions assessing their affective responses (*Positive and Negative Affect Schedule-Expanded Form*; PANAS-X; Watson & Clark, 1994), attitudes (*Multidimensional Attitudes Scale Toward Persons with Disabilities*; MAS; Findler et al., 2007), and willingness to interact (*Shared Activities Questionnaire-Form B*; SAQ-B; Campbell, 2008) with the vignette character.

**Results:** The first multiple regression analysis explained significant variance when predicting peers' attitudes,  $F(5, 463) = 26.28$ ,  $p < .001$ , adjusted  $R^2 = .213$ . Peers' hostility ( $\beta = -.349$ ,  $p < .001$ ) and self-assurance ( $\beta = .318$ ,  $p < .001$ ) emerged as significant predictors of attitudes. The second multiple regression analysis revealed significant variance when predicting peers' willingness to interact,  $F(5, 463) = 35.171$ ,  $p < .001$ , adjusted  $R^2 = .267$ . Peers' hostility ( $\beta = -.330$ ,  $p < .001$ ), shyness ( $\beta = .118$ ,  $p = .012$ ), and self-assurance ( $\beta = .368$ ,  $p < .001$ ) emerged as significant predictors of willingness to interact.

**Conclusions:** The results of this study demonstrate that TD peers' hostility (i.e., anger and disgust) toward a peer with ASD and their self-assurance (i.e., confidence, fearlessness) were the strongest predictors of their attitudes toward and willingness to interact with peers with ASD. Additionally, shyness predicts willingness to interact. These findings provide evidence that measuring affective responses beyond anger, sympathy, and pity may be important for better understanding how TD peers perceive and interact with their peers with ASD.

**415.003 (Poster)** An Examination of Coping Strategies in Relation to Emotion Regulation Difficulties and PTSD-Symptoms Among Autistic Adults  
**T. M. Andrzejewski** and **C. G. McDonnell**, Department of Psychology, University of Wyoming, Laramie, WY

---

**Background:** The Brief-Coping Orientation to Problems Experienced (Brief-COPE) is a widely used measure of coping strategies that has been examined limitedly among autistic individuals, as little is known regarding the general coping skills of autistic adults. Similarly, little research has examined how general coping strategies relate to important clinical outcomes such as emotion regulation and trauma symptoms more broadly among autistic adults, despite research that suggests that autistic individuals may be more vulnerable to emotion regulation difficulties and experiencing traumatic or stressful events. Understanding how autistic adults are impacted by stressful events and how they cope with stress is therefore a critical research priority that holds broad implications for clinical practice and future intervention.

**Objectives:** The goals of the current study were to (1) examine the factor structure of the Brief-COPE among autistic and non-autistic adults, (2) evaluate differences in coping strategies between autistic and non-autistic adults, and (3) explore associations between coping strategies, difficulties in emotion regulation, and PTSD-symptoms among autistic and non-autistic adults.

**Methods:** Participants included 276 autistic adults, including adults who reported being given an autism diagnosis and adults who self-identify as autistic, and 361 non-autistic adults drawn from a United States nationally representative sample. Participants completed an online survey of self-report measures which included the Brief-COPE, Difficulties in Emotion Regulation Scale (DERS), and the PTSD Checklist for DSM-5 (PCL-5).

**Results:** Confirmatory factor analyses showed that the original 14-subscale model of the Brief-COPE had strong fit for both autistic and non-autistic groups. Multivariate analysis of variance (MANOVA) results suggested that autistic adults differ significantly from non-autistic adults in their reports of engaging in 10 of the 14 Brief-COPE subscale coping strategies (see Table 1). In particular, autistic adults reported lower levels of Acceptance and Religion strategies, and higher levels of Self-Distraction, Denial, Emotional and Instrumental support, Behavioral Disengagement, Venting, Humor, and Self-Blaming. Correlations between the coping subscales with emotion regulation and PTSD symptoms are presented in Table 2. Across both groups, results suggested significant associations between the Self-Distraction and Self-Blame subscales across all DERS and PCL domains, as well as between Denial, Substance Use, Behavioral Disengagement, and Venting subscales across most DERS and PCL subscales. Humor more strongly associated with most DERS and PCL domains for non-autistic adults, whereas Religion more strongly associated with PCL domains for autistic adults. Most Brief-COPE subscales were more strongly associated with DERS Goals and PCL-C symptoms for non-autistic adults.

**Conclusions:** Overall, our results support the use of the original proposed subscale structure of the Brief-COPE among autistic and non-autistic adults. Moreover, autistic adults reported differences in coping strategies on this measure, including lower levels of Acceptance and Religion strategies and higher levels of Self-Distraction, Denial, Emotional and Instrumental support, Behavioral Disengagement, Venting, Humor, and Self-Blaming strategies. Among both groups, coping strategies are associated with difficulties in emotion regulation and various PTSD-symptom clusters (i.e., intrusions, avoidance, negative alterations in cognition and mood, alterations in arousal and activity), though additional research is needed to clarify the patterns among these associations.

**415.004 (Poster)** Assessing Retrospective Learning Challenges in Autistic Adults with a Screening Tool Used in Vocational Rehabilitation Settings  
**H. E. Grosman**<sup>1</sup>, **G. L. Wallace**<sup>2</sup>, **G. A. McQuaid**<sup>2</sup>, **N. R. Lee**<sup>1</sup> and **D. Aragon-Guevara**<sup>1</sup>, (1)Department of Psychological and Brain Sciences, Drexel University, Philadelphia, PA, (2)The George Washington University, Washington, DC

---

**Background:** Individuals with autism spectrum disorder (ASD) face a number of unique challenges, including poorer outcomes in adult life across multiple metrics (i.e., employment, social relationships/activities, independent living). While there is clear evidence for this at the group-level, there is also evidence for heterogeneity in outcomes among autistic adults. Identifying potential sources of this heterogeneity may help to provide supports

to those with specific needs. One potential source of heterogeneity is a history of academic/learning challenges. However, measures to assess learning challenges retrospectively are limited, and to the best of our knowledge, have not been validated in samples of autistic adults. The current research presents a first step in validating such a measure, the Learning Needs Screening Tool (LNST), a retrospective, self-report measure of academic challenges used in vocational rehabilitation settings to identify job-seekers who may benefit from additional services.

**Objectives:** The study's primary objective was to evaluate the psychometric characteristics of the LNST by a) assessing its internal consistency, and b) evaluating its external validity through an examination of its association with a history of special education receipt and with current vocational outcomes.

**Methods:** 401 autistic adults, recruited via Simons Powering Autism Research and Knowledge (SPARK) Research Match, participated in this study (40.5% male, mean age=28.9). All participants completed the LNST, which collects responses to 13 questions about learning (such as challenges with memorization, note taking, spelling and identifying arithmetic signs) and yields a total score from 0-30. A score of 12 or greater is considered a "screen positive" on the LNST. In addition, participants completed questionnaires that assessed history of prior educational service provision and current vocational activities. To evaluate internal consistency within the sample, the 13 screening items of the LNST were evaluated using Cronbach's alpha. To evaluate the external or convergent validity of the measure, chi-square was used to examine if screen positive status on the LNST was associated with a history of special education receipt. In addition, vocational status as measured via the Taylor Vocational Index was contrasted for those who screened positive and negative. In particular, rates of independent work/post-secondary educational pursuits vs. no vocational/educational activities were contrasted for those who screened positive vs. negative via chi-square.

**Results:** The 13 screening items of the LNST were found to have high internal consistency (Cronbach's  $\alpha=.81$ ). Overall, 56% ( $n=224$ ) of the sample screened positive on the LNST indicating a history of learning challenges. Individuals who screened positive for learning challenges were more likely to have received special education services as a child [ $\chi^2$  (1, $n=400$ )=29.99,  $p<.001$ ] and to have no vocational/educational activities as an adult [ $\chi^2$  (1,  $n=386$ )=19.5,  $p<.001$ ].

**Conclusions:** These results support the utility of the LNST as a possible screening tool to evaluate retrospective learning challenges in adult job seekers with ASD. As those who screened positive were more likely to have no vocational/educational activities, knowledge of retrospective learning needs may help vocational counselors identify autistic adults who need greater supports when seeking and obtaining jobs.

#### **415.005 (Poster)** Assessing the Association between LGBTQ+ Individuals and Co-Occurring Conditions in Autistic Adults

**M. Enayetallah<sup>1</sup>, P. Feliciano<sup>2</sup>, C. W. Lehman<sup>3</sup>, W. K. Chung<sup>2,3</sup> and A. Holbrook<sup>3,4</sup>**, (1)SPARK, Simons Foundation - SPARK, New York, NY, (2)Simons Foundation, New York, NY, (3)Department of Pediatrics, Columbia University, New York, NY, (4)University of California, Los Angeles, Los Angeles, CA

**Background:** Research suggests that autistic adults have higher rates of co-occurring conditions (e.g., depression) than the general population (Hollocks et al., 2019). One possible explanation is the Minority Stress Model (MSM; Meyer, 2003), which proposes that minority groups may face especially difficult stressors leading to higher rates of mental health problems (Valentine, Shipherd, 2018). According to the MSM, a minority group includes any group that faces prejudice, including gender, racial, or sexual minorities or neurodiverse people. Autistic adults are more likely to identify as LGBTQ+ (Hillier et al., 2019). The potential intersectionality of two minority statuses means autistic individuals may experience greater levels of stress than the general population, placing them at higher risk of negative mental health outcomes.

**Objectives:** 1) To examine the association between co-occurring conditions and dual minority identities (autistic and LGBTQ+). 2) Compare prevalence of co-occurring conditions between LGBTQ+ and non-LGBTQ+ autistic adults. We hypothesized that LGBTQ+ autistic adults would report higher frequencies of co-occurring conditions than autistic adults who do not identify as LGBTQ+.

**Methods:** Our secondary analysis is based on participants enrolled in the Simons Powering Autism Research (SPARK) cohort who participated in a Research Match study (RM0030). SPARK Research Match is a service that helps researchers recruit for their studies. RM0030 invited 2,887 independent autistic adults to participate. Demographic information was collected on 980 respondents between 18-46 years ( $M=31.34$ ,  $SD=6.98$ ). The survey asked about sex at birth, sexuality, gender, and co-occurring diagnoses. The LGBTQ+ identity was used as an inclusive grouping for any participants who did not identify as cisgender and heterosexual. Co-occurring conditions of interest included: depression, anxiety, bipolar disorder, post traumatic stress disorder (PTSD), obsessive compulsive disorder (OCD), panic disorder, eating disorders, and substance abuse disorder.

Chi-square tests were performed to examine the association between co-occurring conditions and having dual identities of autistic and LGBTQ+. Post-hoc pairwise z-tests with Bonferroni correction were used to examine specific differences in proportions of co-occurring conditions between autistic individuals who identify as LGBTQ+ and those who do not.

**Results:** Fifty-five percent of the autistic adults identify as women, and 40% of the sample identify as LGBTQ+ (sexual and/or gender minorities). LGBTQ+ identity is significantly associated with co-occurring conditions in autistic adults (Table 1). As hypothesized, the proportion of individuals with autistic and LGBTQ+ identities and co-occurring conditions was significantly higher than the proportion of autistic adults who do not identify as LGBTQ+ (Table 2).

**Conclusions:** Mental health conditions are significantly related to LGBTQ+ status in autistic adults. Specifically, LGBTQ+ autistic adults have higher rates of co-occurring conditions. These findings suggest that individuals with dual minority identities (autistic and LGBTQ+) may face additional stressors and stigmatization leading to more mental health problems. It is important to provide additional resources and support for these individuals. Future studies should examine LGBTQ+ groups separately to see if differences exist by sexual orientation and/or gender identity.

**415.006** (Poster) Associations between Protective and Vulnerability Factors of Aging: Network Estimation in Subgroups of Autistic Adults  
**T. A. Radhoe, J. Agelink van Rentergem, C. Torenvliet, A. P. Groenman, W. J. van der Putten and H. M. Geurts, University of Amsterdam, Amsterdam, Netherlands**

---

**Background:** Autism spectrum condition (ASC) is considered to be marked by heterogeneity, which complicates the search for causes and support for individuals with an ASC diagnosis. In our previous study (presented at the INSAR 2021 meeting, and currently under review; Preprint: <https://psyarxiv.com/hs4bx/>), we identified two ASC subgroups that differed on cognitive failures, psychological difficulties, and quality of life. We named these subgroups (a) HighSocial/HighGrip and (b) LowSocial/LowGrip.

**Objectives:** We will test whether the previously identified subgroups differ in the interactions between vulnerability and protective factors of aging. Moreover, we aim to identify which variables in the network are most important.

**Methods:** The input for the network analyses were 16 variables measured with self-report questionnaires on the following domains: ASC traits, demography, psychological characteristics, and quality of life. As preregistered (AsPredicted no. 49209), we perform three analysis steps. Step 1: We estimate the network structure separately for autistic adults and comparisons analyzing a data set of N=545 adults (30-85 years, 52% males; 258 ASC, 287 comparisons) using Gaussian Graphical Models. Step 2: We estimate the network structure separately in the previously identified ASC subgroups. Step 3: We test for differences between the ASC subgroups using a network comparison test.

**Results:** Step 1: In the ASC and comparison networks, psychological difficulties appeared most central. Step 2: When we estimated the networks of the two ASC subgroups, psychological difficulties again were most central. In the HighSocial/HighGrip subgroup, they were related to negative affect and level of worries. In the LowSocial/LowGrip subgroup, psychological difficulties next to negative affect and worries, were related to quality of life and cognitive failures. None of the other variables, such as education, ASC traits, and age, reached the set threshold for interpretation.

**Conclusions:** In the HighSocial/HighGrip subgroup, we see more resilience in the network as only two variables are involved in the rise and fall of psychological difficulties, which can prevent spreading of problems across domains. In the LowSocial/LowGrip subgroup, we see that more variables are connected. This could potentially result in spreading of problems across domains, from cognitive failures to psychological difficulties, negative affect, quality of life and worries, or vice versa. Formal statistical network comparisons between the two subgroups (Step 3) will be performed before the INSAR 2022 meeting.

**415.007** (Poster) Autism Severity and Cognitive and Behavioral Studies in Individuals with Fragile X Syndrome

**R. Aishworiya<sup>1</sup>, Y. Tak<sup>2</sup>, M. Salcedo<sup>1,2</sup>, K. Kim<sup>1,3</sup>, H. M. B. Biag<sup>1,2</sup>, A. Schneider<sup>1,2</sup>, S. Afzal<sup>1,2</sup>, F. Tassone<sup>1,4</sup> and R. Hagerman<sup>1,2</sup>, (1)Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, Sacramento, CA, (2)University of California Davis, Davis, CA, (3)Division of Biostatistics, Department of Public Health Sciences, University of California, Davis, Cavis, CA, (4)Biochemistry and Molecular Medicine, UC Davis, SACRAMENTO, CA**

---

**Background:** Fragile X syndrome (FXS) is the most common single-gene disorder causing autism spectrum disorder (ASD). Presence and severity of ASD can modify the profile and have implications for clinical management of FXS.

**Objectives:** To determine the effect of severity of ASD on cognitive and behavioral outcomes in individuals with FXS.

**Methods:** Data for this study was obtained from the baseline data of participants in a clinical trial of metformin in FXS at a tertiary institution. Inclusion criteria included individuals with FXS and 1) age between 6 to 40 years, 2) baseline cognitive IQ score < 75 and 3) minimal verbal language at a 3-word phrase level. Presence and severity of ASD was determined by the Autism Diagnostic Observation Schedule-2 (ADOS-2). Baseline measures for this study included standardized assessments (Leiter-III cognitive assessment and Vineland Adaptive Behavior Scales-third edition (VABS-III)) and caregiver-reported questionnaires (Pediatric Quality of Life (PedsQL), Anxiety, Depression and Mood Screening (ADAMs), Aberrant Behavior Checklist – community edition (ABC-C), and Swanson, Nolan and Pelham questionnaire (SNAP-IV) for inattention and hyperactivity). One-way Analysis of Variance followed by Tukey post-hoc test was used to compare between ASD severity groups on cognitive and behavioral measures. Significance of differences was determined at p-value <0.05.

**Results:** Data from 47 individuals was utilized for this analysis (mean age 15.3, SD 6.25; males 94.2%). ASD severity was classified into no/mild ASD (N=7), moderate (N=17) and severe (N=23) based on ADOS scores. The Leiter-III score of the no/mild ASD group (mean 68.1, SD 12.2) significantly differed from the moderate ASD (mean 44.3, SD 8.9,  $p=0.004$ ) and severe ASD (mean 45.5, SD 14.7,  $p=0.004$ ) groups (Table 1). The Aberrant Behavior Checklist total score was significantly lower in the no/mild ASD group as compared to the moderate ASD group ( $27.3 \pm 19.9$  vs.  $59.3 \pm 29.7$ ,  $p = 0.034$ ). The PedsQL school functioning total score was also significantly lower in the moderate ASD group as compared to the severe ASD group ( $52.5 \pm 12.4$  vs.  $65.0 \pm 16.9$ ,  $p=0.040$ ). Severity of ASD did not significantly associate with any other behavioral outcomes. There was no significant association between ASD severity and the CGG repeat length.

**Conclusions:** The severity of ASD has a negative effect on cognitive outcomes and more challenging behavior of individuals with FXS. Interestingly, caregiver reported school-related quality of life is lowest in individuals with moderate ASD as compared to those with more severe ASD. This could be related to their more severe behavioral problems and perhaps relatively better functional abilities leading to fewer supports at school. Targeted early intervention especially for individuals with FXS and ASD and facilitating school accommodations and inclusion can help to improve their cognition and quality of life.

Table 1:

| Measure                                 | No/Mild Autism             | Moderate Autism          | Severe Autism            | 1-way ANOVA Overall <i>p</i> -value |
|---|----------------------------|--------------------------|--------------------------|-------------------------------------|
| Leiter-III Score                        | 68.1 <sup>1,2</sup> ± 12.2 | 44.3 <sup>1</sup> ± 8.9  | 45.5 <sup>2</sup> ± 14.7 | 0.03                                |
| Aberrant Behavior Checklist total score | 27.3 <sup>1</sup> ± 19.9   | 59.3 <sup>1</sup> ± 29.7 | 49.5 ± 27.7              | 0.04                                |
| PedsQL School Functioning Total score   | 57.2 ± 14.1                | 52.5 <sup>1</sup> ± 12.4 | 65.0 <sup>1</sup> ± 16.9 | 0.005                               |

#### 415.008 (Poster) Characteristics of COVID-19 Vaccine Hesitant Autistic Adults in the SPARK Cohort

N. Nagpal<sup>1</sup>, M. Sabiha<sup>1</sup>, M. Kowanda<sup>1</sup>, J. K. Law<sup>1,2</sup>, C. W. Lehman<sup>1</sup>, A. Daniels<sup>1</sup>, P. Feliciano<sup>1</sup>, S. Consortium<sup>1</sup> and W. K. Chung<sup>1,3</sup>, (1)Simons Foundation, New York, NY, (2)Maryland Center for Developmental Disabilities, Maryland Center for Development Disabilities, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Pediatrics, Columbia University, New York, NY

**Background:** Vaccine hesitancy refers to delay in acceptance or refusal of vaccination despite availability of vaccination services (MacDonald et al. 2015). While preliminary data on the prevalence of vaccine hesitancy during the COVID-19 pandemic is similar to observed trends pre-pandemic (Khubchandani et al. 2021), there is little known about COVID-19 vaccine hesitancy within the autism spectrum disorder (ASD) population—specifically among independent adults. Identifying specific characteristics of the ASD population with regards to vaccine hesitancy may serve to inform public campaigns to vaccinate the ASD community in the US.

**Objectives:** To describe COVID-19 vaccine hesitancy in a sample of independent adults with ASD within the Simons Foundation Powering Autism Research (SPARK) cohort and to elucidate characteristics associated with COVID-19 vaccine hesitancy.

**Methods:** SPARK is a U.S. based online research study with a cohort of over 100,000 individuals with autism. From March 2nd 2021 through March 23rd 2021, SPARK surveyed independent adults to examine the impact of COVID-19 on their lives as well as their sentiment about available vaccines—before the first FDA approval on August 23rd, 2021. 636 participants completed the survey, and those without a completed Basic Medical Screener previously collected in SPARK were excluded from analysis.

Chi-square tests of independence were performed to identify whether there was a link between vaccine hesitancy and age, sex, employment and educational characteristics, metropolitan vs non-metropolitan residence (Urban Influence Code, UIC), personal experience with COVID, and self-reported mood disorder and ADHD. Fisher's exact test was used when  $n < 5$ . Individuals that were missing UIC code data were removed from the chi-square analysis. To analyze race, mutually exclusive race categories were created by splitting the sample into white vs. people of color.

**Results:** Table 1 includes demographic information and chi-square tests of association between vaccine hesitancy and characteristics of the sample.

The individuals who were COVID-19 vaccine accepting were more likely to live in a metropolitan area than the COVID-19 vaccine hesitant individuals,  $\chi^2 (1, N = 282) = 5.62, p < .05$ . COVID-19 vaccine hesitant respondents were more likely to be non-Hispanic than respondents who were not COVID-19 vaccine hesitant. There were no significant associations between vaccine hesitancy and the following variables; age, sex, race, current employment status, enrollment in school, personal experience with COVID-19, and self-reported mood disorder and ADHD.

**Conclusions:** This study elucidates the characteristics of autistic adults with COVID-19 vaccine hesitancy. Overall, 20% of respondents reported COVID-19 vaccine hesitancy, which is comparable to 22% of respondents in the general population (Khubchandani et al. 2021). COVID-19 vaccine hesitant autistic adults in this sample were more likely to reside in non-metropolitan areas—a finding consistent with the regional differences associated with general vaccine hesitancy within the U.S. (Abbas et al. 2018). Additional studies are needed to measure the change in COVID-19 vaccine hesitancy within autistic adults over time, in order to evaluate the impact of emerging FDA approvals and vaccine mandates implemented after initial survey responses were collected.

#### 415.009 (Poster) Depressive Symptoms in Individuals with Autism Spectrum Disorder or Attention-Deficit/Hyperactivity Disorder: A 10-Year Longitudinal Study

S. Orm<sup>1,2</sup>, M. G. Øie<sup>1</sup>, I. N. Fossum<sup>3</sup>, P. N. Andersen<sup>4</sup> and E. W. Skogli<sup>1</sup>, (1)Department of Psychology, University of Oslo, Oslo, Norway, (2)Innlandet Hospital Trust, Lillehammer, Norway, (3)Innlandet Hospital Trust, Lillehammer, Norway, (4)Inland Norway University of Applied Sciences, Lillehammer, Norway

**Background:** Depressive symptoms are common in individuals with Autism Spectrum Disorder (ASD) and contributes to functional impairments and reduced quality of life. Understanding the development of depressive symptoms in individuals with ASD is important for development of preventive interventions and treatment. Since ASD and Attention-Deficit/Hyperactivity Disorder (ADHD) are two related neurodevelopmental disorders, comparing the trajectories of these two groups can provide information about the shared and/or unique factors contributing to depressive symptoms in these individuals.

**Objectives:** To examine the developmental trajectory of depressive symptoms over a 10-year period in individuals with ASD compared with individuals with ADHD and typically developing (TD) individuals.

**Methods:** Individuals with ASD ( $n = 38$ ), ADHD ( $n = 85$ ), and TD individuals ( $n = 50$ ) completed the Short Moods and Feelings Questionnaire (SMFQ) as a measure of depressive symptoms at baseline ( $M_{age} = 11.7$ ,  $SD = 2.1$ , 64% male), two-year follow-up ( $M_{age} = 13.8$ ,  $SD = 2.1$ , 64% male,

97% retention rate), and 10-year follow-up ( $M_{age} = 21.4$ ,  $SD = 2.3$ , 63% male, 73% retention rate). Between baseline and follow-ups, the groups received treatment as usual. We conducted Linear Mixed Models for analysis of the developmental trajectories of depressive symptoms.

**Results:** At baseline, the ASD ( $p < .001$ ; Hedges  $g = 1.17$ ) and the ADHD ( $p < .001$ ; Hedges  $g = 1.13$ ) group displayed significantly more depressive symptoms than the TD group. From baseline to two-year follow-up, all groups displayed a stable trajectory of depressive symptoms. From two-year follow-up to 10-year follow-up, an increase of depressive symptoms across the three groups was found ( $p = .009$ ). The slopes of the three groups were not significantly different. At the 10-year follow-up, both the ASD ( $p = .001$ ; Hedges  $g = .94$ ) and the ADHD ( $p = .001$ , Hedges  $g = .74$ ) group displayed significantly more depressive symptoms than the TD group.

**Conclusions:** Individuals with ASD report more depressive symptoms than TD individuals and similar levels as individuals with ADHD across time. The developmental trajectory of depressive symptoms in individuals with ASD did not differ from that of individuals with ADHD or TD individuals. The similarity in levels of depressive symptoms across individuals with ASD and individuals with ADHD, could indicate that common factors such as executive dysfunction and/or social difficulties contributes to the depressive symptoms. The common trajectory across all three groups, suggests that the transition from childhood to adulthood can be troublesome also for individuals with ASD or ADHD and be accompanied by an increase in depressive symptoms. The results highlight the importance of addressing depressive symptoms in the clinical care and treatment of individuals with ASD and individuals with ADHD, particularly in the transitional period of adolescence. Our findings indicate that depressive symptoms may not wane by themselves. A limitation with our study is that the SMFQ is intended for children and adolescents, however, psychometric analyses indicated good validity and reliability also at the 10-year follow-up.

**415.010 (Poster)** Developing a Measure of Adult Function Outcomes in Autism Spectrum Disorder: Conceptual Model and Item Generation of the Adult Functioning Scale

**K. T. MacKenzie<sup>1</sup>, K. B. Beck<sup>2</sup>, S. M. Eack<sup>1</sup>, K. N. Zeglen<sup>2</sup>, C. M. Conner<sup>3</sup> and C. A. Mazefsky<sup>3</sup>,** (1)University of Pittsburgh School of Social Work, Pittsburgh, PA, (2)University of Pittsburgh, Pittsburgh, PA, (3)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA

**Background:** Autistic individuals continue to experience considerable challenges in adulthood, with difficulty in social functioning, independence, and maintaining competitive employment. However, researchers lack the ability to systematically assess these outcomes, relying on suboptimal reporting across gross categories (i.e. employed, not employed) or adaptive behavior scales developed for use with children. The absence of validated measures of functional outcomes serves as a methodological barrier to supporting positive outcomes for autistic adults.

**Objectives:** This research includes the first steps to develop a proxy and self-report measure of functional outcomes for autistic adults– the Adult Functioning Scale (AFS), reporting on the initial development of the conceptual model. Development occurred in three phases with the following respective aims: 1) to evaluate whether the existing Vineland Adaptive Behavior Scales-3 (VABS-3) was an adequate measure of adult functional outcomes in ASD compared to functional outcome measures not validated in ASD, 2) to generate a conceptual model using stakeholder input to inform AFS measurement development, and 3) to conduct cognitive interviews to assess comprehension of items and response categories, factors that influence how participants respond to items, and the inclusiveness of the item pool in capturing pertinent concerns.

**Methods:** In phase 1, preliminary baseline data were collected from 48 adults participating in an ongoing trial of Cognitive Enhancement Therapy for autistic adults. Participants completed the VABS-3, the Social Adjustment Scale-II (SAS-II), the Specific Levels of Functioning Scale (SLOF), and the Major Role Adjustment Inventory (MRAI). General linear models were constructed to examine differences in functional outcome measures by levels of employment and social functioning. In phase 2, investigators conducted a literature search of existing adult functional outcome instruments and compared instrument domains to inform AFS conceptual model generation. Key stakeholders reviewed the model, which was further revised, and items were generated. In phase 3, autistic adults ( $n = 13$ ) and caregivers of autistic adults ( $n = 13$ ) completed in-depth cognitive interviews assessing the measure.

**Results:** Phase 1 results revealed that the VABS showed poorer sensitivity than the SAS-II, SLOF, and MRAI in detecting differences between adult outcomes in employment and social functioning, suggesting that adult functional outcome measurement in ASD can be improved. Phase 2 yielded a final conceptual model of adult functional outcomes with 3 subdomains (social functioning, employment, and autonomy) including assessment of satisfaction within each domain (see Figure 1). Cognitive interviews indicated that further revision of all subdomains is warranted, given heterogeneity across the adult ASD population.

**Conclusions:** This study developed the first conceptual model of functional outcomes specific for autistic adults utilizing stakeholder input and in-depth feedback from both autistic adults and caregivers of autistic adults. Cognitive interviews revealed substantial heterogeneity necessitating greater attention to measuring nuanced contextual factors related to adult living, potentially explaining why the VABS-3 is insufficiently sensitive to variation in adult functional outcomes. Future work will involve the collection of data from 1000 self-reporters and their caregivers to conduct psychometric analyses and validate an efficient, precise, and broadly applicable measure of adult functional outcomes in ASD.

**415.011 (Poster)** Neuropsychological Profile of Executive Functions in Autism Spectrum Disorder and Schizophrenia Spectrum Disorders: A Comparison Study in Adults

**J. A. Yon-Hernández<sup>1,2</sup>, D. Z. Wojcik<sup>1,2</sup>, L. García-García<sup>1</sup>, M. Magan Maganto<sup>2,4</sup>, M. A. Franco-Martín<sup>1</sup> and R. Canal-Bedia<sup>1,2</sup>,** (1)InFoAutismo-Instituto Universitario de Integración a la Comunidad (INICO), Salamanca, Spain, (2)University of Salamanca, Salamanca, Spain, (3)Zamora Hospital (Complejo Asistencial de Zamora), Zamora, Spain, (4)InFoAutismo- Instituto Universitario de Integración a la Comunidad (INICO), 37004, Spain

**Background:** Autism Spectrum Disorder (ASD) and Schizophrenia Spectrum Disorders (SSD) are two conditions that show similar deficits in Executive Functions (EF) as assessed by neuropsychological tasks. Research suggests that the most affected components of EFs are Inhibition (ability to suppress unwanted responses and irrelevant information), Updating (ability to use or maintain information of ongoing behaviors) and Shifting (ability to disengage from one activity or mental set to another).

**Objectives:** Because there is little known about differences in EF between ASD and SSD our goal was to conduct a comparative study between the two disorders in a series of neuropsychological tasks tapping Inhibition, Updating and Shifting. We wanted to establish whether or not each condition shows a different neuropsychological profile by looking at each of the three EF domains. We further wanted to explore in all groups whether the reaction times (RT) can predict the Hit-Rate performance (HR-P) on these tasks.

**Methods:** Twenty-five controls (TDC), 24 participants with ASD and 9 with SSD took part in the study. We used the Unity and Diversity approach, which consists of assessing the core components of EF, each with 3 tasks. For Inhibition we used Antisaccade, Stop-Signal and Stroop-Task, for Updating we used Keep-Track, Letter-Memory and Spatial 2-Back and for Shifting Number-Letter, Color-Shape and Category-Switch-Task. The tasks were computerized adaptation of this approach. Also, to our knowledge this is the first time these tasks were used in Spanish language. Group differences were examined with Kruskal-Wallis-H test. A linear regression was conducted to assess if delayed RTs predicted a better outcome in HR-P.

**Results:** Significant group differences ( $p > .05$ ) were found on Inhibition-RT (SSD>ASD>TDC), Updating HR-P (TDC>ASD>SSD), Shifting HR-P (TDC>ASD>SSD) and Shifting-RT (SSD>ASD>TDC). No significant group differences for Inhibition HT-P and Shifting Switch-Cost were found. Average delayed RTs of the groups were not statistically significant to predict HR-P. See Figure 1, for visual representation of the neuropsychological EF profile. We used Standardized Mean Differences (SMD) to plot our results.

**Conclusions:** People with autism and schizophrenia seem to share some difficulties in the core components of EFs. We found that SSD group had lower scores in HT-P and had more delayed responses in RT than the other groups. Furthermore, in line with past research, the self-paced task format did not lead to better performance in neither of the groups. We also found that Updating impairments in SSD were greater in tasks that required more than one cognitive task simultaneously (e.g., Keep-Track and Letter-Memory tasks). Lastly, Inhibition difficulties were found in the amount of total RT individuals with ASD and SSD needed to accomplish the inhibition tasks. Our work contributes, thus, to the growing body of evidence towards a better understanding of EF impairments in these clinical groups. We argue that differentiating between spared and impaired components of EF in each disorder is especially important for improving interventions and developing guidelines toward a better quality of life, independence, adaptability and other daily living aspects of these individuals.

#### **415.012 (Poster) Differences in Daily Life Executive Functioning between People with Autism and People with Schizophrenia**

**J. A. Yon-Hernández<sup>1,2</sup>, D. Z. Wojcik<sup>2,3</sup>, L. García-García<sup>4</sup>, M. A. Franco-Martín<sup>4</sup> and R. Canal-Bedia<sup>2,3</sup>, (1)InFoAutismo - Instituto Universitario de Integración en la Comunidad (INICO), Salamanca, Spain, (2)University of Salamanca, Salamanca, Spain, (3)InFoAutismo- Instituto Universitario de Integración a la Comunidad (INICO), Salamanca, Spain, (4)Zamora Hospital (Complejo Asistencial de Zamora), Zamora, Spain**

**Background:** People with Autism Spectrum Disorder (ASD) and Schizophrenia Spectrum Disorders (SSD) share similar impairments associated with executive functions (EF) which impact their independence and their adaptive behavior. The observable executive problems associated with these disorders are often attributed to a Dysexecutive Syndrome (DS) that encompass problems at planning, inflexibility, autoregulation, disinhibition among other everyday EFs. Both conditions are associated with a limited capacity to perform everyday life tasks that are essential to maintain a relatively independent, healthy and safe life.

**Objectives:** Our main objective was to conduct a comparative analysis of everyday executive functioning between ASD, SSD individuals and controls using the Dysexecutive Questionnaire-Spanish (DEX-Sp), to identify patterns of difficulties among the groups. We also wanted to assess the relationship between EF with the DEX-Sp and its role in adaptive behavior using the Vineland Adaptive Behavioral Scale-II (VABS-II). We predicted that both clinical groups would show a DS and therefore score high on the DEX-Sp. We also expected to find an association between the reported deficits in EF and poorer adaptive behavior.

**Methods:** To test our hypothesis we used the DEX-Sp for the first time to compare a sample of 35 adults with ASD, 22 adults with SSD and 32 typically developed controls. Group differences were examined with Kruskal-Wallis test; for the targeted variables multiple ANCOVAs were used. A hierarchical multiple regression was conducted to predict adaptive behavior with the EF measure.

**Results:** We found higher scores in the DEX-Sp and its Disinhibition/Apathy and Disorganization/Impulsivity subscale for the ASD group, showing significant difficulties in everyday executive functioning which are typically associated to a DS. The SSD group showed moderate impairments in everyday EF. Also, we found a strong association of impaired everyday EF and adaptive behavior, using the DEX-Sp and VABS-II, but only for the ASD group.

**Conclusions:** This study found greater deficits in everyday executive functions in ASD than SSD and controls and these difficulties were associated with poor adaptive behavior. Our results revealed that adults with ASD reported severe difficulties in their ability to initiate or maintain a behavior with the purpose of organizing or planning effectively. We also found shared executive function deficits within ASD and SSD groups as compared to typically developing controls in areas related to inhibiting inappropriate behavioral responses and generating impulsive behaviors. The SSD group denoted moderate impairments in EFs, however we did not find an association between their scores on the DEX-Sp and the scores obtained on the VABS-II. Our findings add evidence to existing literature in children and adolescents with ASD, indicating that deficits in everyday executive functioning continue into adulthood. As for the adults with SSD, the moderate difficulties on EF seem to remain relatively constant throughout

development. These findings together suggest that DEX-Sp could be a useful tool in differentiating areas of strength and weaknesses in clinical groups such as ASD and SDD.

**415.013 (Poster)** Direct and Indirect Influences of Depression Symptoms on Subjective Quality of Life Among Autistic Adults

**E. A. Kaplan-Kahn<sup>1</sup>, G. A. McQuaid<sup>2</sup>, N. R. Lee<sup>3</sup>, G. L. Wallace<sup>2</sup> and B. E. Yerys<sup>1</sup>,** (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)The George Washington University, Washington, DC, (3)Department of Psychological and Brain Sciences, Drexel University, Philadelphia, PA

---

**Background:** Quality of life (QoL) is repeatedly identified as a leading research and clinical priority by the autistic community. Autistic adults often report significantly lower subjective QoL (i.e., one's evaluation of their own outcomes, such as 'Is one happy with their job?') than neurotypical adults across a range of domains, including their physical health, emotional well-being, living environment, and social functioning. While some research has examined predictors of QoL among autistic adults, investigations often examine the impact of a single predictor (e.g., anxiety symptoms, autism traits) on QoL using hierarchical regression analyses. While these approaches have been helpful in elucidating factors that contribute to subjective QoL, they fail to capture the potentially meaningful interplay of multiple factors and mediating variables, which are undeniably influential during early adulthood.

**Objectives:** To determine the association of multiple interacting factors (activities of daily living, anxiety symptoms, depressive symptoms, autistic traits) with subjective QoL in autistic adults during early adulthood.

**Methods:** Participants included 398 autistic adults (ages 18-39 years), who were recruited via Simons Powering Autism Research and Knowledge (SPARK) Research Match. All participants completed surveys measuring autistic traits (Autism Quotient Short Form; AQ28), daily living skills (Waisman Activities of Daily Living; W-ADL), depression symptoms (Patient Health Questionnaire-9 – PHQ-9), anxiety symptoms (General Anxiety Disorder-7; GAD7), and two QoL instruments (abbreviated World Health Organization Quality of Life measure; WHOQOL-BREF and Autism Spectrum Quality of Life; ASQoL supplement). To achieve the study objective, eight path analysis models were run and compared using maximum likelihood estimation (Figure 1); significance testing of mediation effects were complemented with estimates of indirect effect sizes using a 95% bootstrapped confidence interval (CI) based on 20,000 bootstrapped samples. CIs that do not contain zero indicate significant mediation.

**Results:** In Models 1-4, depressive symptoms mediated the relationship between the predictors of daily living skills and autistic traits and the outcome of subjective QoL in all path analyses (all  $ps < .03$ , all CIs do not contain 0, see Table 1 and Figure 1a). In contrast, in Models 5-8, daily living skills did not mediate the relationship between the predictors of autistic traits, depressive and anxiety symptoms, and the outcome of subjective QoL (all  $ps > .06$ , all CIs contain 0, values not displayed in Table 1 but see Figure 1b). Though autistic traits correlated significantly with all subjective QoL measures in isolation, path analysis models demonstrated that the direct paths between autistic traits and QoL on the WHOQOL-BREF (Social, Environmental and Physical) domains were not significant after accounting for the mediating effects of depressive symptoms (Models 1-4, see Table 1).

**Conclusions:** This study supports the call by the autistic community to focus on mental health in adulthood because it plays a major role in their subjective QoL. Here, depressive symptoms influence subjective QoL across all five domains both directly and indirectly. These findings emphasize the importance of developing and implementing evidenced-based depression interventions for autistic adults during early adulthood, as they may cascade from improving mental health to improving subjective QoL.

**415.014 (Poster)** An Examination of Connectedness and Socialization in an Autistic and Neurotypical Sample in the United States

**S. R. Dufresne and E. T. Crehan,** Eliot-Pearson Department of Child Study & Human Development, Tufts University, Medford, MA

---

**Background:** Individuals with autism spectrum disorder (ASD) generally experience more challenges with socializing than neurotypical (non-autistic) individuals due to the inherent social communication differences in autism (American Psychiatric Association, 2013). These challenges can lead to difficulty with forming friendships and romantic relationships and higher levels of internalizing disorders (Mazurek, 2014; Stice & Lavner, 2019). The present study examines the relationship between social connectedness and assurance, autism characteristics, and psychosexual socialization. A better understanding of the intersection of these elements of social functioning may help to inform future intervention work with autistic individuals.

**Objectives:** To understand whether feeling more connected to others and assured in social situations can predict level of psychosexual socialization beyond the effects of an autism diagnosis.

**Methods:** A total of 132 adults participated in this study from across the United States, representing 23 states. Participants included both adults with ASD without intellectual disability (44 ASD) and neurotypical adults (88 NT). Diagnostic group was based on self-report. Mean age was 26.89 (SD = 5.929). Participants completed an anonymous online survey; measures for this survey included the Social Connectedness and Social Assurance Scales (Lee & Robbins, 1995). and the Teen Transition Inventory, Psychosexual Socialization subscale (Dekker et al., 2017). A sequential linear regression model was estimated to determine if social connectedness and assurance predicted any variation in psychosexual socialization over and above the variation predicted by autism diagnostic group.

**Results:** Diagnostic group was a significant predictor of psychosexual socialization score by itself,  $R^2 = .068$ ,  $F(1,130) = 9.45$ ,  $p = .003$ , when social connectedness/assurance was added the model,  $R^2 = .072$ ,  $F(2,129) = 4.99$ ,  $p = .008$ , and when the interaction between the two predictors was further added,  $R^2 = .075$ ,  $F(3,128) = 3.48$ ,  $p = .02$ . However, neither social connectedness/assurance nor the interaction term were significant predictors over and above diagnostic group, indicating that significant findings were driven by diagnostic group.

**Conclusions:** Due to the inherent social challenges that are part of the autism diagnosis, it was expected that autistic participants would be predicted to score lower on socialization, which was supported by the analysis. This finding contributes to the ongoing conversation about the nature of sociability in autism spectrum disorder. However, failing to find significant predictive power of social connectedness and assurance for psychosexual socialization opens the door to additional analysis of interpersonal and intrapersonal domains of social functioning for autistic and neurotypical adults. It is likely that diagnostic group was such a strong predictor of psychosexual socialization than any additional variable would not have an impact on the model. Because of the inherent social differences in autism, distinct aspects of social functioning may need to be looked at separately for autistic and neurotypical people.

**415.015 (Poster)** Exploring the Experiences of Physical Fitness with Autistic Adults

*S. R. Dufresne, O. Ward and E. T. Crehan, Eliot-Pearson Department of Child Study & Human Development, Tufts University, Medford, MA*

---

**Background:** Understanding the motivation and barriers of physical fitness for autistic adults is an understudied research area. Autistic children and adolescents are less physically active compared to their neurotypical peers (Stanish et al., 2017). These gaps in activity widen as youth get older (Stanish et al., 2015), and contribute to health risks in adulthood including heart disease and diabetes (Must et al., 2017; Wright, 2015) and can exacerbate mental health conditions like anxiety and depression. By qualitatively exploring the physical activity experiences of autistic adults, we can better understand characteristics that are associated with engagement in or avoidance of physical activity. In the future, these findings can inform exercise and trainer education programs that are more inclusive and tailored to meet the needs of a neurodiverse population.

**Objectives:** Explore the motivation, barriers, and experiences of physical fitness of autistic adults. Through understanding these elements, we believe that physical exercise programs can adapt to meet the needs of autistic adults, benefiting both their physical and mental health.

**Methods:** Seven autistic adults, who were over the age of 18 and diagnosed with autism, participated. Participants completed a semi-structured interview via Zoom that was then transcribed. Qualitative analyses were completed on these transcripts and themes/sub-themes were organized into a visual network.

**Results:** Seven main themes emerged from the data: health benefits, sense of accomplishment, sensory issues, having a structured plan, being alone, being with others, and a broad definition of physical activity. From these themes, sub-themes were developed as seen in Figure 1.

**Conclusions:** There is much to be learned from exploring the motivation and barriers of physical activity for autistic adults. This study highlights some expected themes, such as health benefits, sense of accomplishment, and sensory sensitivities, but also brought to light new elements that may not have been discovered if not having talked directly to autistic adults about their experiences. Participants tended to have much broader definitions of physical activity than what is considered typical when thinking about fitness. This is important to consider as physicians may ask these adults if they are physically active by listing more traditional fitness activities like running, biking, or swimming. Additionally, understanding the social needs of autistic individuals related to fitness may help physical fitness programs become more inclusive and welcoming to neurodivergent members. Future research into this area would allow better insight into the needs of autistic adults to overcome barriers to fitness, stay motivated, and have more positive experiences with physical activity.

**415.016 (Poster)** Improvements in Social and Role Functioning in Autistic Youth Transitioning to Young Adulthood

*R. A. Wulff<sup>1</sup>, M. K. Krug<sup>1</sup> and M. Solomon<sup>2</sup>, (1)Department of Psychiatry & Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA, (2)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA*

---

**Background:**

Given the ever-growing number of autistic teenagers transitioning to adulthood, determining effective interventions to help the transition to independent life is crucial. This study adapted the Global Social Global Role (GS/GR) scale, originally developed for schizophrenia (Cornblatt et. al., 2007), to measure social (friendships) and role (school/work) functioning in an autistic sample. This clinical interview was administered at two time points (T1, T2) of a longitudinal study of teenagers and young adults with ASD and without (TYP). The present analyses explore cognitive and psychological factors related to improvements, to inform future interventions.

**Objectives:**

- Determine if autistic participants improve in their GS/GR functioning with time.
- In those who do improve, see if measures of cognition and psychopathology are different compared to those who do not improve.
- Compare cognition in ASD and TYP groups with equivalent levels of functioning.

**Methods:**

75 autistic and 70 TYP participants completed the modified GS/GR scales twice, on average 2 years apart. Each GAF-type scale ranges from 1-10 (10 = highest functioning). Mean age at T1 was 17 years for both groups. ASD diagnosis was confirmed using the ADOS-2, with IQ (WASII),

cognition (NIH Toolbox Cognition Battery) and adaptive functioning (The Maps task (McLaughlin et. al., 2016)) also assessed at T1. Parents completed the ASEBA to assess psychopathology at T1 and T2. T-tests were used to compare groups.

#### Results:

Fifty percent of the ASD group improved in their GS/GR scores from the first to the second time point (Table 1). In both groups, change in GS correlated moderately with change in GR (ASD:  $\rho=.253$ ,  $p=.028$ ; TYP:  $\rho=.310$ ,  $p=.009$ ).

Autistic participants who improved GS scores had lower ADOS CSS scores ( $M=7$ ,  $SD=2$ ) compared to those who didn't change ( $M=8.5$ ,  $SD=1$ ;  $t(60)=2.8$ ,  $p=.007$ ). Those who improved their GR scores had significantly lower non-verbal IQ scores ( $M=102$ ,  $SD=20$ ) compared to those who decreased their GR ( $M=112$ ,  $SD=16$ ;  $t(62)=2.1$ ,  $p=.041$ ). Autistic participants who improved GR also had significantly lower parent-reported Anxiety Problems on the ASEBA at T2 ( $M=55$ ,  $SD=6$  vs.  $M=61$ ,  $SD=9$ ;  $t(32)=2.8$ ,  $p=.008$ ) (Figure 1).

In matched groups equal on T1 GS or GR scores, ASD and TYP did not differ on IQ, age, adaptive functioning (Maps Task), and crystalized cognition. The TYP group had higher fluid cognition scores by 10 points compared to ASD ( $p<.001$ ).

#### Conclusions:

Many autistic youth increased in their social and role functioning over two years. However, the relationship between improving in social functioning was only moderately correlated with improving in role functioning, suggesting varied patterns of improvement between social and role domains. In the ASD group, increasing social ability was related to lower autism symptom severity scores, but increasing role ability was related to lower anxiety. Many autistic participants with lower non-verbal IQ scores improved GR, and between the TYP and ASD groups equal in GS/GR scores, only a deficit in fluid cognition remained. These results suggest nonverbal ability does not impede improvement, and interventions might benefit from focusing on verbal skills. Anxiety treatment may also help improve role functioning during development.

#### **415.017 (Poster)** Development of a Self-Report Tool for Measuring Change in Aspects of Autism

**M. Meyer<sup>a</sup>**, A. Bangerter<sup>a</sup>, B. L. Leventhal<sup>b</sup>, V. H. Bal<sup>c</sup>, S. Bishop<sup>d</sup>, R. Hendren<sup>e</sup>, J. Trudeau<sup>a</sup> and G. J. Pandina<sup>a</sup>, (1)Janssen Research & Development, Titusville, NJ, (2)Department of Psychiatry and Behavioral Sciences, University of California San Francisco, San Francisco, CA, (3)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (4)University of California San Francisco, San Francisco, CA, (5)Psychiatry, University of California, San Francisco, San Francisco, CA, (6)Janssen Global Services, Raritan, NJ

---

#### Background:

There are few self-report measures developed specifically for use in ASD. Existing tools are not designed for assessing clinical outcomes, nor are they validated for use in therapeutic treatment trials (Brugha et al., 2015). Further, few measures were developed with input from autistic people to help establish content validity. Representative input from the autistic community is critically important for identifying meaningful outcomes, particularly when developing novel therapeutics.

#### Objectives:

Understanding autistic adults' perspectives on treatment of autism-related features

#### Methods:

Participants in the current study were adults ( $n=30$  TDI,  $n=10$  CI) over aged 18 years with a confirmed diagnosis of ASD before age 18 by a qualified clinician using DSM IV/5 criteria. Participants had reading ability at or above a 3rd / 4th grade level and a high school certification, GED or diploma. Interviews were conducted by a moderator trained in qualitative research methods, with special focus on how to avoid introducing bias during the interview process.

There were two study phases: 1) anonymized exploratory Telephone In-Depth Interviews (TDI), and; 2) cognitive interviews (CI) to test potential items for a self-report measure. Respondents were given a 'study preparation exercise' prior to interview. The in-depth interview format was semi-structured concept elicitation, following 3 topic areas: 1) Introduction and Patient History; 2) Symptomology, and; 3) Identification of Relevant Aspects of Autism and Interest in Treatment. A draft item set was derived from the TDI and presented in Cognitive interviews prior to the planned development of a self-report measure.

#### Results:

Preliminary data from 9 participants in the Autistic Community reflected a high level of agreement about the need for a self-report tool to track changes in symptoms of autism (89% of participants). Qualitative analysis suggested that autistic adults desired support (via individual treatment and/or environmental modifications) to help to manage sensory issues, social communication difficulties and social anxiety (100%), sensitivity to change (89%), restlessness/stimming (56%), insomnia and depression (22%). 34% of participants identified that their interest in treatment was not completely individual as their desire for change in some areas was driven by stigma and judgment from peers. 11% of participants spontaneously

expressed preferences for an environment that was more supportive of their differences. Further qualitative analysis is underway and detailed descriptive data on items tested during cognitive interviews will be available for presentation at the time of the conference.

#### Conclusions:

Preliminary information collected via in-depth interviews of autistic people during the development of a self-report tool identified symptom targets for which autistic adults were interested in support and, consistent with previous literature (Kapp et al., 2019), highlighted perspectives in support of individual treatment and environmental modifications. This work will aid in the development of self-report tools that can be used to measure changes in symptoms associated with autism in adulthood. Information gained from this project will also provide insight into the types of supports and/or interventions that autistic adults may be interested in seeking.

**415.018 (Poster)** Physical, Psychological and Environmental Barriers and Facilitators to Physical Activity Engagement in Autistic Adults with Mild Intellectual Disability: A Qualitative Study

*M. L. Mylett, T. Q. Boucher, C. L. McIntyre and G. Iarocci, Psychology, Simon Fraser University, Burnaby, BC, Canada*

---

**Background:** Physical activity (PA) involvement among autistic people and those diagnosed with intellectual disability is significantly lower than the general population (Borland et al., 2020), which is related to increased mortality, obesity, and lower quality of life (Feehan et al., 2012). Moreover, the risk of adverse health outcomes is more severe for the one-third of autistic people who are also diagnosed with intellectual disability (CDC, 2020; van Dooren et al., 2016). To help address the health needs that uniquely affect autistic adults with intellectual disability, more research is needed to identify the factors influencing their PA engagement.

**Objectives:** Explore the self-reported barriers and facilitators to PA involvement of autistic adults with mild intellectual disability.

**Methods:** Fifteen adults diagnosed with autism and mild intellectual disability between the ages of 19 and 56 years ( $M_{age}=26.11$ ,  $SD=10.81$ , 10 males) completed a semi-structured interview about their PA engagement, adapted from van Schijndel-Speet et al. (2014). Diagnosis was confirmed through provision of their clinical diagnostic report for their autism and intellectual disability diagnoses. A phenomenological approach was followed to understand how the unique experiences of participants have influenced their behaviours and thoughts about PA. Interviews were transcribed verbatim. Codes were created from the transcriptions and thematically analyzed. Patterns and themes were inductively created from the codes by the first and second authors using QSR NVivo 12.

**Results:** Three main themes were identified: Physical factors, Psychological factors, and Environment factors. With regard to barriers that limited or deterred participants from activities, continuing health problems was a common physical barrier and negative past experiences with PA, such as being yelled at by coaches or bullied by peers, was a common psychological barrier. These experiences reportedly had adverse effects on self-confidence and overall attitudes towards PA. The most frequent environmental barrier was the lack of accommodation, support, or opportunities available in the community. Many participants stated that they have difficulties learning the rules of an activity, do not know who or how to ask for help, and do not have access to opportunities that accommodate their physical or cognitive needs. With regard to facilitators that encouraged PA engagement among participants, a common psychological facilitator was participants' intrinsic motivation to improve skills and achieve personal goals. Common environmental facilitators included extrinsic motivation, such as receiving prizes from local organizations or traveling to new places with their sports team, as well as support through non-profit organizations like Special Olympics.

**Conclusions:** These findings suggest that autistic participants with mild intellectual disability are intrinsically motivated to engage in PA, but face significant barriers to engagement, predominantly from the lack of support or access to accommodations for physical activities in community settings. More education for staff, appropriate support for individuals and attention to motivational factors may help to expand access to inclusive activities for autistic adults with intellectual disability and, in turn, reduce their physical health risk.

**415.019 (Poster)** Positive Repetitive Thinking Predicts Quality of Life in Autistic Adults

*T. Scull<sup>1</sup>, C. Pellegrino<sup>1</sup>, K. O. Gotham<sup>1</sup> and S. Mattheiss<sup>2</sup>, (1)Department of Psychology, Rowan University, Glassboro, NJ, (2)School of Arts and Sciences, Felician University, Rutherford, NJ*

---

**Background:** Autistic adults often report poorer quality of life than typically developing adults (Mason et al., 2018; Cai et al., 2020). Autistic adults also engage in higher rates of repetitive thinking, such as rumination and engagement in inflexible circumscribed interests (CI), which has broadly been linked with adverse outcomes (e.g., Gotham et al., 2014). The valence and purpose of repetitive thought likely matters, however: Repetitive thinking that is solution-oriented (Watkins, 2008), focuses on positive experiences (i.e. savoring; Ma et al., 2020; Bryant & Veroff, 2007; Smith et al., 2015), and is communicated to others (Tedeschi & Calhoun, 2004) is tied to positive outcomes in the general population. Despite high rates of repetitive thinking in the autistic population, research examining the benefits of positive repetitive thinking and savoring in this population is limited.

**Objectives:** We aimed to examine which cognitive-affective and behavioral factors related to repetitive thinking predict improved quality of life among autistic adults. We hypothesized that forms of positive repetitive thinking, including solution-oriented thinking and savoring positive memories, as well as engaging in one's circumscribed interest with others, would predict improved quality of life among autistic individuals.

**Methods:** Seven hundred sixty-two autistic adults (age  $M=30.89$ ,  $SD=7.05$  years;  $n=414$  females,  $n=77$  nonbinary) were recruited through the Simons Foundation Powering Autism Research (SPARK) registry to complete a survey battery on repetitive thinking and emotional health. A composite "quality of life" score was generated using items from the Autism Specific Quality of Life assessment (ASQoL; McConachie et al., 2018) and the World Health Organization Quality of Life assessment (WHOQoL-BREF; WHO, 1998). A solution-oriented thinking score was generated

based on the results of a network analysis (Gotham & Williams, 2021) on items from various measures of repetitive thinking, such as the Analytical Rumination Questionnaire (ARQ; Barbic et al., 2014) and Measure of Mental Anticipatory Processes (MMAP; Feldman & Hayes, 2005); the final score was comprised of 11 items assessing aspects of adaptive cognition such as the degree to which one sees events from different perspectives and the degree to which one envisions solutions. Savoring was measured with two novel items assessing the degree to which one repeatedly recalls positive memories. Finally, a single item from the Interest Scale (Turner-Brown, Lam, Holtzclaw, Dichter, & Bodfish, 2011) assessed the degree to which one engages in their circumscribed interest with others. A linear regression model was conducted to examine whether these cognitive affective factors predicted increased quality of life.

**Results:** Repetitive positive thinking ( $B=0.28$ ,  $p<0.001$ ), savoring ( $B=0.07$ ,  $p<0.001$ ), and engaging in interests socially ( $B=0.20$ ,  $p<0.005$ ) all predicted increased quality of life independently within the same model,  $F(7,731)=23.64$ ,  $R^2=0.177$ .

**Conclusions:** While repetitive thinking has typically been associated with poorer outcomes in the autistic population, our findings suggest that forms of positive repetitive thinking, such as problem-solving and savoring, as well as engaging in special interests with others (versus alone), are associated with increased quality of life. These findings may help leverage existing strengths and inform intervention targets for improving quality of life in the autistic population.

#### **415.020 (Poster)** Predictors of Suicide Risk in Transition-Aged Youth and Young Adults on the Spectrum

**M. L. Cook<sup>1</sup>**, **B. Tomaszewski<sup>2</sup>** and **L. G. Klinger<sup>3</sup>**, (1)TEACCH Autism Program; Psychology & Neuroscience, University of North Carolina, Chapel Hill, NC, (2)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC, (3)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

---

**Background:** Autistic individuals are at higher risk to ideate, attempt, and die by suicide than non-autistic individuals (Oliphant et al., 2020), with transition-aged adolescents and young adults at the highest risk (Kirby et al., 2019). While research examining risk factors of suicide for this population is limited, considerable evidence suggests that autistic individuals with higher levels of depressive symptoms are at higher risk of suicidal ideation and attempt (Costa et al., 2020; Hand et al., 2019). Lower executive function skills have also been significantly associated with suicide risk in non-autistic individuals (Bredemeier & Miller, 2015). Given the high prevalence of executive function challenges for autistic individuals, its inclusion in the conceptual model of suicide risk for autistic young adults is overdue.

**Objectives:** In order to expand the evidence base for suicide-related intervention targets for individuals on the spectrum, this study aimed to examine executive function and depression as potential risk factors of suicidality in a transition-aged population of autistic adolescents and young adults.

**Methods:** 183 transition-aged autistic adolescents and young adults (ages 16-21) enrolled in a larger randomized controlled trial examining the effectiveness of the TEACCH School Transition to Employment and Post-Secondary Education Program (T-STEP) submitted measures of executive function (BRIEF-A per parent report) and depression (CESD-R per self report) at baseline. Each participant was also administered a suicide risk assessment (P-4 Suicidality Screener) in which they were asked whether they had thoughts of harming themselves, any prior attempts to harm themselves, any specific thoughts of how they might harm themselves, any intent to harm themselves in the future, and any protective factors which may prevent them from doing so. A series of hierarchical logistic regressions were performed to assess the unique effects of executive function and depression on the endorsement of suicidal ideation.

**Results:** Approximately 33% ( $n=61$ ) of the sample reported having thoughts of harming themselves. Of those who endorsed ideation, approximately 34% ( $n=21$ ) reported a previous attempt, approximately 43% ( $n=26$ ) reported specific thoughts of how they would harm themselves, and approximately 10% ( $n=6$ ) reported intent to act on thoughts of harming themselves in the next month. Both executive function (per the BRIEF-A) and depression (per the CESD-R) demonstrated significant effects on suicidal ideation such that participants with greater impairment in executive functioning ( $b=.015$ ,  $SE=.007$ ,  $Wald=5.16$ ,  $p<.05$ ) and higher levels of depression ( $b=.062$ ,  $SE=.014$ ,  $Wald=19.52$ ,  $p<.05$ ) were each more likely to endorse suicidal ideation. No interactions effects were found.

**Conclusions:** In this sample, 33% of autistic individuals endorsed ideation and 11% reported a prior attempt; both executive function impairment and depression independently predicted suicidality. Treatments that aim to improve executive function skills and ameliorate depressive symptoms may help mitigate suicide risk amongst autistic individuals. Despite the high prevalence of co-occurring executive function challenges and depression amongst this population, service delivery is often siloed between ASD specialists and mental health professionals. These findings underscore the need for service accessibility and integration across Developmental Disability and Mental Health systems to target malleable predictors of suicide risk in this population.

#### **415.021 (Poster)** Preliminary Analyses of a Randomized Control Trial of Training to Understand and Navigate Emotions and Interactions

**J. A. Rankin<sup>1</sup>**, **R. Rasty<sup>2</sup>** and **E. S. Brodtkin<sup>3</sup>**, (1)Department of Psychiatry, University of Pennsylvania, Perelman School of Medicine, Philadelphia, PA, (2)The University of Pennsylvania, Philadelphia, PA, (3)Department of Psychiatry, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

---

**Background:** Autism spectrum disorder (ASD) is characterized by difficulties with social interaction, cognition, and communication (Howlin, Moss, Savage, & Rutter, 2013). These difficulties can severely impact functioning and quality of life in family, school, and community settings and persist well into adulthood (Shattuck et al., 2012). Few social functioning treatment programs exist for adults (White, Keonig, & Scabill, 2007; Pallathra et al., 2019). TUNE In (Training to Understand and Navigate Emotions and Interactions) is a novel cognitive behavioral based social skills treatment aimed at improving social functioning in late adolescents and adults with ASD, which has shown preliminary evidence of effectiveness at reducing social functioning impairments in ASD (Pallathra et al., 2018).

**Objectives:** To further test the efficacy of TUNE In. We are conducting a randomized control trial (RCT) of TUNE In with a sample of adults with ASD. Participants complete three, consecutive phases of TUNE In (17 weekly sessions in total) which consist of individual therapy (5 sessions), group therapy (8 sessions), and volunteer/advocacy work (4 sessions).

**Methods:** 27 participants (Mean + SD age = 25.85 ± 8.42; 14 Female) were randomly assigned to either receive TUNE In (treatment) or no treatment (control). The Social Responsiveness Scale, Second Edition for Adults (SRS-2; Constantino, 2005) is the primary outcome measure in the trial and evaluates the presence and severity of the social impairments for each participant. Participants complete the SRS-2 at pre-treatment and post-treatment in both treatment and control groups, while participants in the treatment group additionally complete the SRS-2 after each of the three phases of TUNE In. To date 10 participants in the treatment group and 14 in the control group have completed pre-treatment measures, with the 10 participants in the treatment group also completing the SRS-2 after the first phase of TUNE In. Differences between groups were assessed by an independent samples t-test, while differences within the treatment group were assessed by a paired-samples t-test.

**Results:** At pre-treatment, SRS-2 scores did not significantly vary between treatment and control groups ( $t(23) = -.33, p = .74$ ). After completing the first phase of TUNE In, participants' (in the treatment group) scores on the SRS-2 ( $M \pm SD = 71.10 \pm 10.10$ ) were significantly reduced from pre-treatment scores ( $M \pm SD = 73.90 \pm 10.80$ ), indicating significant improvements in ASD symptomology ( $t(9) = 2.45, p = .04$ ). Participants are currently completing the second phase of treatment. Further SRS-2 scores after the second and third phase of TUNE In, as well as post-treatment scores in both groups, will be available and included in the presentation at the INSAR meeting in May.

**Conclusions:** Overall, early results from the first cohort of this RCT support TUNE In's efficacy in addressing social functioning symptoms of ASD in adults. Specifically, results highlight possible improvements in ASD symptoms from even the brief 5-session individual therapy phase of TUNE In. However, complete data across the further time points, for both treatment and control groups, is required to adequately examine the effectiveness of TUNE In.

#### **415.022 (Poster) Psychometric Properties of the Perma Profiler in Autistic Adults**

**L. P. Grosvenor<sup>1</sup>, C. Hood Bey<sup>2</sup>, C. B. Holingue<sup>1,2</sup>, C. Errichetti<sup>2</sup>, J. McLaren<sup>3,4</sup> and L. G. Kalb<sup>1,2,3</sup>**, (1)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (3)National Center for START Services, University of New Hampshire, Durham, NH, (4)Geisel School of Medicine, Dartmouth-Hitchcock University, Hanover, NH

#### **Background:**

Historically, mental health research in autism spectrum disorder (ASD) has been deficits-focused. Positive psychology, a rapidly maturing discipline that has established well-being as a scientifically valid field of discovery, offers a new lens to view disability from a strengths-based perspective. For instance, the PERMA Profiler, a 23-item questionnaire, measures overall well-being across five pillars (Positive emotion, Engagement, Relationships, Meaning, and Accomplishment). To date, very few studies have leveraged positive psychological frameworks to examine well-being in ASD. No studies, to our knowledge, have examined well-being from the first-person perspective/self-report of autistic adults.

#### **Objectives:**

The objective of this study was to examine the psychometric properties (reliability, internal validity, and convergent/divergent validity) of the PERMA Profiler in independent autistic adults.

#### **Methods:**

Participants (ages 21 and older) were recruited through Simons Powering Autism Research for Knowledge Research Match (SPARK; [sparkforautism.org](http://sparkforautism.org)), a national autism registry. All surveys were filled out online (17% response rate). Incentives included raffling off seventy-five \$25 gift cards. The PERMA Profiler, which rates each item on a 10-point likert scale, has strong psychometric properties within general population samples (Butler & Kern, 2006). The reliability, internal validity, and convergent/divergent validity of the PERMA Profiler were assessed via measures of internal consistency, confirmatory factor analysis and correlations between well-being and measures of life satisfaction, excitement about life, and mental health diagnoses, respectively. Life satisfaction/excitement and mental health diagnoses were measured via custom survey items. PERMA scores were reported descriptively.

#### **Results:**

A total of 517 independent autistic adults ( $M_{age} = 39$ ;  $SD_{age} = 13$ ; 85% White; 40% Male; 51% with a collegiate degree; 50% employed) were included. The PERMA Profiler demonstrated strong reliability (Cronbach's  $\alpha = 0.93$ ; min/max split-half reliability = 0.81/0.97). Confirmatory factor analysis revealed strong internal validity ( $\chi^2(80) = 350, p < 0.001$ ; CFI = 0.94, TLI = 0.93, RMSEA = 0.08). Overall PERMA scores were positively correlated with life satisfaction ( $r = 0.76, p < .01$ ) and excitement ( $r = 0.72, p < .01$ ), and negatively correlated with anxiety ( $r = -0.20, p < .01$ ) and depression ( $r = -0.42, p < .01$ ), supporting convergent and divergent validity. The only construct that demonstrated lower psychometrics properties was the engagement subscale. PERMA scores were highest for engagement ( $M = 6.8$ ), accomplishment ( $M = 5.6$ ), relationships ( $M = 5.2$ ), meaning ( $M = 5.2$ ), and positive emotions ( $M = 5.0$ ).

#### **Conclusions:**

The PERMA Profiler demonstrated strong reliability and internal validity, as well as good convergent and divergent validity, among autistic adults. This finding supports the use of gathering information on well-being directly from independent autistic adults. Our findings should encourage researchers to move away from proxy informants when first-person report is possible. The PERMA Profiler, and similar measures of well-being, should also be considered for inclusion in future mental health research, particularly intervention trials. Lastly, findings highlight the need for PERMA interventions, given the average score was at the mid-point for most subscales. Incorporating positive mental health interventions within employment programs may hold particular value given the low employment rate in this sample. Meaningful employment itself holds the potential to increase many pillars of PERMA (e.g., engagement, relationships, meaning).

**415.023** (Poster) Quality of Life, Life Satisfaction, and Psychiatric Comorbidities in ASD and Loss of Autism Diagnosis (LAD) Compared to TD. **J. Crutcher<sup>1</sup>**, **E. Taverna<sup>2</sup>**, **M. F. Dieckhaus<sup>1</sup>**, **C. Larson<sup>1</sup>**, **A. Mohan<sup>1</sup>**, **D. A. Berger<sup>1</sup>** and **I. M. Eigsti<sup>1</sup>**, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Department of Psychological Sciences, University of Connecticut, Storrs, CT

---

**Background:** Individuals with autism spectrum disorder (ASD) report reduced quality of life (QoL) compared to typically developing (TD) peers (van Heijst & Geurts, 2015). Psychiatric comorbidities and autism symptomatology, among other factors, likely impact QoL in ASD (Chiang & Wineman, 2014). Our research group has studied individuals with a clear history of ASD who have *lost* the ASD diagnosis (LAD); that is, they no longer display any symptoms of ASD (Fein et al., 2013). These individuals have lower rates of lifetime psychiatric diagnoses than peers with current ASD, but higher rates compared to TD peers (Orinstein et al., 2015).

**Objectives:** The current study asks whether LAD individuals report less depression and anxiety, and greater QoL and life satisfaction, relative to peers with and without ASD.

**Methods:** Adolescents ( $n=14$ ) and their parents completed in-person evaluations; young adults ( $n=34$ ) completed telehealth appointments. Both groups completed Qualtrics questionnaires. Young adults completed an ASD Quality of Life questionnaires and a Satisfaction with Life questionnaires. Psychiatric comorbidities and suicidal ideation (SI) were measured using the Kiddie Schedule for Affective Disorders and Schizophrenia (KSADS) parent interview for adolescents or the Structured Clinical Interview for DSM-5 (SCID-5) self-report for young adults. Symptoms were assessed with the age-appropriate Achenbach Checklist (CBCL/ABCL) parent report. Groups differed in chronological age (the ASD group participants were younger), Table 1; as such, age was considered as a covariate in analyses.

**Results:** Young adult groups did not differ in QoL or life satisfaction; Table 1. Groups did not differ in self-reported depression or anxiety; however, parents reported greater anxiety and depression in the ASD compared to LAD and TD groups. More individuals with ASD reported recent SI; lifetime reports of SI were non-significantly elevated in both LAD and ASD groups compared with the TD group. Lifetime symptoms of depression and life satisfaction were negatively correlated; Table 2.

**Conclusions:** Quality of life and life satisfaction did not differ in young adults with either ASD or LAD, as well as not being different from TD. Both ASD and LAD groups had relatively high rates of lifetime depression, anxiety, and SI, but they were not significantly different from the TD group. However, parents of young adults with LAD indicated lower anxiety and depression compared to same aged individuals with ASD and similar to parent-reported rates of depression and anxiety in the TD group. Individuals with LAD were also less likely to report past-week SI than their peers with ASD, despite similarly elevated levels of lifetime SI. This suggests that the severity of current psychiatric comorbidities and SI may be less frequent or persistent for individuals who lose an ASD diagnosis. Symptoms of psychiatric comorbidities may decrease in severity over time, along with characteristics of ASD. The strong, negative relationship between lifetime depressive symptoms and life satisfaction highlights the importance of identifying and treating mood disorders in individuals with ASD/LAD.

**415.024** (Poster) Quantitative and Qualitative Examination of Dating Experience in College Students with Autism **J. McCleery<sup>1</sup>**, **T. Fryczynski<sup>2</sup>**, **K. Ryan<sup>3</sup>**, **C. Rose<sup>4</sup>**, **H. M. Mattern<sup>4</sup>**, **T. McFall<sup>5</sup>**, **A. McDougall<sup>1</sup>**, **A. Gatta<sup>5</sup>**, **M. A. Newell<sup>5</sup>**, **R. Haft<sup>5</sup>**, **C. Morrin<sup>3</sup>** and **A. Jayroe<sup>3</sup>**, (1)Psychology, Saint Joseph's University, Philadelphia, PA, (2)Interdisciplinary Health Studies, Saint Joseph's University, Philadelphia, PA, (3)Saint Joseph's University, Philadelphia, PA, (4)Developmental Psychology, Penn State University, University Park, PA, (5)Kinney Center for Autism Education and Support, Saint Joseph's University, Philadelphia, PA

---

**Background:** There is extremely limited research on the dating experiences or dating support needs of individuals with autism spectrum disorder (ASD). A recent study found that 85% of autistic individuals expressed an immediate desire for a romantic relationship, with only 35% in a relationship at the time (Heifetz et al., 2020). It is a common misconception that autistic individuals either do not want, or may not be capable of, a romantic relationship (McMahon et al., 2020). Furthermore, prioritization of academic and other needs in educational and clinical interventions during late childhood and adolescence may result in de-prioritization of supports which would help autistic people fulfill their desire to establish and maintain romantic partnerships.

**Objectives:** To collect and analyze a combination of quantitative and qualitative information about the dating experiences of people with ASD through semi-structured interviews.

**Methods:** College students, autism-specialist clinicians, and autism-specialist researchers developed a semi-structured interview to collect quantitative and qualitative information about the dating experiences of college students with ASD. Interview development included direct input from autistic individuals. Interviews are conducted by undergraduate students, and last 45- to 120-minutes. Quantitative questions address educational experiences and activities, age of onset of dating, number of individuals dated, duration of romantic relationships, and dating network support, among other topics. Qualitative questioning focuses around these same topics, including participants beliefs regarding how their own dating experiences have been similar to and different from those of their peers.

Results: Eleven autistic male college students have completed the study thus far. Eight reported having a “straight” sexual preference, 1 reported “bisexual,” 1 reported “gay,” and 1 reported being “not anything.” The focus of the current analysis includes interest in marriage, age of first date, and self-reported issues which they believe may have negatively affected their previous or current romantic and/or plutonic relationships. Ten out of 11 participants reported that they would like to marry, and 1 reported that they are “not sure.” Of the 6 participants who have dated, 5 had their first date in either 8<sup>th</sup> or 9<sup>th</sup> grade, while 1 had their first date in their first year of college. Regarding issues which may negatively affect their romantic and/or plutonic relationships, 8 listed communication. In addition, 3 listed problems with boundaries, 3 listed opinion disagreements, 1 each listed arguments, control, time, effort, differences in wants, effort, or commitment.

Conclusions: The findings of the current study provide additional support for the notion that the majority of autistic people have a desire for a long-term romantic relationship. Age of first date data suggest that those individuals with ASD who are interested and successful in initiating their dating career during adolescence have their first date around the same age as neurotypical peers (i.e., 8<sup>th</sup> or 9<sup>th</sup> grade). Finally, the majority of the autistic college students in our study recognize the importance and challenges of communication when it comes to establishing and maintaining relationships with others, and also show significant insight into a number of other factors which may be affecting their relationships with others.

**415.025 (Poster)** Sensory Issues Are Linked to Menopausal Symptoms in Autistic Women  
Y. Lohuis, M. L. Bezemer and E. M. Blijd-Hoogewys, INTER-PSY, Groningen, Netherlands

---

## **Background:**

The menopause is an often-challenging time women’s life, where a change in hormone levels create physical and psychological symptoms. Little is known about how autistic women experience menopause, though it is shown that menopause can affect their health and well-being (Moseley et al., 2020).

## **Objectives:**

To assess which menopausal symptoms autistic women experience, and whether this is linked to autistic traits and sensory issues.

## **Methods:**

We approached females through social media. The participant group ( $n = 183$ ) consisted of Dutch women in (peri)menopause who reported (1) being formally diagnosed as autistic (ASD,  $n = 134$ ;  $M_{\text{age of diagnose}} = 48.46$ ,  $SD = 7.58$ ) or (2) neurotypical (control group,  $n = 49$ ). Both groups differed significantly on AQ scores ( $M = 34.45$ ,  $SD = 5.57$  and  $M = 12.35$ ,  $SD = 5.54$ , respectively;  $p < .001$ ), not on age categories. Most participants were between 50-54 years (ASD: 43%, control: 51%).

All filled in three online questionnaires: (1) the Menopause-Specific Quality of Life Questionnaire (MENQOL, 29 items; Hilditch et al., 1996), measuring vasomotor, physical, psychosocial, and sexual menopausal symptoms; (2) the Senses (27 items; Turkensteen & Blijd-Hoogewys, 2020), measuring hyper- and hyposensitivity; and the Autism-spectrum Quotient (AQ, 50 items; Baron-Cohen et al., 2001).

## **Results:**

The ASD group had significant higher scores on MENQOL Physical, MENQOL Psychosocial, Senses Total, Senses Hypersensitivity, and Senses Hyposensitivity (Table 1). There were significant positive correlations for Senses Total, Senses Hypersensitivity and Senses Hyposensitivity with both MENQOL Physical and MENQOL Psychosocial. The AQ had significant positive correlations with MENQOL Physical and MENQOL Psychosocial (Table 2).

A hierarchical multiple regression showed that Senses Total improved the prediction of MENQOL Physical and likewise of MENQOL Psychosocial above AQ Total ( $R^2\text{-Total} = .189$  &  $R^2\text{-change} = .112$  and  $R^2\text{-Total} = .282$  &  $R^2\text{-change} = .078$ , respectively, all  $p < .001$ ).

On the question if menopause was associated with more/less/equal number of sensory issues as before, the distribution between both groups differed significantly ( $U = 4069$ ,  $z = 2.83$ ,  $p < .001$ ). Most controls reported no difference (61%), while most autistic women reported more sensory issues in menopause (also 61%).

## **Conclusions:**

In agreement with Groenman et al. (submitted), autistic women experienced more physical and psychosocial, but not more vasomotor menopausal symptoms. However, it is unclear whether these MENQOL statements are truly reflective of menopausal symptoms, or also common in fertile autistic women.

Sensory issues were linked stronger to menopausal symptoms, than were autistic traits to menopausal symptoms. Notable is the positive association of menopausal symptoms with hyposensitivity. This was not an artefact of a possible underlying ASD diagnosis. The same associations were apparent when both groups were analyzed separately.

Autistic people experience more sensory issues, also as was measured with the Senses before menopausal age (Turkensteen et al., 2020). Menopause may worsen these sensory issues. Groenman et al. (submitted) hypothesized that autistic women may be more sensitive to bodily changes during (peri)menopause due to an overall increased sensitivity, making them vulnerable to experience menopausal complaints sooner and longer than non-autistic women.

**415.026 (Poster)** Social Self-Esteem and Social Media Use in College Students with Autism Spectrum Disorder: A Case-Control Study  
**K. N. Dvogan**, *Psychology, Marist College, Poughkeepsie, NY*

---

**Background:** Despite academic success, college students with Autism Spectrum Disorder (ASD) experience more social rejection, stigma, isolation, and difficulties making or maintaining friendships than typically developing (TD) peers or peers with other disabilities, although some studies have found little difference between students with ASD and students with other disabilities. The core social communication deficits in students with ASD are associated with lower self-esteem and subsequently poorer mental health in a college setting. Individuals with ASD may spend more time using screen-based media than any other activity; however, some research has found that high levels of social media use in ASD are associated with loneliness and depression, while others have found that social media use can mitigate feelings of isolation. With the covid-19 pandemic lockdown came an abrupt switch to remote online learning associated with quarantines. The impact of this isolation on students with ASD, and the potential long-term effects on social success in college has not been investigated.

**Objectives:** This was an exploratory study performed during the initial pandemic response (summer 2020), aiming to examine the relationship between social self-esteem and social media use in college students with ASD and matched TD peers and peers with Attention Deficit Hyperactivity Disorder (ADHD).

**Methods:** 176 undergraduate students from a private liberal arts college participated in an online survey including demographic information, diagnostic self-identification, the Social Self-Esteem Scale, the Social Media Engagement Questionnaire, average screen time, and self-reported experiences of mental health issues. Eight individuals with ASD were matched on age, gender, and GPA to individuals with ADHD ( $n=9$ ) and TD peers ( $n=10$ ). A one-way ANOVA was used to assess differences in social self-esteem and social media use across diagnostic groups. Bivariate correlations between social self-esteem and social media use were compared across diagnostic groups. A multiple linear regression was used to predict social self-esteem from key variables.

**Results:** There were no significant differences in social self-esteem [ $F(2, 24) = 2.575, p = .097$ ] or social media use [ $F(2, 24) = .398, p = .676$ ] across the diagnostic groups. Social self-esteem was positively correlated with social media use in students with ADHD ( $r = .715, p = .046$ ), but unrelated in students with ASD ( $r = .061, p = .876$ ) or TD ( $r = .165, p = .648$ ). A multiple regression explained 78.5% of the variance in social self-esteem, and social media use was a significant predictor ( $\beta = .732, p = .009$ ). For every single point increase in social media use, social self-esteem increased by .732 points, holding screen time, ASD presence, and presence of depression and anxiety constant.

**Conclusions:** Students with ASD were similar to students with and without disabilities in terms of social media use, screen time, and social self-esteem. Previous studies have argued that social media holds promise as a tool to facilitate social success of students with ASD in college settings, since it requires less decoding of complex social information. However, during periods of isolation, the social self-esteem of individuals with ASD appears unrelated to social media use.

**415.027 (Poster)** Teaching Employment-Related Skills to Autistic Workers; A Review and Call for Research  
**D. Schena<sup>1</sup>, A. Hillier<sup>2</sup> and V. Rosado<sup>2</sup>**, *(1)University of Massachusetts, Lowell, Lowell, MA, (2)University of Massachusetts Lowell, Lowell, MA*

---

**Background:** Adult outcomes for those with autism are below expectations and rates of employment are lower than those with other disabilities (Shattuck et al., 2012). Individuals with autism spectrum disorder (ASD) frequently experience difficulties with employment despite an ability to perform essential job functions (Hagner & Cooney, 2005). However, research on employment support seems to concentrate on a few areas of the employment process (such as interview preparation) while neglecting other areas. We aimed to review the literature in order to identify these areas of job support, as well as what methods were used to teach employment-related behaviors in these areas.

**Objectives:** To discover which areas of the employment process have been targeted for employment support via teaching-based interventions by researchers.

**Methods:** We employed a traditional literature search in order to identify areas of the employment process targeted for employment supports as described in research literature. Using nine databases and search engines, we extracted manuscripts discussing employment among individuals with ASD. We also identified existing literature reviews on related topics and extracted reference information from each literature review with full text available (18). This method identified 1063 potentially usable manuscripts. We then used PRISMA guidelines for our literature review as described in Figure 1, screening out duplicates (412 removed) and filtering articles based on abstract and full-text screening (366 and 240 studies excluded, respectively). This resulted in 60 usable manuscripts.

**Results:** Of the 60 studies reviewed, average sample size was 18.32 participants ( $SD = 29.35$ ) with an average age of 22.5 (full range 10-47). Studies largely consisted of three basic groupings. The first group of studies (12) targeted job interviews as the primary focus of the study. The second grouping (32) consisted of teaching individuals to do a specific job-related task or series of tasks, which usually used behaviorist methods such as mastery criteria or behavioral skills training. The third and final grouping, "other" (16) consisted of a wide variety of studies, from program reviews to multi-year follow-up studies to studies using traditional instruction methods or group discussions as primary methods of study. Studies tended to

focus on either the interview process or preparations beforehand (12), teaching behaviors relevant to a specific present or future job (36), cognitive, social, or emotional processes related to employment (4), or job outcomes after program participation (6). Certain areas of the employment process, such as identifying and requesting accommodations, transportation, the process of identifying potential job openings, managing a job search, and completing job applications were the target of one or fewer manuscripts.

**Conclusions:** Significant research exists on the topic of teaching employment-related information and behaviors to prospective and current workers with ASD. However, much of this research seems to cluster around certain aspects of job acquisition or retention while neglecting other areas. It is our opinion that study on these areas of the employment process may be beneficial and could lead to programming which positively impacts employment outcomes for autistic adults.

#### **415.028 (Poster)** Longitudinal Effects of Age-Related Cognitive Decline in Autistic Adults

**C. Torenvliet, A. P. Groenman, T. A. Radhoe, J. Agelink van Rentergem, W. J. van der Putten and H. M. Geurts, University of Amsterdam, Amsterdam, Netherlands**

---

**Background:** Cognitive aging in autistic adults has mainly been tested in cross-sectional studies. We (Torenvliet et al., 2021; <https://psyarxiv.com/47tyc>), for example, observed that, difficulties in theory of mind and verbal fluency were present in both younger and older autistic individuals. Moreover, age-related cognitive effects did not differ between autistic- and non-autistic adults (i.e., parallel aging). However, these cross-sectional results could be biased by cohort effects, which warrants longitudinal studies. **Objectives:** In this study, we aim to (1) replicate these previously observed parallel age-related effects in a longitudinal sample, and (2) identify those individuals who might be most vulnerable for cognitive decline.

**Methods:** In a sample of 85 adults (24-79 years,  $N_{ASC}=52$ ,  $N_{non-ASC}=33$ ) we administered several cognitive tasks at two time-points (average interval: 5.8 yrs.) Preliminary results on verbal- and visual memory are presented here. During INSAR 2022 we present data from more cognitive domains, and include the participants currently tested ( $N_{tot} \sim 200$ ). First, reliable change indices were used to estimate the extend of age-related cognitive decline. Second, we used multilevel regression analysis to identify the effects of baseline age, interval, and age\*interval interactions. Changes over time were freely estimated in each individual (random intercepts/slopes). Next, we added group to assess differential aging effects of autism. Finally, we assessed effects of baseline IQ and sex.

**Results:** Preliminary results showed that many participants decreased (42-57%), but also increased (27-42%), and remained stable (11-24%) over time on direct- and delayed verbal- and visual memory. On average, negative interval effects were observed on all tasks. Negative age effects were also present on all tasks, except direct visual memory. Results were neither indicative of faster decline with increasing age nor of differential effects of being autistic. Finally, we observed no differences in cognitive aging based on IQ or biological sex.

**Conclusions:** In this longitudinal study, reliable changes over time were present, with large variability in the extend of age-related changes. However, this variability was not related to autism, age, IQ, or biological sex. Most importantly, we seem to confirm our previous cross-sectional results of parallel cognitive aging in autistic and non-autistic adults.

#### **415.029 (Poster)** The Role of Gender, Interests, and Diagnosis Age in Camouflaging ASD

**M. Swisher<sup>1</sup>, D. V. Chan<sup>2</sup>, O. C. Putnam<sup>3</sup> and C. Harrop<sup>1</sup>, (1)The University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (3)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC**

---

**Background:** Autism Spectrum Disorder (ASD) historically has a 4:1 male-to-female prevalence ratio. Emerging research on differences in gender phenotypes suggests females are underrepresented, calling this ratio into question (Loomes et al., 2017). Further, research has highlighted that females may experience autism through different expressions of current ASD diagnostic criteria, or they may have additional characteristics that are currently not considered in diagnostic criteria or typically experienced by males (Hull, Petrides, et al., 2020). Specifically, females have been reported to have less focused interests, and these interests tend to be in different subjects than males (Antezana et al., 2019; 2011; Hiller et al., 2014). Females also demonstrate and report increased social camouflage behaviors. Camouflaging is a technique used by individuals with ASD to suppress their autistic traits in social situations through masking, assimilating, and compensating (Hull et al., 2017), which has been found to report to late diagnosis of ASD (Hull et al., 2020). A late diagnosis for females on the spectrum increases the risk for psychiatric comorbidities (Cassidy et al., 2014; Geurts & Jansen, 2012; Lai & Baron-Cohen, 2015).

**Objectives:** The purpose of this study is to explore the significance that gender, focused interest types, and age of diagnosis have on social camouflaging behaviors. Understanding the interactions of these factors can help the diagnostic process of autistic adults, while also understanding gender differences and vulnerabilities.

**Methods:** 50 participants (n=30 female, n=9 male, and n=11 non-binary people) completed an online survey which included the Camouflaging Autistic Traits Questionnaire (CAT-Q; Hull et al. 2019) and an adapted Interests Scale from Bodfish's Interests Scale (2003). By spring 2022, we anticipate having 66 participants (n=25 males). Reported primary interests were coded and grouped for commonality by two independent researchers.

**Results:** As shown in Figure 1, CAT-Q scores differed across the three genders [ $F(2, 46)= 9.486$ ,  $p = .000$ ], where non-binary participants reported greater camouflaging behavior than females and females reported greater camouflaging behaviors than males. There was a significant effect of age of diagnosis on CAT-Q scores [ $F(1, 42)= 4.446$ ,  $p = .041$ ]; those not formally diagnosed, or diagnosed after 13 reported more camouflaging behaviors than those diagnosed before the age of 13. Figure 2 illustrates the relationship between gender, age of diagnosis, and CAT-Q scores. There was no

effect of gender on the sociability of interests [ $F(2, 47) = 1.023, p = .367$ ]. Further, CAT-Q scores did not impact the average of interests [ $F(1, 48) = 1.252, p = .269$ ]. Most frequent common interests for males were games and sports; most frequent common interests for females were art, reading and writing, science, and psychology. The nonbinary group's interests aligned most with the female interests with the most common being psychology, reading and writing.

**Conclusions:** These preliminary results support previous findings of a gender difference in camouflaging behaviors, while critically including a non-binary group. These implications can help clinicians to be more sensitive to gender differences and promote early conversations about camouflaging behaviors to encourage and support self-acceptance, especially around those who were diagnosed later in life.

**415.030 (Poster) The Role of Internalizing & Externalizing Behaviors on Adaptive Behavior in Autistic Adults**

*L. F. Rentschler<sup>1</sup>, Y. C. Syu<sup>2</sup>, S. Kawabata<sup>3</sup>, B. Tomaszewski<sup>4</sup> and B. B. Maddox<sup>5</sup>, (1)School of Education, University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Frank Porter Graham Child Development Institute, University of North Carolina at Chapel Hill, TEACCH Autism Program, Chapel Hill, NC, (5)University of Pennsylvania, Philadelphia, PA*

**Background:** Autistic adults, across a wide range of cognitive abilities, often need supports related to adaptive functioning, internalizing behaviors, and externalizing behaviors; however, little is known about the way these areas of need impact one another. Adaptive skills are a key predictor of adult outcomes like social engagement, employment, and independent living. Effective educational and psychological evidence-based practices exist for both adaptive functioning and mental health challenges (Hume et al., 2021; Keefer et al., 2018). However, the manifestations of internalizing and externalizing behaviors may create barriers to support implementation. For example, anxiety may cause a person to abstain from group learning situations or aggression may pose safety concerns. Developing an understanding of the association between internalizing and externalizing behaviors and adaptive functioning could inform the sequence and content of support planning.

**Objectives:** The objective of this study is to examine whether internalizing and externalizing behavior predicts adaptive functioning in autistic adults.

**Methods:** We conducted a secondary data analysis of the clinical records of 64 autistic adults (49 male, 15 female) seeking an autism diagnostic evaluation at university-affiliated clinics across a southern state. The battery of assessments included for analysis were the Childhood Autism Rating Scale, 2nd Edition High Functioning rating scale (CARS2-HF) or the Autism Diagnostic Observation Schedule (ADOS), the Vineland Adaptive Behavior Scales Third Edition (VABS-3) or Adaptive Behavior Assessment System Third Edition (ABAS-3), the Adult Self Report (ASR) and the Adult Behavior Check List (ABCL), and a normed IQ assessment. Multiple imputations were employed for missing data on all measures. Hierarchical regression analysis was performed on the imputed dataset to investigate the unique contributions of IQ, autism severity, and self-reported (ASR) and informant-reported (ABCL) externalizing and internalizing behaviors in explaining the variance in adaptive behavior.

**Results:** The sample has an average IQ of 100.74, with ten participants having an IQ score <80. The majority of the participants scored low on the adaptive functioning assessment and reported internalizing and/or externalizing behaviors in the clinically significant range (see Table 1). The results of the hierarchical regression analysis indicate that externalizing and internalizing behaviors predict adaptive functioning for autistic adults, but the measure informant (self- vs. informant-report) impacts the strength of the prediction (see Table 2). Internalizing behavior, as reported by a familiar informant, accounts for the greatest amount of variation and shows an inverse relationship to adaptive behavior. However, self-report is also a significant predictor yet indicates the opposite relationship. Externalizing behavior as reported by a familiar informant is the final significant predictor and shows a positive association.

**Conclusions:** Adaptive behavior is predicted by internalizing and externalizing behaviors, but the direction of the association differs depending upon the identity of the assessment informant. During clinical assessments and research, assessors should include both self and other informant reporting methods. Additionally, quality mental health services may result in an added benefit of improving adaptive functioning in autistic adults.

**415.031 (Poster) Vocational Trajectories and Well-Being in Young Adults with Autism Spectrum Disorder**

*E. B. Clarke<sup>1</sup>, K. Sterrett<sup>1</sup> and C. Lord<sup>2</sup>, (1)University of California, Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA*

**Background:** Vocational activities are a key component of adulthood and a predictor of well-being (Kaya et al., 2016; Schulenberg et al., 2004). However, the relationship between vocational activities and well-being in autism spectrum disorder (ASD) is unknown. Adults with ASD experience limited social connectedness (Orsmond et al., 2013), difficulty living independently (Anderson et al., 2018; McCauley et al., 2020), and other poor outcomes at high rates (Lord et al., 2020; Shattuck et al., 2012). Understanding vocational trajectories could provide insight into supporting well-being in adults with ASD.

**Objectives:** Characterize vocational trajectories in a sample of adults with ASD ages 18-28, examine the slope of said trajectories, and explore relationships between inclusion in each trajectory group and psychosocial outcomes including subjective well-being, living status, and social connectedness.

**Methods:** 151 adults with ASD were drawn from an ongoing longitudinal study. Data on vocational activities were compiled from parent-report demographic forms and scored using the Vocational Index (VDI). A happiness composite score (McCauley et al., 2020) was used to measure subjective well-being. Vocational trajectories were identified via group-based trajectory modeling. Multilevel modeling was used to investigate the slope of trajectories. One-way ANOVAs and chi-square analyses were used to examine differences in outcomes between trajectory groups.

**Results:** A four-group model best fit the data; the slopes of all four groups were linear (Figure 1). The first trajectory group, No Activities, was characterized by little participation in vocational activities. The second group, Volunteer Activities, was characterized by participation in volunteer activities or sheltered employment for 10 hours/week or less. The third group, Supported Activities, was characterized by participation in supported community employment and/or sheltered employment for more than 10 hours/week. The fourth group, Independent Activities, was characterized by participation in postsecondary educational programs and/or independent employment for more than 10 hours/week. There was no significant effect of age on VDI scores ( $p = .787$ ). Participants in the Independent Activities group had significantly higher parent-report well-being than participants in the No Activities group and significantly higher self-report well-being than participants in the Volunteer Activities group (Table 1). The Independent Activities group was also significantly more likely to have at least one social contact ( $X^2(3, 118) = 10.54, p = .014$ ). There was no difference between groups in the likelihood of living independently ( $X^2(3, 120) = 1.71, p = .634$ ).

**Conclusions:** This study investigated the relationship between vocational trajectories and well-being in adults with ASD. We identified four distinct trajectories. The slopes of all four trajectories were stable, suggesting individuals not engaged in vocational activities early in adulthood are unlikely to transition to independent employment or an appropriate educational placement later in adulthood. Participants who engaged in independent activities had higher parent- and self-reported well-being and were more likely to have social contacts than participants who did not engage in vocational activities or engaged only in volunteer activities. Future studies should assess change in vocational activities in later adulthood and identify intervention targets to increase the likelihood adults with ASD engage in vocational activities.

**415.032 (Poster)** Work-Related Psychological Needs and Job Satisfaction of Autistic Adults: The Mediating Role of Self-Determined Work Motivation

**Y. Goldfarb<sup>1</sup>, E. Gal<sup>2</sup> and O. Golan<sup>3</sup>,** (1)Department of Occupational Therapy, Ben Gurion University of the Negev, Israel, Haifa, Israel, (2)Department of Occupational Therapy, University of Haifa, Haifa, Israel, (3)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel

**Background:** Self-Determination Theory (SDT) of motivation has been widely substantiated in the general population, providing work-related theoretical insights and practical implications. It has been suggested as a useful framework for understanding and promoting employment integration of autistic adults, addressing both personal and environmental factors (Goldfarb et al., 2019, 2021). SDT theorizes that: (a) work motivation that is self-determined in a sense that it is driven by choice and autonomy, leads to positive employment outcomes such as job satisfaction (b) all employees share the aspiration to satisfy three work-related psychological needs: autonomy, social-relatedness, and competence. Satisfaction of these needs promotes Self-Determined Motivation (SDM) and its' positive outcomes (Gagné & Deci, 2005).

**Objectives:** To explore the relevance of SDT in employed autistic adults, hypothesizing that higher satisfaction of the work-related psychological needs (autonomy, social-relatedness and competence) will lead to higher SDM, which will in turn lead to increased job satisfaction.

**Methods:** Data was collected from a sample of 36 autistic employees (5 females) aged 19-53, who filled a cross-sectional survey. Self-reports included measures of: satisfaction of psychological needs at work (Psychological Need Satisfaction and Frustration – Work domain); SDM (the Multidimensional Work Motivation Scale) and job satisfaction (Minnesota Satisfaction Questionnaire).

**Results:** To test the hypothesis, three mediation analyses were computed, using the Process Macro for SPSS (Model 4), predicting job satisfaction by each of the three work-related psychological needs, with SDM as the mediator. Results are illustrated in Figure 1.

The predictive model for *social-relatedness* ( $R^2=0.33, F(1, 34)=16.52, p<0.001$ ) indicated that the association between social relatedness and job satisfaction was fully mediated by SDM ( $\beta=0.40, C.I. 0.15-0.61$ ). Similarly, the predictive model for *autonomy* ( $R^2=0.32, F(1, 34)=16.32$ ) indicated that SDM fully mediated the path between satisfaction of autonomy and job satisfaction ( $\beta=0.34, C.I. 0.14-0.51$ ). Finally, the predictive model for *competence* ( $R^2=0.09, F(1, 34)=3.31$ ) showed a marginally significant effect for SDM ( $\beta=0.30, p<0.08$ ), indicating that higher satisfaction of competence is associated with higher SDM, with marginal significance. Estimates of the indirect effect for SDM ( $\beta=0.22, C.I. 0.0042-0.4056$ ) were significant, indicating that SDM fully mediated the path between competence and job satisfaction.

**Conclusions:** Results confirm the relevance of work-related SDT constructs for autistic adults. Autistic employees who feel competent, socially connected to their employer and colleagues, and are given a feeling of choice, will consequently present work motivation which is self-determined and volitional. The emphasis on the work environment, which can be shaped and adjusted to respond to employees' psychological needs, contributes the notion that motivation is not just a given state, but can rather be facilitated towards a feeling of autonomy and volition. Findings can inform the implementation of SDT driven practice in vocational rehabilitation services and work-related supports of autistic adults.

**415.033 (Poster)** “F\*\*\*\*\*!”: The Impact of COVID-19 on the Well-Being of Autistic Adults

**K. M. Normansell-Mossa<sup>1</sup>, D. L. Limon<sup>2</sup>, S. Y. Park<sup>3</sup>, N. Daines<sup>4</sup>, M. South<sup>5</sup> and R. A. Lundwall<sup>5</sup>,** (1)Clinical Psychology, Brigham Young University, Provo, UT, (2)308 W North Temple, Brigham Young University, Salt Lake City, UT, (3)Brigham Young University, Provo, UT, (4)Psychology & Neuroscience, Emory Autism Center, Provo, GA, (5)Psychology & Neuroscience, Brigham Young University, Provo, UT

**Background:** Autistic adults may be at increased risk for anxiety related to increased day-to-day experiences of uncertainty and changes in routines caused by the global COVID-19 pandemic. Yet, some autistic adults may feel more at ease in pandemic times due to the decreased expectation for socialization. More research is needed on how autistic communities in the U.S. will need support in navigating a post-COVID world.

**Objectives:** To explore positive and negative themes on how the COVID-19 pandemic has impacted autistic adults' well-being and moods. Results from this study will shed light on specific challenges, targets for intervention, and potential health outcomes that many autistic adults may face post-pandemic.

**Methods:** A total of 143 adult participants with a self-reported autism diagnosis (118 confirmed) electronically consented to complete a 30-minute survey regarding their mental health, employment and education. Participants were recruited from our existing research database and through word-of-mouth. The survey was open from February to May 2021. As part of the survey, participants were asked an open-ended question "How has the COVID-19 pandemic affected your overall health, well-being, and daily life?"

**Results:** Descriptive analysis indicated that more than 60% of survey respondents reported some impact, although a significant minority of individuals ( $N = 56$ ; 39%) described no impact from COVID-19. However, even within those reporting no to minimal change, some individuals reported either positive or negative changes. About 83% of participants' responses contained negative themes and about 31% contained positive themes. Commonly reported positive themes were the benefits of limited social interactions. Some participants also reported making adjustments to adapt to the changes from COVID-19, for example "taking up drawing as a hobby to fill free time." Common negative themes were feeling isolated by limited social interactions, financial distress from reduced hours or job loss, and health decline. Many participants reported that transition to remote work and school limited social opportunities and increased difficulty in physically interacting with family and friends. Responses also include "difficulties making ends meet," "rapidly running out of money." Some of the health compromises were weight gain and sleep changes. Perhaps our most poignant response began with a strong expletive, beginning with an F then strung out across the page with the main vowel typed 57 times.

**Conclusions:** Autistic adults have been greatly impacted by the COVID-19 pandemic including struggles with social interactions, financial concerns, work changes, and physical health. These stressors are likely associated with major change and upheaval, which may disproportionately impact autistic people due to their tendency to prefer sameness and difficulty managing uncertainty. Changes in routines are generally challenging for autistic people, and the many changes caused by the pandemic have created a great deal of uncertainty surrounding when life will go back to normal. Autistic adults will benefit from extra support and understanding from family and friends, employers, and health/mental health professionals is needed. Recognizing how hard this unusual but intense situation has been for autistic adults may improve self-awareness and connection to others with similar struggles.

**415.034 (Poster)** "Social Vulnerability" Is Predicted By Cognitive More Than Emotional Factors in Women with Social Difficulties  
**M. South<sup>1</sup>, J. S. Beck<sup>2</sup>, K. M. Normansell-Mossa<sup>3</sup>, D. L. Limon<sup>4</sup>, T. P. Gabrielsen<sup>5</sup>, J. Cox<sup>6</sup> and R. A. Lundwall<sup>7</sup>,** (1)Psychology & Neuroscience, Emory Autism Center, Provo, GA, (2)Psychology, Brigham Young University, Provo, UT, (3)Clinical Psychology, Brigham Young University, Provo, UT, (4)308 W North Temple, Brigham Young University, Salt Lake City, UT, (5)Counseling & Special Education, Brigham Young University, Provo, UT, (6)Counseling and Career Center, Brigham Young University, Provo, UT, (7)Psychology & Neuroscience, Brigham Young University, Provo, UT

**Background:** Autistic adults without language or cognitive delays may succeed academically in school but struggle to make the transition to independent living and pursuit of higher education and employment as much as they would like. Emerging research in this area has targeted outcomes in everyday adaptive behavior and quality of life. The concept of "social vulnerability" was developed to describe the risk for victimization including financial, emotional and physical exploitation that is common in individuals diagnosed with intellectual disabilities but has not been frequently used in samples with average to above-average intellectual function.

**Objectives:** To explore contributing factors to social vulnerability in a sample of adult women with social difficulties including autistic and/or socially anxious women. We examined three core factors including cognitive, social communication, and emotional domains.

**Methods:** The study consisted of 46 adult women (age range 18-42, mean=25) who responded to an advertisement asking "In social situations, do you often find yourself confused, anxious, or exhausted?" and who further scored at least moderately high on the BAPQ measure of broader autism traits. IQ, executive function, anxiety and depression, and social responsiveness scores were collected from the women in the study. Data for the Social Vulnerability Questionnaire were collected from parents of the women participants (38 mothers, 1 grandmother, 7 fathers). We have been analyzing these samples dimensionally rather than by diagnosis to better understand the shared factors underlying social difficulties that contribute to real-life challenges.

**Results:** Mean score from the WASI-2, 2-subtest IQ estimate was 114.21 (range 83-137, SD=11.507), indicating a sample with overall strong cognitive ability. Descriptive analyses indicated compared to previously-reported samples with intellectual disability, several domain scores were a bit lower but this group scored especially high on the Parent Independence domain ( $M=10.80$ , previous ID samples  $M=5.87$ ), meaning more dependence on parents despite their high average IQ. A regression model including measures of each domain (IQ, executive function, social responsiveness and mental health) was statistically significant  $R^2=.586$ ,  $F(5,37)=12.873$ ,  $p < .001$ . The strongest predictors were in the cognitive domain including the BRIEF Behavior Regulation Index ( $\beta=.623$ ,  $p<.001$ ) and the WASI-2-2 estimate ( $\beta=.214$ ,  $p=.044$ ). SRS-2 and ADOS scores (social responsiveness) and mental health (DASS-21 anxiety, depression and stress) scores did not add predictive value to the model.

**Conclusions:** High verbal skills and cognitive ability do not always protect against victimization and social vulnerability and autistic adults can be highly susceptible to exploitation by others and remain dependent on parent guidance more than they wish. In this sample of women with IQ in the average to above-average range who find social situations challenging, executive function especially around behavioral regulation (including flexibility and inhibition), along with IQ, best predict this everyday vulnerability. Helping individuals, family systems, and other social support to be aware of the risk for exploitation and develop active avoidance strategies is a vital component of success in adulthood.

**415.035 (Poster)** Atypical Cortical and Subcortical Brain Activation Associated with Precision Visuomotor Control in Autistic Adults

**Z. Wang<sup>1</sup>, S. A. Coombes<sup>2</sup>, D. E. Vaillancourt<sup>3</sup>, D. J. Shirley<sup>2</sup>, G. Valcante<sup>4</sup>, A. M. Orlando<sup>5</sup>, R. A. Romero<sup>5</sup>, B. Karmakar<sup>6</sup>, A. A. Wagle Shukla<sup>1</sup> and M. W. Mosconi<sup>6</sup>,** (1)Department of Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (2)Applied Physiology and Kinesiology, The University of Florida, Gainesville, FL, (3)Applied Physiology and Kinesiology, University of Florida, Gainesville, FL, (4)University of Florida, Gainesville, FL, (5)The University of Florida, Gainesville, FL, (6)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS

**Background:** Although conceptualized as a childhood disability, autism spectrum disorder (ASD) has increasingly been recognized as a lifelong neurological condition that could significantly impact adult functioning and quality of life. A recent clinical study has identified a more than 25-fold increased risk of Parkinsonism from two independent cohorts of autistic adults, suggesting that neurological conditions may evolve and even become more prominent as affected individuals age. However, studies focused on neuromotor control in autistic adults are scant, and we do not yet know to what degrees autistic adults might be at risk of developing neurological symptoms and neurophysiological systems show abnormal levels of degeneration.

**Objectives:** The objective of this study is to elucidate cortical and subcortical brain activation associated with precision visuomotor control in autistic adults.

**Methods:** Sixteen autistic adults ages 30-73 years and 19 age-, sex-, and IQ-matched non-autistic controls completed a visually guided precision grip task during fMRI. Participants pressed an MRI-compatible load cell with their thumb and forefinger while viewing two horizontal bars from a visual display inside the scanner. Participants pressed to move the lower force bar upwards to the height of the static target bar and maintained a constant grip force for 2 sec followed by a one sec rest. This was completed 10 times per block. A total of 4 blocks were administered and alternated with 10 sec rest. The target bar was set at 15% of individuals' maximum voluntary contraction (MVC). This design has shown strong sensitivity in probing basal ganglia and cerebellar activations in neurotypical controls, autistic children, and Parkinson's disease patients. Grip force variability and peak force were examined. Whole brain, voxelwise analyses were conducted on the fMRI imaging data.

**Results:** Our results showed no group differences in MVC. Autistic adults showed both mean and peak force reductions relative to non-autistic controls. Increased BOLD signal was observed in well-established regions of the visuomotor network including motor and premotor cortex, inferior parietal lobule, extrastriate visual cortex, thalamus, putamen, and cerebellum. Autistic adults showed greater BOLD activation than controls in the left precentral (M1) and postcentral (S1) gyrus, bilateral inferior frontal gyrus (IFG), and right cerebellum lobule VIII (CBL.VIII). Increased age was associated with increased task-related activation in bilateral IFG and right CBL.VIII in ASD. On the contrary, increased age was associated with activation reductions of the left M1, RIFG, and right CBL.VIII in non-autistic controls. In autistic adults, decreased activation of RIFG was associated with more severe clinical ratings of repetitive behaviors.

**Conclusions:** Overall, these results provide new evidence that neuromotor alterations in autistic adults involve aberrant cortical and subcortical organization that may contribute to critical aging-related clinical issues in ASD.

**515.001 (Virtual Poster)** Autism-Friendly Public Bus Transport: Hearing the Voices of Autistic Persons to Better Understand Their Needs

**H. Dirix<sup>1</sup>, V. Ross<sup>1</sup>, K. Brijis<sup>1</sup>, L. Bertels<sup>2</sup>, W. Alhajyaseen<sup>3</sup>, T. Brijis<sup>1</sup>, G. Wets<sup>1</sup> and A. Spooren<sup>4</sup>,** (1)School for Transportation Sciences, Transportation Research Institute, Hasselt University, Diepenbeek, Belgium, (2)Master program occupational sciences, Faculty of Medicine and Health Sciences, Ghent University, Ghent, Belgium, (3)Qatar Transportation and Traffic Safety Center, College of Engineering, Qatar University, Doha, Qatar, (4)Faculty of Medicine and Life Sciences, Rehabilitation sciences, Hasselt University, Diepenbeek, Belgium

**Background:**

Being able to participate fully in the community and form social networks is crucial for leading a qualitative life. To this end, transportation plays an essential role. Autistic persons often rely on public transport to fulfill their mobility needs. Nevertheless, previous research shows that it is not always easy for them to use it. What issues autistic people face while traveling with public bus transport and how to make public bus transport more autism-friendly has not been researched in-depth to date.

**Objectives:**

The current case study in Flanders aimed to (1) allow autistic persons to express the issues they face while using public bus transport and (2) create awareness for more autism-friendly public transportation.

**Methods:**

A qualitative hermeneutic phenomenological study was carried out. Semi-structured interviews were conducted and processed based on the interpretative phenomenological analysis method.

**Results:**

The interviews were conducted with 17 autistic individuals (mean age: 23.4 years, 53% male) and 3 non-autistic employees of a public transportation company about their experiences when taking (autistic individuals) or driving (employees) the bus. After analysis, three main themes emerged: (1) creating predictability (subthemes: providing an overview, presence of consistency, and providing factual and accurate information), (2) limiting

stimuli, and (3) communication tailored to autistic persons. In addition, various coping strategies were described, such as using noise-canceling headphones or using a smartphone application to follow the route.

#### Conclusions:

The current study was one of the first to give an indication of how autistic persons experience public bus transportation. The results are both interesting to the autism community and public bus transportation companies. The coping strategies described are relevant for autistic persons in case they feel reluctant to use public bus transport. Furthermore, the current study's findings could also help public bus transportation companies further develop a universal and inclusive design to provide access to public transport at the same level of service for everyone.

#### 515.002 (Virtual Poster) A Snapshot of Self-Reported Experiences Under the COVID-19 Pandemic

W. Song<sup>1</sup>, D. Cooper<sup>2</sup>, K. Koffer Miller<sup>3</sup> and L. Shea<sup>4</sup>, (1)Temple University, Philadelphia, PA, (2)AJ Drexel Autism Institute, A.J. Drexel Autism Institute, Philadelphia, PA, (3)Policy and Analytics Center, A.J. Drexel Autism Institute, Philadelphia, PA, (4)A.J. Drexel Autism Institute, Philadelphia, PA

---

**Background:** Previous research studies have demonstrated negative impacts of COVID-19 on psychological and mental health of autistic adults greater than that of the general population (Oomen et al., 2021). However, the impact of COVID-19 pandemic on overall well-being of autistic adults remains largely unknown. Given that autistic individuals are a particularly vulnerable population, understanding various challenges this population experiences regarding social interactions, daily routines, service access, and other life domains is crucial in identifying priority areas that maximize meaningful community participation.

**Objectives:** Using self-reported survey data, we provided a point-in-time profile of personal experiences during the COVID-19 pandemic in five areas: social outcomes, mental well-being, activities, services, and personal experiences with COVID-19.

**Methods:** The data were collected from March to September 2021 from a pool of autistic adults who participated in a previous study. Individuals in the previous study who consented to future contact were recruited through mail, email, telephone, and text messages. A total of 189 autistic adults responded to this new survey. Respondents were an average age of 27.8 years (SD=26.0) and mostly white (n=161, 85%). About 25% (n=47) were women and 7% (n=13) reported a non-binary gender.

#### Results:

**Social Outcomes.** About 43% (n=81) of the participants were employed. Twenty-four (13%) participants reported that their employment status changed due to COVID 19. Regarding social interaction, 40% of the participants (N=82) reported lost contact with some or most of family or friends, while 40% of participants (N=82) reported increased interactions with others virtually or online. Most participants (n=134, 71%) reported decreased participation in the community under the pandemic compared to before the pandemic.

**Mental Well-Being.** Most of the participants (n=160, 85%) experienced some level of stress related to the pandemic. About 41% (n=78) had felt lonely more frequently than before COVID-19.

**Activities.** About 86% (n=162) of participants reported a change in their daily routines. More than one-third of participants (n=74, 39%) reported major changes where most or all activities they normally participated in were canceled, delayed, or substantially changed.

**Health Care Access.** Nearly 20% (n=35) reported not being able to access needed mental health care or experienced delays in making appointments or getting prescriptions. However, 21 of them accessed telehealth. Similarly, 34 (18%) reported no access to needed mental or behavioral health services or experienced delays in making appointments, and 22 participants accessed telehealth.

**Experiences with COVID-19.** More than half of respondents had or knew someone that was diagnosed with COVID-19 (n=112, 59%). About two-thirds of participants (n=127, 68%) felt unsafe participating in the community to some extent because of COVID-19.

**Conclusions:** Results highlight the burden of COVID-19 on autistic adults across different life domains and provide insights on crucial supports. It is likely that autistic adults will continue to experience challenges in coping with ongoing uncertainty, transitions, and life changes resulting from the pandemic. Guidance may focus on maintaining social interactions, either in-person or online, and adjusting to rapidly changing information and the impact on daily routines.

#### 515.003 (Virtual Poster) Case Study of an Autistic Calendar Calculator

J. Desrosiers<sup>1</sup> and L. Mottron, M.D., (1)University of Montreal, Montreal, QC, Canada, (2)Autism Research Group, CIUSSS du Nord-de-l'Île-de-Montréal, Montréal, QC, Canada

---

**Background:** The savant syndrome is characterized by exceptional abilities contrasted with lower cognitive and/or adaptive functioning (Miller, 1999). Its prevalence is around 0.06%. About 75% of savant individuals are on the autism spectrum. Most studies on the savant syndrome have focused on single cases, given its low prevalence and the heterogeneity of the abilities presented. In savants with autism, calendar calculation is the most common exceptional skill. It consists to complete calendar information. There is no consensus on the process(es) used by calendar calculators, especially since the case studies generally involve one participant, whose unique characteristics are described in uneven detail across studies.

**Objectives:** To explore the exceptional ability of an autistic adult with different questions that may reveal possible mechanisms used.

**Methods:** A 21-year-old autistic male capable of calendar calculation, FB, with unique access conditions (interest in and enjoyment of the tasks, supportive family), was evaluated. FB was diagnosed with autism at age four by a multi-disciplinary team. His exceptional ability was explored during two sessions with a total of 468 questions. All questions were presented nonverbally. The session was recorded and for each question, the reaction time and the success rate were compiled.

**Results:** A series of pre-test questions determined which question and answer mode he was most comfortable with. He preferred handwritten questions with nonverbal response choices. FB responded to simple questions (such as: what day of the week is March 21, 2016;  $M = 3.90$  seconds;  $SD = 1.80$ ) significantly faster ( $p < .001$ ) than to reverse questions (such as: what years have March 1 as a Tuesday;  $M = 21.55$  seconds;  $SD = 25.94$ ). However, both question types had similar success rates ( $p = .457$ ). FB succeed 93.50 % ( $n = 72$ ) of the simple questions and 90.00 % ( $n = 54$ ) of the reverse questions. FB limits (the dates for which the response rate is above the chance level) were set between 1945 to 1955 for the past and 2040 to 2055 for the future. The potential role of synesthesia in its performance was explored in the context of the calendar. Three conditions were compared to see if the colors of the questions and answer choices could influence reaction times and success rates. However, at this stage, the results did not allow us to propose a conclusion on its implication. The year 2001 was explored in its entirety. However, with the preliminary data, no error pattern was observed in the success rates and reaction times for each day of the week and for each month.

**Conclusions:** Although the results are preliminary, they suggest that calendar information is not accessed by following explicit algorithms. However, the perceptual or memetic nature of this information remains to be determined. Further sessions will be conducted with FB to better understand its capabilities. Other calendar calculators will also be tested to compare their results.

**515.004 (Virtual Poster) Continuity and Change in Loneliness and Stress during the COVID-19 Pandemic: A Longitudinal Study of Autistic and Non-Autistic Adults**

**A. M. Scheeren<sup>1</sup>, P. Howlin<sup>2</sup>, E. Pellicano<sup>3</sup>, I. Magiati<sup>4</sup> and S. Begeer<sup>5</sup>,** (1)Vrije Universiteit, Amsterdam, Netherlands, (2)King's College London, London, United Kingdom, (3)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia, (4)School of Psychological Science, University of Western Australia, Perth, WA, Australia, (5)VU University Amsterdam, Amsterdam, Netherlands

---

**Background:**

Several studies have reported a deterioration in the mental health of autistic adults during the COVID-19 pandemic (Adams et al., 2021; Oomen et al., 2021; Pellicano et al., 2021). This deterioration comes on top of a higher co-occurrence of mood disorders, more psychological distress and increased risk of loneliness in autistic people compared to the general population in pre-pandemic times.

**Objectives:**

We aimed to examine continuity and change in, and predictors of, self-reported loneliness and stress during the COVID-19 pandemic in autistic and non-autistic adults living in the Netherlands utilizing data from the Netherlands Autism Register (NAR) cohort study. We hypothesized that:

- 1a) stress and loneliness would increase in autistic adults from pre-lockdown (T0) to first lockdown (T1) but 1b) would remain stable from the first (T1) to the second lockdown (T2) in both groups;
- 2) autistic adults would report more loneliness and stress than non-autistic adults; and
- 3) autistic and non-autistic adults would share similar risk factors for more loneliness and stress (i.e., being female, younger, a prior mental health condition, unemployment, low social support, few social contacts, and more COVID-19 related worries).

**Methods:**

We measured loneliness and stress via online surveys in autistic and non-autistic adults at different time-points (see Figure 1): pre-lockdown (T0: March 2020; autism group only), during the first lockdown (T1: April 2020) and during the second lockdown (T2: October 2020). We used repeated-measures analyses of variance (ANOVAs) and multiple hierarchical linear regression analyses.

**Results:**

1a) Contrary to expectations, loneliness and stress levels did not increase from pre-lockdown to lockdown in autistic adults (no Time effect on loneliness:  $F(2, 596) = 0.77, p = .46$ ; or stress:  $F(2, 606) = 0.87, p = .42$ ). 1b) Bayesian ANOVAs indicated moderate evidence in favor of the hypothesis that autistic and non-autistic adults would show stable loneliness and stress levels from the first to the second lockdown.

2) Autistic adults reported more loneliness (autism: T1  $M = 16.65$ , T2  $M = 16.87$ ; non-autistic: T1  $M = 13.67$ , T2  $M = 13.40$ ) and stress (autism: T1  $M = 19.13$ , T2  $M = 19.57$ ; non-autistic: T1  $M = 13.87$ , T2  $M = 13.44$ ) compared to non-autistic adults, even after controlling for other factors in the regression model.

3) Predictors of more loneliness and stress were similar in both groups: lower perceived social support, more COVID-19 related worries, younger age (stress only), and a prior mental health condition (stress only). We found no significant effects of gender, unemployment or amount of social contact.

#### Conclusions:

Overall, loneliness and stress levels remained stable in autistic adults in the Netherlands over a period of eight months during the COVID-19 pandemic. They reported more loneliness and stress than non-autistic adults, possibly indicating unmet social needs and stressful daily lives. Although, on a group level, we noticed stability of loneliness and stress over time, on an individual level the wellbeing of some autistic individuals worsened during the pandemic while others remained stable or even, in some cases, improved. Individual differences deserve further attention.

#### **515.005 (Virtual Poster)** Coping-Resilience Profiles and Experiences of Stress in Autistic Adults

**M. Muniandy<sup>1</sup>**, A. L. Richdale<sup>2</sup> and L. P. Lawson<sup>1</sup>, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Cooperative Research Centre for Living with Autism (Autism CRC), Brisbane, QLD, Australia

---

**Background:** Emerging studies have alluded to high stress and frequent stressful encounters in the autistic adult population. Stressful encounters that characterise everyday life (i.e., daily hassles) and the degree to which one's life is perceived as stressful (i.e., general perceived stress) are suggested to be elevated in autistic individuals. Given the detrimental impact of stress on physical and psychological health outcomes, it is important to examine malleable individual resources such as coping and resilience, which may influence the extent to which stress is experienced.

**Objectives:** Using a person-focused approach, the objectives of this study were to: 1) derive coping-resilience profiles based on patterns of coping strategies and resilience, and 2) examine profile-level differences in relation to general and domain-specific stress (i.e., general perceived stress and daily hassles stress) in a sample of autistic adults.

**Methods:** The sample consisted of 86 Australian-based autistic adults, aged 19-74 years, recruited through an online study. Using cluster analytic procedures, coping-resilience profiles were derived based on the characterisation of coping strategy use (i.e., engagement coping and disengagement coping strategies; Brief COPE) and resilience (Connor-Davidson Resilience Scale). Profile-level differences in relation to daily hassles (Daily Stress Inventory) and total perceived stress (Perceived Stress Scale) were examined using ANOVA.

**Results:** Coping-resilience profiles were derived based on patterns of coping, which either reflected degrees to which *both* strategies were used (i.e., high or low use) or a dominance of one strategy over the other (i.e., high engagement and low disengagement, or vice versa), and levels of resilience, characterised as high or low. Four coping-resilience were identified (see Figure 1): *high cope/ low resilience* ( $n = 15$ ), *low cope/ high resilience* ( $n = 27$ ), *adaptive cope/ high resilience* ( $n = 20$ ), and *maladaptive cope/ low resilience* ( $n = 18$ ). Significant profile-level differences in general perceived stress [ $F(3,76) = 6.40, p < .001$ ] were noted. Individuals in the *high cope/ low resilience* and *maladaptive cope/ low resilience* profiles had higher general perceived stress than those in the *low cope/ high resilience* and *adaptive cope/ high resilience* profiles. Further, individuals in the *high cope/ low resilience* profile reported higher general perceived stress than those in the *low cope/ high resilience* group. Similar patterns were noted in daily hassles stress; however, these differences did not reach statistical significance [ $F(3,76) = 1.74, p = 0.17$ ].

**Conclusions:** Our findings suggest that jointly addressing coping and resilience (i.e., honing engagement coping and resilience, reducing disengagement coping) has the potential to cumulatively benefit the levels of perceived stress in autistic adults. Practical implications of utilising coping-resilience profiles may include: 1) the personalisation of stress management options, where individual-specific aspects of coping and/or resilience that need to be addressed can be determined, and 2) the identification of individuals who might be most at risk for experiencing high stress (i.e., *maladaptive cope/ low resilience* profile). Importantly, addressing the high levels of stress increasingly reported by the autistic adult population may have a cascading effect into other areas of life otherwise impacted by stress.

#### **515.006 (Virtual Poster)** Developing a Tool to Measure Frequency, Severity, and Impact of Meltdowns and Shutdowns in Autistic Adults

**L. F. Lewis, M. Cleary, M. Page, M. Layton and A. Burfoot**, College of Nursing & Health Sciences, University of Vermont, Burlington, VT

---

**Background:** Autistic meltdowns and shutdowns have been explored from the perspective of parents of children on the autism spectrum and extensively discussed in online autistic spaces, but there is little research on how these events are experienced from the perspectives of autistic adults. Previous research on childhood meltdowns identifies these as "problem behaviors" that are a significant cause of parental stress and stigma.

**Objectives:** To develop and pilot test a tool to measure the frequency, severity, and perceived impact on overall wellbeing of meltdowns and shutdowns based on interviews with autistic adults.

**Methods:** In an initial qualitative strand, we used Krippendorff's method of content analysis to conduct a secondary analysis of interviews with 33 autistic adults about the experience of having an autistic meltdown and/or shutdown. Meaning units were identified and clustered into themes using dendrograms, or tree-like diagrams. Then, items for the tool were developed using in-vivo quotes from participants to capture identified themes. The pilot tool included 73 items, with most items rated on a 5-point Likert-type agreement scale. Identity-first language was used throughout the tool. The tool was distributed to 54 autistic adults via an online survey with areas for open-ended comments to explore understandability, acceptability, and psychometric properties of the tool.

**Results:** Initial qualitative analysis revealed four themes that captured the experience of meltdowns, including: triggered by social or sensory stress, loss of control, expression is outward, and intense negative emotions. Four themes that captured the experience of shutdowns included: triggered by social or sensory stress, inhibited functioning, expression is internalized, and negative or dulled emotions. However, participant comments on the pilot test revealed flaws in our initial analysis, leading us to stop data collection prematurely. While some participants provided positive feedback about the tool, others shared that they detected an underlying sense of ableism throughout the tool. Participants questioned our very assumption that such a tool would be helpful. One participant shared that he was offended by items that sought to measure aggressive and/or violent behavior. Participants also expressed a perceived diversity in experiences that were difficult to capture in close-ended items. For example, participants frequently added individualized details in comment boxes because they perceived the items to be too broad to be applied to their specific experiences. Finally, one participant commented on the importance of meltdowns and shutdowns as coping mechanisms, which was not captured in our tool.

**Conclusions:** Participant feedback highlights the need to reapproach this project with a strengths-based lens, acknowledging that meltdowns and shutdowns hold different meaning for different people. We now recognize that we cannot (and should not) attempt to measure this experience in a tool that presumes that certain feelings, thoughts, and behaviors correspond to a negative experience for the person living it. We plan to redevelop this tool as a communication aid for autistics to share information about their own experience of meltdowns and shutdowns, including open-ended opportunities to share strengths and challenges.

**515.007 (Virtual Poster)** Differences in Self-Reported Mental Health Diagnoses between Autistic Adults Diagnosed before and after 21 Years of Age

**N. Jadav<sup>1</sup>, V. H. Bal<sup>2</sup> and E. Wilkinson<sup>1</sup>,** (1)Graduate School of Applied and Professional Psychology, Rutgers University-New Brunswick, Piscataway, NJ, (2)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ

---

**Background:** Adult autism studies are increasingly comprised of later-diagnosed adults. Little is known about how the mental health of these adults compares to those diagnosed earlier in life. In a Danish cohort registry, children diagnosed with autism in later childhood (11-15 years) were more frequently diagnosed with co-occurring psychiatric conditions, such as affective or anxiety disorders, than children diagnosed in early-to-mid-childhood (Rødgaard et al., 2021). Analyses comparing mental health conditions of those diagnosed in childhood vs. adulthood could provide important insights with which to contextualize findings in the adult autism literature.

**Objectives:** The present study aims to characterize the SPARK independent adult sample and document differences between adults diagnosed with autism before age 21 and later-diagnosed adults (those diagnosed at 21 or older).

**Methods:** The present study focused on 4,657 independent adults drawn from SPARK (V5, 12/2020) who completed a medical questionnaire. Participants were 18 years of age or older, legally independent (i.e., not have a conservator or guardian), able to read and understand English, had a professional diagnosis of ASD, and resided in the United States. Age at completion of questionnaires ranged from 18 to 85 ( $M=33.4$ ), with more females than males (1.41:1 female:male). For analytic purposes, age of diagnosis was divided at age 21 (to maintain consistency with Fombonne et al., 2020's characterization of SPARK dependent adults). Chi-square analyses and logistic regressions were used to compare self-reported behavioral and psychiatric conditions in adults diagnosed before 21 years and later-diagnosed adults.

**Results:** Just over half (52.4%) of all participants were diagnosed before the age of 21. The proportion of later-diagnosed adults was higher in older age groups, ranging from 13.2% in the 20-24 year old group to 80.3% in the 40+ year old group ( $X^2(20)=1478.95$ ,  $p<0.001$ ; Table 1). A higher proportion of males (58.2%) than females (48.4%) were diagnosed before 21 ( $X^2(1)=42.72$ ,  $p<0.001$ ). High rates of co-occurring psychiatric conditions were reported across the age groups. Those diagnosed at 21+ were more likely to report anxiety ( $OR=2.37$ ,  $p<0.001$ ), affective ( $OR=2.05$ ,  $p<0.001$ ), personality ( $OR=1.38$ ,  $p=0.002$ ), and eating ( $OR=1.58$ ,  $p<0.001$ ) disorders, even after controlling for age at reporting. Differences in attention or behavioral concerns (e.g., conduct disorder) were nonsignificant after controlling for age at reporting.

**Conclusions:** In the independent adult SPARK sample, older age groups, especially those 40+ years, had higher proportions of adults diagnosed later in life. Those diagnosed later in life also showed higher rates of co-occurring psychiatric conditions, even after controlling for current age. These findings suggest attention is needed to the timing of ASD diagnosis when conducting adult research. It is critical that researchers report timing of diagnosis and consider how timing of diagnoses may affect comparisons across studies. Findings also underscore previous research demonstrating high rates of co-occurring mental health challenges in autistic adults (Hollocks et al., 2019). Further research is needed to understand whether the mental health needs of childhood- vs. later-diagnosed adults are similar and whether these groups will require different types of adaptations to therapeutic programs to support psychological well-being.

**515.008 (Virtual Poster)** Dropping the Mask: It Takes Two

**J. Cook<sup>1</sup>, L. Crane<sup>2</sup> and W. Mandy<sup>3</sup>,** (1)Psychology and Language Sciences, University College London, London, United Kingdom, (2)Centre for Research in Autism and Education, UCL Institute of Education, University College London, London, United Kingdom, (3)Department of Clinical, Educational and Health Psychology, University College London, London, United Kingdom

---

**Background:**

Autistic people are a minority group, comprising approximately 1% of the population (Baio, et al., 2018). Consequently, everyday social situations for many autistic people predominately involve interacting with non-autistic work colleagues, family members, and friends. Often, autistic people report feeling that they need to camouflage or mask their natural or usual behaviour during these cross-neurotype social situations in order to cope, fit in, or get by (e.g., Hull et al., 2017; Livingston et al., 2020). Such camouflaging or masking is associated with negative consequences including feelings of exhaustion, identity confusion and mental health difficulties (e.g., Hull et al., 2017, 2021). However, some autistic people report that in

certain social situations or around certain non-autistic people they feel less pressure or need to camouflage or mask. Instead, they feel they can be more like their natural, authentic, or true selves. This later experience has rarely been examined within the camouflaging/masking literature.

#### Objectives:

We aimed to explore autistic adults' experiences of interacting in ways that felt natural or authentic to them during cross-neurotype interactions.

#### Methods:

The current study involved an online qualitative survey. To ensure the quality of data collected, we developed the survey in consultation with members of the autistic community using cognitive interviewing techniques. Cognitive interviewing is a qualitative methodology used in survey design to examine how participants interpret and respond to questions with respect to their idiosyncratic lives, experiences, and perceptions (Miller & Baena, 2014). Whilst the use of online surveys with autistic populations is recommended, in practice the use of online qualitative questionnaires is relatively novel, and thus little is known regarding the ways in which autistic people interpret and respond to qualitative questions presented in this format. One hundred and thirty-three autistic adults (58 women, 57 men, 12 non-binary individuals and 6 individuals who preferred not to disclose their gender) completed the survey. Survey responses were analysed thematically following the reflexive thematic analysis approach developed by Braun and Clarke (2006, 2013, 2019).

#### Results:

The degree to which participants felt they could safely and enjoyably engage in a manner that felt authentic or natural to them during cross-neurotype interactions, was related to the interpersonal behaviour of their non-autistic social partners. In this way, authentic engagement appeared to be best understood as an interpersonal process, dependent on the actions of both autistic and non-autistic social partners. Four themes were generated related to participants' experiences of authentic engagement within the context of safe and comfortable cross-neurotype interactions: (i) embracing diverse communication styles interests and perspectives; (ii) creating a more inclusive social environment together; (iii) minimising and managing miscommunication in mutually beneficial ways; and (iv) enjoyable interactions involving reduced anxiety and exhaustion as well as genuine connection and rapport.

#### Conclusions:

Given the growing body of research demonstrating the negative consequences of camouflaging/masking for autistic people (e.g., Hull et al., 2021), the knowledge and insights gained from this study will contribute to the development of systemic approaches for improving the social experiences and wellbeing of neurodivergent people.

#### **515.009** (Virtual Poster) Examination of Differences in Enrollment, Attendance, and Participation in an Intervention to Increase Community Participation in Rural Communities

**A. Pearl<sup>1</sup>, J. Nagle<sup>2</sup> and M. Salzer<sup>3</sup>,** (1)Department of Psychiatry/Division of Autism Services, Penn State Hershey/Penn State College of Medicine, Hershey, PA, (2)Psychiatry, Penn State College of Medicine, Hershey, PA, (3)Temple University, Philadelphia, PA

**Background:** Community participation is defined as engagement in natural contexts with others with or without disabilities within the general community outside of supported environments. Deficits in individuals with Autism Spectrum Disorder (ASD) result in significant challenges to and impairment in the ability of these individuals to gain greater inclusion and integration into the community in the way that they choose to. Community participation is further impacted for those living in rural communities as opportunities to fully participate may be more limited. Preliminary data from a pilot project examining the feasibility of an intervention to increase community participation in adults with ASD points to variable engagement in the intervention.

**Objectives:** To explore patterns of engagement including enrollment, attendance, and participation in an intervention to increase community participation for adults with Autism Spectrum Disorder living in rural communities.

**Methods:** Data is currently being collected as part of a larger longitudinal study of an intervention consisting of a 12-week module with the option of completing 3 additional 12-week modules targeting community participation. Twenty participants will be enrolled by March, 2022 (15 enrolled to date). Inclusion criteria is diagnosis of ASD, 18- to 40-years-old, and ability to self-report. At enrollment, participants will complete the Temple University Community Participation measure (quantity and variability of community participation) and the Visual Activity Sort (activities sorted by activity preference and desire to engage in the activity). Each participant will complete a 60-minute semi-structured qualitative interview with probes such as "What makes these activities important to you?" and "How do you choose which activities to do?" Additional predictors of engagement collected include demographics (including level of geographic rurality), severity of ASD, motivation for behavior change, perceived community discrimination, self-efficacy, physical health and mental health symptoms. Finally, during the intervention in addition to attendance ratings of engagement were scored by the clinician including percent completion of homework and engagement during the session.

**Results:** To date, all 13 participants completed the initial 12-week module with variable levels of engagement (2 individuals are still in Module 1 at this time). Following the first 12-week module, 3 participants exited the intervention (23% attrition rate). Following the second 12-week module, 2 more participants exited the intervention (20% attrition rate). Of the 13 who completed Module 1, we identified sub-groups of high, moderate, and low engagers. Preliminary results indicate that severity of ASD is not correlated with type of engagement. We will be exploring these classes of

engagers in light of the additional variables listed above. We anticipate high engagers will report higher access to resources (e.g., active natural supporters, higher socioeconomic status), higher motivation for behavior change, and lower comorbid physical and mental health symptoms.

**Conclusions:** Given the recent emphasis by experts in ASD and providers of services for adults with ASD on increasing community participation, it is important to understand who may be the most receptive to interventions to increase community participation and for those who demonstrated moderate to low engagement, what barriers may be modifiable to improve engagement and likely outcome.

**515.010 (Virtual Poster) Eye-Tracking on the Eyes Task in Adults with Autism Spectrum Disorder**

**Y. L. Chien<sup>1</sup>, J. P. Lee<sup>2</sup> and H. L. Li<sup>3</sup>,** (1)*National Taiwan University, Taipei, Taiwan,* (2)*National Taiwan University, Taipei, Taiwan,* (3)*University of Amsterdam, Amsterdam, Netherlands*

---

**Background:**

Theory of mind was hypothesized as core deficits in autism spectrum disorder (ASD). Processing emotion through facial expression is a fundamental mechanism of theory of mind. The Eyes task developed by Baron-Cohen et al. tests the attribution of mental states from the eye region of the face alone. It involves both complex emotion recognition and the first stage of theory of mind, namely mental state attribution. Little is known whether the difficulty in attribution of mental states in ASD children persisted in to adulthood particularly in cognitive able adults.

**Objectives:**

This study aims to investigate theory of mind deficits on the Eyes task by using eye-tracking and pupil dilatation measurement in Taiwanese adults with ASD.

**Methods:**

This cross-sectional case-control study compared emotion reading between adults with ASD and age- and sex-matched typically-developing controls (TDC). Autism spectrum disorders (ASD, n=30; mean age 26.0, SD 5.1). The inclusion criteria was cognitive-able adults (aged > 18 years) with a DSM-5 diagnosis of autism spectrum disorder. We also recruited 30 typically-developing controls (TDC, mean age 23.0, SD 2.2). All participants completed the Eyes tasks, in which each photo with a forced choice between four mental state terms printed around each picture, including complex emotions such as reflective, arrogant, scheming, planning, etc. The gazing points were recorded with Tobii X2-30 Eye Tracker. The specified areas of interest are defined onto each frame of the stimuli to enable the subsequent statistical analysis of the gazing points. The behavioral response, eye region gazing durations and pupil dilatation of each stimulus were compared between ASD and TDC groups.

**Results:**

For the Face task response, the ASD group correctly answered 14.8 items in total 20 items, performed significantly lower the TDC group. For the Eyes task response (Taiwanese version), the ASD group (19.2 items/37 items) still performed worse than the TDC group. The items of complicated expression showed significant difference between ASD and TDC. For the UK version, although the ASD group (27.4 items/43 items) still performed worse than the TDC group, the two groups showed no statistical difference. In the Taiwanese version, different set of complicated emotions showed significant difference between ASD and TDC. Eye tracking analysis suggests eye region gazing percentage overall was not statistically different between ASD and TDC. The analysis on pupil dilatation is undergoing and will be added later.

**Conclusions:**

Our findings suggest that adults with ASD may have difficulties in reading emotions, supporting theory of mind deficits in adults with ASD even in cognitive-able individuals. The eye gazing percentage was not significantly different between ASD and TDC, suggesting that the Eyes task may not be suitable for eye tracking analysis in cognitive-able ASD adults.

**515.011 (Virtual Poster) Interpersonal Violence in Autism Spectrum Conditions: A Systematic Review and Meta-Analysis**

**K. Cooke<sup>1</sup>, K. L. Ridgway<sup>1</sup>, D. Hedley<sup>2</sup>, E. Westrupp<sup>3</sup>, M. Hooley<sup>4</sup> and M. A. Stokes<sup>5</sup>,** (1)*Healthy Autistic Life Lab; School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia,* (2)*Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia,* (3)*School of Psychology, Deakin University, VIC, Australia, Melbourne, VIC, Australia,* (4)*Psychology, Deakin University, Burwood, VIC, Australia,* (5)*Deakin University, Burwood, VIC, Australia*

---

**Background:** Interpersonal violence is an issue of critical importance in autism spectrum disorder (henceforth, autism). Research shows autistic individuals are at heightened risk for victimisation relative to the general population, and also experience worsened outcomes associated with such experiences. Further, the *multiple minority stress* model, suggests that within autism, gender minorities (i.e., females and non-binary individuals) may be at increased vulnerability. To address concerns relating to the heightened vulnerability of autistic individuals, the current study involved a comprehensive systematic review of the current findings on experiences of interpersonal violence in autism.

**Objectives:** A systematic database search was conducted to identify studies assessing exposure to interpersonal violence. Interpersonal violence was defined as any act resulting in physical, sexual, or psychological violence that occurs between individuals.

**Methods:** We selected papers relating to autistic participants of any age and level of autism severity, compared by gender. From the search, 49 studies of varying methodologies and designs were identified as meeting inclusion criteria.

**Results:** A comprehensive synthesis of the findings indicated potential prevalence and identified several risk factors, and outcomes associated with interpersonal violence among autistic individuals in relation to age, gender, and autism severity. The types of interpersonal violence that are more prevalent among autistic individuals of varying gender identities were identified, while individual and contextual risk factors and mental health outcomes associated with these experiences were identified among autistic individuals, in relation to gender.

**Conclusions:** Findings reveal key areas of concern for autistic individuals by age, gender, and level of autism severity in relation to interpersonal violence prevalence, risk factors, and outcomes. In particular, findings provided initial insight into the significant role violence exposure has on worsened mental health outcomes for this population, and indicate the need for further research on this topic.

**515.012 (Virtual Poster) Multi-Layer Temporal Network Analysis Reveals Differences in Psychopathology Dynamics across Neurodevelopmental Disorders**

**C. Sandini<sup>1</sup>, C. Feller<sup>2</sup>, S. Eliez<sup>3</sup>, D. Van De Ville<sup>4</sup> and M. Schneider<sup>1</sup>, (1)Université de Genève, Geneva, Switzerland, (2)University of Geneva, Geneva, Switzerland, (3)Office Medico-Pedagogique, Geneva, Switzerland, (4)University of Geneva, Geneva, Switzerland**

---

**Background:** Traditional psychiatric assessments rely on the retrospective descriptions of the average intensity of clinical manifestations. Clinicians are therefore typically blind with regards to the dynamics of how different psychiatric symptoms fluctuate in daily life. However, the dynamics of how symptoms fluctuate and interact with one another and with the environment could carry important information for determining prognosis, predicting treatment response, or understanding underlying pathophysiological mechanisms. Novel tools of digital phenotyping, such as the Experience Sampling Method (ESM), promise to “open the black box” of daily life, by allowing to evaluate symptoms when and where they occur. Still the application of digital phenotyping tools to clinical practice has been limited by difficulties in drawing clinically meaningful conclusions from statistically complex data.

**Objectives:** Here we propose a novel approach based on Dynamic Multi-Layer Temporal Network Analysis, to analyse ecological data derived from the Experience Sampling Method (ESM). The approach provides an intuitive characterization of differences in the dynamic interactions between symptoms. We employ this approach to explore whether differences in psychopathology dynamics can help differentiate subjects affected from two different neurodevelopmental disorders from one another and from healthy controls. Multiple ecological self-assessments of psychopathology were collected over the course of 6 days for 33 individuals with 22q11.2 Deletion Syndrome (22q11DS) (13 females), 28 individuals with Autism Spectrum Disorders (ASD) (13 females), and 44 typically developing healthy controls (HCs). Multilayer temporal networks were reconstructed by considering both the propensity for symptoms to manifest together and the propensity for symptoms to dynamically influence one another across time. Networks were compared using non-parametric permutation testing.

**Methods:** Multiple ecological self-assessments of psychopathology were collected over 6 days for 33 individuals with 22q11.2 Deletion Syndrome (22q11DS) (13 females), 28 individuals with autism (13 females), and 44 typically developing controls (TD). Multilayer temporal networks were reconstructed by considering both the propensity for symptoms to manifest together and to dynamically influence one another across time. Networks were compared using non-parametric permutation testing.

**Results:** Network analysis provided an intuitive characterization of the propensity for different symptoms to manifest together, revealing an overall similar network structure across samples. However the relationship between real-time social context and symptoms of psychopathology differed significantly across populations. Moreover, samples differed substantially in terms of the dynamics interaction between symptoms across-time. Individuals with 22q11DS and idiopathic autism were located at opposite ends of a spectrum compared to TD. 22q11DS was characterized by weaker within-time correlations but stronger across-time correlations compared to autism and TD. Individuals with autism presented more coherent fluctuations of symptoms within a same time-point that were however more erratic and less stable across time.

**Conclusions:** These results suggest that different neurodevelopment disorder, that appear similar to clinical diagnostic assessment, can be differentiated in terms of psychopathology dynamics. Such differences in dynamic interactions between symptoms can be intuitively captured using temporal network analysis techniques. These results suggest that high-resolution ecological behavioural phenotyping could help identify patients affected by different neurodevelopmental disorders, and ultimately help path the way to a more personalized approach to clinical care.

**515.013 (Virtual Poster) Psychological and Sociocultural Influences in Camouflaging and Its Relationship with Mental Health in Autistic Adults: Findings from a Cross-Sectional Survey**

**S. Zhuang<sup>1</sup>, M. J. Liang<sup>2</sup>, B. Loo<sup>3</sup>, D. J. Leong<sup>4</sup>, L. William<sup>5</sup>, M. Bougoure<sup>6</sup>, L. Hull<sup>7</sup>, L. A. Livingston<sup>5,6</sup>, W. Mandy<sup>8</sup>, F. Happé<sup>9</sup>, D. W. Tan<sup>8,9</sup> and I. Magiati<sup>1,2</sup>, (1)School of Psychological Science, University of Western Australia, Perth, WA, Australia, (2)Department of Psychology, National University of Singapore, Singapore, Singapore, (3)Disabled People's Association, Singapore, Singapore, (4)Department of Clinical, Educational and Health Psychology, University College London, London, United Kingdom, (5)Social, Genetic and Developmental Psychiatry Centre, Cardiff University, London, United Kingdom, (6)Wales Autism Research Centre, School of Psychology, Cardiff University, Cardiff, United Kingdom, (7)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)School of Psychological Science, Macquarie University, Perth, WA, Australia, (9)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia**

---

**Background:** Camouflaging (also known as masking) involves the use of strategies by autistic people to minimise the visibility of their autism in social situations. While camouflaging can be an adaptive social strategy at times, it has also been consistently associated with poorer mental health outcomes. Most quantitative research to date has largely focused on individual correlates of camouflaging that are largely biologically determined or

stable over time (e.g., age, sex/gender, IQ, executive functioning). Given that camouflaging is a response predominantly driven by an individual's social environment, the process by which it develops is likely also influenced by an interplay of psychological characteristics and social experiences. However, little is known about psychosocial variables associated with camouflaging or implicated in the relationship between camouflaging and mental health.

**Objectives:** This study aims to investigate (a) whether specific hypothesised psychological (i.e., autistic burnout, autistic identity, fear of negative evaluation) and social experiences (i.e., perceived social support, stigma, vulnerability events, perceived social norms, desire to individuate or maintain social harmony) predict camouflaging, and (b) whether these psychosocial factors mediate or moderate the relationship between camouflaging and mental health in autistic adults.

**Methods:** This study was developed in partnership with an autistic consultant. Approximately 300 autistic adults were recruited through Prolific, autism organisations, and social media between 2019 and 2021. Inclusion criteria for participants were (a) individuals 18 years old and above, (b) able to self-report in English, and (c) have a professional diagnosis of autism or self-identify as autistic. Participants completed online self-report measures on demographic information, autistic traits, camouflaging, and the aforementioned psychosocial factors. Hierarchical linear regression analyses were performed to investigate whether psychosocial factors predict self-reported camouflaging, after controlling for age, gender, and autistic traits. Moderation and mediation analyses were conducted to examine the role of psychosocial factors in the relationship between camouflaging and mental health.

**Results:** Data analysis of the full dataset is ongoing. Preliminary analyses based on a subsample of 77 autistic (18-57 years; 62.3% female) suggest that camouflaging in autistic adults was largely driven by perceptions of stronger social norms and lower tolerance for deviance. Having a weaker autistic identity, a greater fear of negative evaluation, and a weaker desire to individuate from others also predicted higher levels of different camouflaging behaviours in autistic adults. The relationship between camouflaging and depressive/ anxiety symptoms was weakened among autistic individuals who reported a stronger autistic identity. We will present findings from our full analyses at INSAR 2022.

**Conclusions:** Camouflaging as a social coping strategy is likely influenced by individual psychological characteristics and perceived sociocultural pressures to conform. Our preliminary analyses suggest the need for both individual psychological and societal-level changes to shift from pathologising to accepting and embracing autistic differences, to alleviate the negative impact of camouflaging on mental health, and to minimise the need for autistic individuals to camouflage at the outset.

#### **515.014** (*Virtual Poster*) Repetitive Behaviors and Restricted Interests in Different Age and Cognitive Level Groups in Children and Youth with ASD

*S. Jasim and A. Perry, Psychology, York University, Toronto, ON, Canada*

---

**Background:** Individuals with Autism Spectrum Disorder (ASD) exhibit repetitive behaviors, which range from lower-order behaviors that require less cognitive engagement (e.g., hand flapping) to higher-order behaviors that require more cognitive engagement (e.g., narrow interests; Turner, 1999). Although classifying repetitive behaviors into lower- vs. higher-order behaviors is helpful in elucidating the complexities of the behavior, it may obscure important differences within each "order". Thus, there is growing interest in using a more comprehensive classification of repetitive behaviors (Lam & Aman, 2007). Interestingly, research has shown that the severity and presentation of repetitive behaviors differ depending on an individual's age and IQ (Leekam et al., 2011). However, findings on age and IQ differences in repetitive behavior presentations have been ambiguous and further research is needed. The use of IQ in neurodevelopmental research has been debated and some researchers have encouraged the use of an uncorrected cognitive level (i.e., not corrected for age as IQ scores are; Rizeq et al., 2017). Individuals with ASD also experience a range of comorbid psychopathology (Gabriels et al., 2005; Stratis & Lecavalier, 2013). Despite the high overall prevalence of comorbid problems, more research is needed to elucidate the level of different comorbid problems present in different age and cognitive level groups.

**Objectives:** Thus, this research addressed the following research questions: 1) What are the levels of comorbid internalizing and externalizing psychopathology present in different age and cognitive level groups?; and 2) What are the different severities and presentations of repetitive behaviors in different age and cognitive level groups?.

**Methods:** These questions were addressed using secondary data analyses from the Simons Simplex Collection (SSC) dataset, which is part of a larger database the Simons Foundation for Autism Research Initiative (SFARI). The sample consists of over 2000 children and youth with ASD, ranging in age from 4 to 18 years with a wide IQ range. The research questions were addressed via ANOVA. Psychopathology was measured using the Internalizing and Externalizing scores from the Child Behavior Checklist (Achenbach, 1992) and repetitive behaviors using the Repetitive Behavior Scale-Revised (Lewis & Bodfish, 1998) using the Lam & Aman (2007) 5-factor scores: ritualistic/sameness, self-injurious, stereotypy, compulsive, and restricted interests.

**Results:** In terms of age differences, early and middle childhood groups showed more externalizing behaviors and more stereotypy than the adolescence group. Further, the middle childhood group demonstrated more ritualistic/sameness than the early childhood group. Those in the early childhood and adolescence group showed more internalizing behaviors than the middle childhood group. In terms of cognitive level, the overall trend was that the lower functioning groups demonstrated more externalizing and repetitive behaviors than the higher functioning. Further, the highest functioning group showed significantly more internalizing behaviors than all the lower functioning groups.

**Conclusions:** There are robust differences in comorbid psychopathology and repetitive behaviors in different age and cognitive level groups. This is clinically valuable as clinicians would benefit from considering the role of age and cognitive level in determining the repetitive behavior presentations and risk of comorbid psychopathology.

**515.015 (Virtual Poster)** Symptom Profiles in Autism Spectrum Disorder Versus Attention Deficit Hyperactivity Disorder Versus Autism Spectrum Disorder Comorbid with Attention Deficit Hyperactivity Disorder: A Systematic Review

**H. Kandel**, *Psychiatry, SUNY Downstate Health Sciences University, Brooklyn, NY*

---

**Background:** Attention deficit hyperactivity disorder (ADHD) is the most common comorbid psychiatric disorder diagnosed in children with autism spectrum disorder (ASD), particularly in those with intact intellectual capacity. The comorbidity estimates reported for ADHD fall within the range of 30% to 80%. A comorbid diagnosis of ASD and ADHD can be made in DSM-5, this represents a significant step forward and likely boosted research on the shared and specific pathways related to comorbid ASD and ADHD. It is important to study ASD and ADHD symptomatology as the comorbidity places children at a higher risk for psychiatric hospitalization, positively correlated with receiving mental health services, also side effects of medications are seen more in patients with comorbid ADHD and ASD.

**Objectives:** To present common symptoms reported in ASD versus ADHD versus ASD comorbid with ADHD (ASD + ADHD) regarding cognitive deficits, adaptive, and social functioning.

**Methods:** PRISMA (preferred reporting items for systematic reviews and meta-analyses) guidelines were used in conducting this systematic review. A literature search was conducted using the databases PubMed and Web of Science to identify the relevant studies (January 2000 to September 2021) using the combination of keywords as follows: ADHD AND Autism, social cognition, social impairments, language difficulties, behavioral difficulties, attentional problems, executive dysfunction, memory. Inclusion criteria were studies that (1) Investigated comorbid symptomatology with ADHD and ASD diagnosis (2) children aged 5-18 (4) boys and girls (5) Low (<70) and high (> 70) IQ (6) English language journals. Papers excluded when (1) main area of study was treatment (pharmacological/ nonpharmacological), classification, genetics, or imaging, (2) Included only ADHD or only ASD diagnosis, and (3) studies included other psychiatric disorders like OCD, tic disorder, anxiety disorder, sleep problems, auditory processing disorder, and Specific learning impairment. We found 978 papers, 53 papers were included and reviewed, as demonstrated in (figure 1).

**Results:** Data is presented on clinical and neurocognitive levels. Common symptoms reported in ASD versus ADHD versus ASD + ADHD are shown in (table 1 and table 2), it includes executive dysfunction, aberrant reward processing, impaired social cognition, biased self-recognition/perception, memory problems, adaptive dysfunction, and differences in attention/ hyperactivity/ impulsivity symptoms profile. ASD + ADHD present with greater deficits in working and verbal memory, recognizing facial affect, regulating impulsivity, more socio-emotional and behavioral impairment, and more psychopathology than ASD or ADHD subgroups. Girls diagnosed with ASD+ADHD were found to have more impaired executive functions and scored less on the theory of mind tasks than boys. children with ASD+ADHD had a lower cognitive functioning, more severe social impairment, and greater delays in adaptive functioning than children with ASD only.

**Conclusions:** The overlapping domains found in ASD+ADHD category can guide the evaluation for comorbidity, in patients presenting with either ASD or ADHD diagnosis. Utilized at an early age, this can provide a more comprehensive evaluation for better treatment planning and outcomes.

**515.016 (Virtual Poster)** The Relationship between Autism Spectrum Quantitative Phenotypes, Resilience, and Anxiety during the COVID-19 Pandemic.

**Z. L. Smernoff<sup>1,2</sup>**, **S. C. Taylor<sup>3,4</sup>**, **B. N. Gehringer<sup>2,4</sup>**, **S. Steeman<sup>2,4</sup>**, **H. C. Dow<sup>2,4</sup>**, **L. Almasy<sup>2</sup>**, **D. J. Rader<sup>2</sup>**, **M. Bucan<sup>2</sup>** and **E. S. Brodtkin<sup>1</sup>**, (1)Department of Psychiatry, UPENN, Philadelphia, PA, (2)Department of Genetics, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA, (3)Neuroscience Graduate Group, University of Pennsylvania, Philadelphia, PA, (4)Department of Psychiatry, Perelman School of Medicine University of Pennsylvania, Philadelphia, PA

---

**Background:** Resilience refers to the complex process through which deleterious effects of stressors can be diminished and prevented (Bitsika & Sharpley, 2014). Previous work examining resilience and autism primarily focuses on the family members of autistic people, rather than on autistic people, themselves. We sought to better understand the relationships among autism spectrum traits, resilience, anxiety, and depression during the COVID-19 pandemic. This builds upon previous work by this group in that it seeks to establish this relationship when autistic traits are parsed into dimensions of social and restricted repetitive behavior.

**Objectives:** To evaluate the interaction between autism-related traits, other psychiatric constructs (i.e., anxiety and depression), and resilience during the COVID-19 pandemic in a sample enriched for adults high in autistic traits.

**Methods:** Two hundred and seven participants were recruited from the Autism Spectrum Program of Excellence (ASPE) genetics study at the University of Pennsylvania, including autistic individuals (n = 92) and their family members (n = 115), (57.4% female, 89.4% white, mean of 39.7 (+18.5 SD) years old). An additional one thousand four hundred and eighty-one participants were recruited from the general population during the COVID-19 pandemic (73.3% female, 88.5% white, mean of 48.3 (+15.7 SD) years old). Each participant completed self-report questionnaires about their autistic traits (SRS), severity of anxiety symptoms (GAD7) and depression symptoms (PHQ2), and resilience (Penn Resilience and CD-RISC). The SRS was examined as a total score and through its subscales (restricted repetitive behavior, social motivation, social communication, social cognition, and social awareness) to understand dimensions within the overall autism phenotype. Resilience is categorized differently by each questionnaire, with the CD-RISC being less predicated on social attributes than the Penn Resilience Questionnaire.

**Results:** Pearson correlations showed strong negative associations between resilience as measured by the CD-RISC and overall autistic traits as measured by the SRS ( $r = -0.52$ ,  $p < 0.01$ ), as well as restricted repetitive behaviors and social motivation, communication, cognition, and awareness. Similar results were found when measuring resilience through the Penn Resilience Questionnaire. Pearson correlations also showed strong positive associations between severity of anxiety and depression and quantitative autistic traits. All correlation findings are shown in Table 1. Moderation

analysis demonstrated that resilience (Penn Resilience and CD-RISC) has a strong, positive moderating effect on the relationship between anxiety and autistic traits but not on the relationship between depression and autistic traits (Table 2).

**Conclusions:** We found that autism-related traits across several dimensions are highly correlated with resilience and anxiety and depression, and that this association is maintained when examining specific dimensions of the autism phenotype. We also found that resilience moderates the interaction between anxiety and autistic traits, with resilience appearing to buffer the association between autism-related traits and heightened risk for anxiety. Further, despite different conceptualizations of resilience, there were minimal differences in both analyses between the two resilience questionnaires. Future analyses will investigate which dimensions of anxiety (i.e., social anxiety) drive the association between anxiety, autistic traits, and resilience.

**515.017 (Virtual Poster)** Health Related Quality of Life in Children with Autism Spectrum Disorder: A Cross-Sectional Study from Apex Center in North India

**S. Gulati<sup>1</sup>, P. K. Panda<sup>2</sup>, S. Sharma<sup>3</sup>, S. Khan<sup>3</sup>, P. Madaan<sup>3</sup>, S. Singh<sup>4</sup>, G. Kamila<sup>4</sup> and B. Gupta<sup>5</sup>,** (1)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India, (2)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, Rishikesh, India, (3)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (4)All India Institute of Medical Sciences, New Delhi, New Delhi, India, (5)All India Institute of Medical Sciences, New Delhi, India

---

**Background:**

Health related quality of life (HRQOL) of children with autism spectrum disorder (ASD) and caregivers is thought to be affected negatively, but exact measures and domains have not been clearly determined.

**Objectives:**

To determine the HRQOL parameters, its determinants and correlation with severity and behavioral comorbidities of autism.

**Methods:**

The HRQOL of children aged 3 -12yrs with ASD (DSM-V criteria) as measured by PedsQL-TM (Pediatric Quality of Life Inventory TM) Version 4.0 was compared with age and sex matched controls. Correlation of HRQOL with severity of autism {Childhood Autism Rating Scale (CARS) score}, development/intelligence quotient (Development Profile 3), behavioral co-morbidities {Child Behavior Checklist (CBCL)} and sleep disturbances {Childhood Sleep Health Questionnaire (CSHQ)}, HRQOL of caregivers by World Health Organization Quality of Life (WHOQOL), General stress levels of parents {Parenting Stress Index (PSI)} and coping strategies of parents (COPE inventory) were also analyzed.

**Results:**

141 children with ASD and age/sex matched controls were enrolled between August 2017 and April 2018. HRQOL of ASD children ( $p=0.0001$ ) and caregivers ( $p=0.001$ ) were significantly impaired as compared to controls. The HRQOL of autism children had strong negative correlation with severity of autism (CARS score) {co-relation coefficient( $r$ ) = 0.63}, moderate negative correlation with behavioral co-morbidities( $r=0.57$ ), total stress of parents( $r=0.53$ ), development quotient( $r=0.51$ ) and sleep disturbance ( $r=0.46$ ). Commonest coping strategies of parents were suppression of competing activities, behavioral disengagement, mental disengagement and religious coping. Parents of children with hyperactivity and CSHQ score  $>41$  had more impairment in HRQOL and parental stress ( $p=0.02$  and  $0.04$  respectively).

In a previous study on 125 ASD children in our center, more than three-quarters (76.8%) of the mothers reported depression. Most (60%) of them had mild and moderate depression. One seventh (14.4%) of mothers had severe depression and 2.4% had very severe depression. Levels of depression in the mothers were significantly associated with their physical health and quality of life. Mothers of children with severe autism (44.8%) had higher levels of depression than those with mild (25.6%) and moderate (29.6%) degrees of autism.

**Conclusions:**

Impairment of HRQOL of autism children correlates with the severity of autism and behavioral co-morbidities. Impairment of HRQOL of caregivers has also been observed and we need to develop coping strategies for the same.

**515.018 (Virtual Poster)** Being Autistic and Bilingual: A Thematic Analysis of the Experiences of Autistic Bilingual Adults Living in the UK  
**B. G. Digard<sup>1</sup>, S. Fletcher-Watson<sup>2</sup>, A. Sorace<sup>3</sup>, A. C. Stanfield<sup>4</sup> and R. V. Davis<sup>4</sup>,** (1)Division of Psychiatry, University of Edinburgh, Edinburgh, United Kingdom, (2)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom, (3)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom, (4)University of Edinburgh, Edinburgh, United Kingdom

---

**Background:** While being bilingual or living in a bilingual environment is becoming a more common experience around the world, little is known about the combined experience of bilingualism and autism. Most of the research available focuses on quantifying the language and cognitive development of autistic bilingual children, and the only qualitative accounts of the first-hand experience of autistic bilinguals are from either bilingually-raised children or highly multilingual adults (with 4 languages or more), which may not represent the wider autistic bilingual population.

**Objectives:** This qualitative study aims to report the experiences of autistic bi- and multilingual adults living in the UK, focusing on their perceived benefits of bilingualism, and on the barriers and enablers to bilingualism.

**Methods:** A group of 39 autistic bilingual adults (41% female, mean age = 33.2 years, range = 16-61) with reported knowledge of 2 to 7 languages (mean = 3.6, SD = 1.4) and residing in the UK completed an online Demographic and Language Questionnaire including three open-ended questions about the interplay between autism and bilingualism. A thematic analysis was conducted on the responses to these open-ended questions.

**Results:** Respondents reported social communication as being a major benefit of being bilingual, as well as being better able to both understand other perspectives, and express their own self. They also perceived many opportunities and benefits brought by bilingualism, in terms of relationships, hobbies, mobility, employment, education, or cultural insight. They also discussed how bilingualism had shaped their self-understanding, in terms of increased awareness of their own skills, broadened mindset, and identification of difficulties linked with autism. Finally, they also identified several factors that had enabled or challenged their language learning journey, especially the learning environment, the opportunities for practice or specific language competences that were considered by some as difficult and by others simple.

**Conclusions:** This study builds upon the few qualitative reports available to highlight experiences that are shared by autistic bilingual people regardless of the number of languages they know. It is the first study to report the perspectives of autistic bilingual adults who, in most cases, did not have a special interest in languages and simply became bilingual through their life journey. Importantly, their accounts of the factors that can facilitate or hinder language learning will inform the development of adapted strategies to better support autistic people in their bilingual journey. Overall, these findings will have implications for bilingual families and the clinical and educational practitioners accompanying autistic bilingual people.

---

**515.019 (Virtual Poster)** Conversational Dynamics during Interactions between Autistic and Non-Autistic Partners

A. Castillo<sup>1</sup>, E. Stack<sup>2</sup>, **K. M. DeBrabander<sup>3</sup>**, D. R. Jones<sup>1</sup> and N. J. Sasson<sup>1</sup>, (1)University of Iowa, Iowa City, IA, (2)The University of Texas at Dallas, Richardson, TX, (3)University of Texas at Dallas, Richardson, TX

---

**Background:** Autistic adults (AA) are characterized by differences in social communication and interactions which can include reduced reciprocity and verbal fluency. However, these differences are based upon interactions with non-autistic (NA) people, who tend to evaluate AA negatively compared to NA controls (Sasson et al 2017). Previous studies suggest that AA may have enhanced interaction quality and outcomes—and establish greater rapport—with other AA who more similarly reflect their communication preferences (Crompton et al 2020). Such findings are consistent with the Double Empathy theory of autism (Milton 2012), which conceptualizes social interaction difficulties between AA and NA people as not solely driven by autistic “deficits” but by a mutual lack of understanding and a difference in communication styles.

**Objectives:** The current study tests whether, as predicted by the Double Empathy theory, autistic adults demonstrate different conversational dynamics when interacting with other autistic people compared to NA people.

**Methods:** Sixty-nine autistic and 71 NA adult males, comparable on age, ethnicity, and intelligence, participated in a 5 minute “get to know you” conversation with an unfamiliar partner in one of three dyadic conditions: both AA, both NA, or one AA and one NA. Transcripts of the conversations were analyzed to determine if the number of questions asked, the amount of turn-taking, and the number of words spoken during conversations for AA differed when interacting with NA adults compared to another AA.

**Results:** AA demonstrated significantly less turn-taking ( $p < .001$ ) and words spoken ( $p = .004$ ) compared to NA participants. Questions asked did not differ significantly between AA and NA participants ( $p = .393$ ). AA-AA dyads had reduced turn-taking compared to NA-NA and AA-NA dyads ( $p < .001$ ), but questions asked and number of words spoken did not significantly differ between dyad types. AA demonstrated significantly more turn-taking when interacting with NA partners than with AA partners ( $p = .039$ ), but diagnosis and dyad type did not significantly interact for number of questions asked or word count.

**Conclusions:**

Turn-taking and words spoken were significantly higher for NA than AA participants, confirming different social communication preferences in the two groups. Turn-taking was lower in conversational dyads whenever an autistic person was present, regardless of whether the partner was AA or NA. Although AA participants did not significantly differ on the number of words spoken or questions asked when their partner was NA relative to AA, they increased their turn-taking in conversations when their partner was NA compared to AA. NA people may be pushing for more interaction than AA partners, and AA may be increasing their turn-taking to meet NA conversation demands within mixed dyads. While previous research has found that NA individuals attempt to match the conversational dynamics of autistic individuals (Feldstein et al 1982), here we find evidence that this works in the other direction as well: AA strive to meet the turn-taking demands of NA partners.

---

**515.020 (Virtual Poster)** Beyond Friendship: The Spectrum of Meaningful Social Participation of Autistic Adults

**D. V. Chan<sup>1</sup>** and J. D. Doran<sup>2</sup>, (1)Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Pediatric School Psychology, East Carolina University, Greenville, NC

---

**Background:** While other symptoms of autism often plateau or improve in adulthood, social interaction difficulties persist and potentially contribute to lower rates of social participation, friendships/close relationships, and increased isolation (Mazurek, 2014; Tobin et al., 2014). Yet having a broader network of social contacts supports neurotypical healthy aging and mental health. Measures focused on assessing number of friendships,

frequency of contact or activities with friends, or presence/absence of social activity within a defined period may not accurately capture the extent of social participation of autistic adults.

**Objectives:** This qualitative study describes the range of social participation activities and contacts, from acquaintances to close relationships, of autistic adults to better understand, from the individual's perspective, where and how meaningful social interactions occur.

**Methods:** Two semi-structured interviews assessed the importance of community activities, feelings of belonging, and social connectedness from the autistic adult's perspective. Interviews were conducted before and after a week-long community activity data tracking process. Questions surrounded activities that occurred that week, the importance of different locations visited, and feelings of belonging and social support in the community. Qualitative data from interviews were analyzed using a multi-step approach focused on social and community involvement.

**Results:** Forty adults (24-62 years,  $M=37.8$ ) participated in the study (demographics in Table 1). Participants described meaningful social participation beyond typical friendships in various contexts that contributed to their feelings of community and belonging. Contexts for social participation clustered around five main themes: 1.) Vocational, 2.) Neighborhoods, 3.) Common interests, 4.) Support services and inclusive environments, and 5.) Online networks and apps. In all contexts, participants reported experiences across the spectrum of social participation including casual encounters, engaging with known acquaintances, or engaging in close friendships/relationships. Notably, participants used some contexts to practice social interactions for application in other settings or at other levels of engagement.

For example, participants described work as an important avenue for practicing social interactions. Common interest activities of church, gaming, or improv also offered opportunities for social engagement or practice for many participants. Walking pets promoted social interaction within neighborhoods, which contributed to feeling part of the community. Online platforms such as MeetUp and dating apps were used to facilitate in-person gatherings, while Facebook, online groups, and Twitter provided important connection with others or valued engagement in online communities.

**Conclusions:** With a significant focus in research on loneliness, isolation, and friendship quality in autistic adults, these findings provide initial support to think more broadly about where social participation and meaningful interactions take place. As autistic adults navigate social experiences, this study found evidence of individuals using a variety of in-person and online community contexts to intentionally practice and improve social participation skills. Findings also support adults used specific apps to facilitate in-person meet ups, at times merging the preference for online communication with the desire for in-person connection. These findings suggest moving away from social skills training groups toward more structured opportunities for social interactions and exploring new ways to tailor interventions to support a range of desired social participation preferences.

**515.021 (Virtual Poster) COVID-19 As a Natural Experiment Paradigm: Implications for Personal Wellbeing and Stress in Autistic Adults.**  
**C. M. Brown<sup>1</sup>, D. Hedley<sup>2</sup>, M. Fuller-Tyszkiewicz<sup>3</sup>, M. Hooley<sup>4</sup> and M. A. Stokes<sup>5</sup>,** (1)School of Psychology, Deakin University Australia, Melbourne, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia, (3)Deakin University, Melbourne, Australia, (4)Psychology, Deakin University, Burwood, VIC, Australia, (5)Deakin University, Burwood, VIC, Australia

---

**Background:**

In 2020, COVID-19 restriction measures introduced by the Victorian and Australian governments impacted aspects of most people's daily life. It is currently unclear what implications these restrictions had for the mental health and wellbeing of Autistic adults, who are known to experience disproportionately high rates of mental health concerns.

**Objectives:**

The aims of the present study were threefold: To measure mental health and personal wellbeing in Autistic and Non-Autistic adults in Australia during the first six months of the COVID-19 pandemic; to understand aggregate changes to mental health and personal wellbeing against baseline levels collected prior to the COVID-19 pandemic; and to understand and compare group level changes by both location and by autism diagnosis.

**Methods:**

We recruited 391 Australian adults, comprised of 199 autistic ( $M_{age}=43.71$ ,  $SD=14.40$ ) and 192 non-autistic participants ( $M_{age}=38.38$ ,  $SD=9.92$ ). Severity of depression, anxiety, stress, eating disorder symptoms (DASS-21 & EDE-QS) and personal wellbeing (PWI) data were collected in two discrete phases. Phase 1: 2019 baseline levels; and Phase 2: at monthly intervals from June to November 2020.

**Results:**

We found that autistic traits were associated with lower personal wellbeing and increased mental health symptom severity. However, relative to 2019 baseline levels, aggregate severity of depression, anxiety and stress decreased among autistic adults across the Victorian second wave of the COVID-19 pandemic in Australia. We also found that stress significantly mediated the relationship between autistic traits and personal wellbeing at all time points.

**Conclusions:**

The results show personal wellbeing and mental health symptoms were not worsened by government COVID-19 restrictions. In fact, they appear to have had a somewhat protective effect. These results provide some insight into the difficulty autistic individuals experience in many daily situations, and suggest paths toward supportive measures that may be undertaken in future. In a clinical setting, understanding the critical role of stress for Autistic people will be crucial for managing mental health and poor ratings of satisfaction with life.

**515.022 (Virtual Poster)** Cardiovascular Risk Factors in Middle-Aged and Older Autistic People and Their Associations with Depression Symptoms and Executive Function

**R. A. Charlton<sup>1</sup>**, G. A. McQuaid<sup>2</sup> and G. L. Wallace<sup>2</sup>, (1)Psychology, Goldsmiths University of London, London, United Kingdom, (2)The George Washington University, Washington, DC

---

**Background:** Cardiovascular risk factors (CVRF) increase during later life and are significantly associated with the presence of depression symptoms and difficulties with executive function among older adults. Few studies have examined CVRF among older autistic adults, including whether CVRF influence depression symptoms or are linked to executive function, as has been shown for non-autistic older people.

**Objectives:** This study examines the frequency of CVRF and associations between CVRF, depression symptoms and executive function in a large group of middle-aged and older autistic adults.

**Methods:** 387 participants (52.9% were assigned female at birth) aged 40-83 years old, were recruited online via Simons Foundation Powering Autism Research for Knowledge research match. Individuals provided demographic and health information in order to assess the number of CVRF (overweight/obesity, hypertension, high cholesterol, diabetes). Participants also self-reported their autistic traits (Autism Quotient-28), depression symptoms (Patient Health Questionnaire, 9 item), and executive functions in the domains of inhibitory control and emotional regulation (Barkley Deficits in Executive Functioning Scale).

**Results:** CVRF were common among middle-aged and older autistic people (Mean number CVRF=2), see Figure 1. Age was positively correlated with the number of CVRF ( $r=.183$ ,  $p<.001$ ) but not self-reported executive function. A negative correlation between age and depression symptoms was found ( $r=-.149$ ,  $p=.003$ ), indicating lower depression symptoms among older people.

Stepwise regressions were conducted to explore the variables that predicted depression symptoms (see Table 1). After accounting for the effects of age and sex assigned at birth, CVRF contributed to explaining a small but significant (1.6%,  $p=.004$ ) proportion of the variance in depression symptoms ( $F=6.82$ ,  $p<.001$ ). This pattern of results remained when autistic traits were included in the model. A final regression model examined the impact of executive function. Emotional regulation (unlike inhibitory control) explained a significant proportion of the variance in depression symptoms (24.2%,  $p<.001$ ), with CVRF and age also contributing to the model ( $F=50.06$ ,  $p<.001$ ).

**Conclusions:** CVRF are common among middle-aged and older autistic adults; in this sample autistic people reported CVRF more frequently than in the general population. As expected, CVRF increase with age in autism. CVRF explain a significant (albeit small) proportion of variance in depression symptoms. In this study, CVRF occur at high rates in middle-aged and older autistic adults but may not be as important a mechanism for developing depression as among typical older people. Among middle-aged and older autistic adults in this study, depression symptoms are primarily explained by executive function – specifically emotional regulation. Difficulties in emotional regulation have been linked with depression in many previous studies of neurotypical older adults. Further studies are required to examine the impact of CVRF on outcomes for autistic older people and to explore factors important for late-life depression.

**515.023 (Virtual Poster)** Effectiveness of a Peer Support Transportation Intervention Program for Individuals with Autism Spectrum Disorders

**B. Pfeiffer<sup>1</sup>**, E. Brusilovskiy<sup>2</sup>, A. P. Davidson<sup>3</sup>, M. Salzer<sup>2</sup> and C. Feeley<sup>4</sup>, (1)Rehabilitation Sciences, Temple University, Philadelphia, PA, (2)Temple University, Philadelphia, PA, (3)Health and Rehabilitation Sciences, Temple University, Philadelphia, PA, (4)School of Engineering, Rutgers CAIT, Piscataway, NJ

---

**Background:** Transitional age youth and young adults with Autism Spectrum Disorders (ASD) often face serious transportation challenges that impede healthcare access, community participation, and employment opportunities (Risser et al., 2015). Interventions to support travel skills, which makes use of one-on-one instruction, may help people with ASD overcome transportation barriers and increase community mobility. Peer support is identified as an effective mediator when implementing interventions for people with ASD (Chan et al., 2009). Peer support interventions are founded on the concept that someone with lived experience can best understand the unique perspective of the individual while increasing the acceptability and feasibility of an intervention.

**Objectives:** The objective of this study was to examine the impact of a peer support intervention on the travel skills and individualized community mobility goals of youth and young adults with ASD.

**Methods:** A quasi-experimental pre-test post-test design was used to evaluate travel skills before and after a travel training intervention delivered through peer support. Thirty-eight transitional age youth and young adults with ASD aged 16-27 were recruited through local service agencies to participate in an eight-step plan for teaching independent travel on public transit (Kennedy Center, 2021). The program was delivered using certified Peer Support Specialists who were individuals with ASD. Pre and post-test data were collected on the Progressive Evaluation of Travel Skills (PETS) and individualized Goal Attainment Scaling (GAS), as well as mode(s) of public transportation used, purpose of use, and number of training sessions collected. Qualitative and quantitative data was collected on feasibility and acceptability of the intervention. Quantitative analysis included both descriptive statistics and paired sample t-tests. Qualitative data was coded into themes using a grounded theory approach.

**Results:** Participants made substantial gains on the competencies needed for independent travel. Paired t-tests were conducted to examine the differences between the baseline and follow-up scores on the GAS and the PETS measures. There were large, statistically significant increases on the GAS ( $t(df=32) = 26.12$ ;  $p < .0001$ ) and the Travel Skills measure ( $t(df=35) = 10.56$ ;  $p < .0001$ ). Feasibility data identified that 98% of all data was collected and there were no drop-outs in the study. Qualitative themes identified strong acceptability for peer support and individualized community mobility goals.

**Conclusions:** Effective interventions for youth and young adults with ASD to improve independent transportation use are essential for access to healthcare, community participation, and employment. The results of this study provide preliminary support for the use of a structured and comprehensive travel intervention program delivered using peer support to improve overall travel skills needed for public transportation. Further research is needed using experimental designs, larger sample sizes, and broader outcomes.

**515.024 (Virtual Poster) How Have Participation Outcomes of Autistic Young Adults Been Measured? a Scoping Review**

**E. G. Munsell<sup>1,2</sup>** and **W. J. Coster<sup>3</sup>**, (1)*Center for Rehabilitation Outcomes Research, Shirley Ryan AbilityLab, Chicago, IL*, (2)*Center for Education in Health Sciences, Northwestern University, Feinberg School of Medicine, Chicago, IL*, (3)*Department of Occupational Therapy, Boston University, Boston, MA*

---

**Background:** Participation has been identified as an important overall indicator of the impact of services, treatments, and supports provided to autistic individuals. However, autistic young adults are reported to experience challenges participating in the workforce, post-secondary schooling, and living in the community. Evidence from multiple fields of inquiry has shown that gains in skills or alleviation of impairments often do not correspond to improved participation. Thus, participation must be examined directly in order to determine the overall impact of services, treatments, and supports provided to individuals with disabilities.

**Objectives:** This scoping review was undertaken to examine how participation outcomes have been measured in young adults on the autism spectrum. The purpose of this scoping review was to identify aspects of participation in need of further study and measurement issues that may be limiting our understanding of participation outcomes for autistic young adults.

**Methods:** A total of 113 articles employing quantitative methodology to capture participation in autistic young adults were identified through a search of six databases and citation tracking. Using a previously published model of participation from the literature, two reviewers extracted data for each measure of participation that was identified in the selected articles.

**Results:** Study participants in the included articles were from 14 countries, with the majority from the USA (58%), followed by the UK (9%) and Australia (7%). Studies that employed measures of participation for autistic young adults reported participant details inconsistently, often neglecting to provide data on co-occurring conditions or race and ethnicity. Although there was some breadth to the diversity of life situations examined, there was limited depth in how participation life situations was captured. Twenty-nine percent of measures were simple dichotomous outcomes (e.g., has at least one friend vs. does not), and 58% of measures captured only the presence or absence of an occurrence (e.g., employed full time, employed part time, unemployed). Only 15 of the measures we identified were pre-existing measures; accordingly, psychometric support for measures were rarely reported (6.5%).

**Conclusions:** Over the past 10 years, there has been a significant increase in studies examining participation outcomes of autistic young adults, which are building a more detailed picture of the young adults' engagement in important life roles and situations. However, there are a number of areas where refinement of measures or application of alternative approaches would greatly enhance the quality of information obtained and help distinguish meaningful variations in participation outcomes. Addressing these short-comings would support efforts to provide services that enhance autistic young adults' access to opportunities and their experience of participation in their communities.

**515.025 (Virtual Poster) Internalizing Symptoms in Autistic Young Adults: The Role of Emotion Regulation**

**S. A. Lehman<sup>1</sup>**, **E. J. Adler<sup>1</sup>**, **H. K. Schiltz<sup>2</sup>**, **A. D. Haendel<sup>2</sup>**, **M. Carlson<sup>3</sup>**, **N. S. Gordon<sup>1</sup>** and **A. V. Van Hecke<sup>1</sup>**, (1)*Psychology, Marquette University, Milwaukee, WI*, (2)*Speech-Language Pathology, Concordia University Wisconsin, Mequon, WI*, (3)*Education, Marquette University, Milwaukee, WI*

---

**Background:** Autistic people are at heightened risk for experiencing co-occurring mental illness (Simonoff et al., 2008), particularly internalizing disorders (depression and anxiety) (Joshi et al., 2012). Emerging evidence points to emotion regulation strategies (e.g., cognitive reappraisal and emotion suppression) as a key factors to explicating this phenomenon. Prior research has focused primarily on anxiety in autistic adolescents (Cai et al., 2018; Rieffe et al., 2011), with less emphasis on emotion regulation and *depression*, or the extent to which these relationships continue into *young adulthood*; a critical transition period associated with decreased access to age-appropriate services, and slowed progress in the improvement of internalizing symptoms (Tantam 2003; Taylor & Seltzer, 2010).

**Objectives:** The present study explores 1) whether emotion suppression is predictive of increased internalizing symptoms and 2) whether cognitive reappraisal is predictive of decreased internalizing symptoms in a sample of autistic young adults.

**Methods:** 64 autistic young adults ages 17-29 ( $M = 20.11$ ; 17.2% female) completed self-report measures assessing symptoms of depression (BDI; Beck et al., 1988), symptoms of social anxiety (LSAS; Fresco et al., 2001), and uses of specific emotion regulation strategies (cognitive reappraisal and emotion suppression) (ERQ; Gross & John, 2003). Autism diagnoses were confirmed using the ADOS-G (Lord et al., 2002) and IQ information was obtained using the KBIT (Brian & Jaspers, 2010). IQ among the sample was  $\geq 70$ . SPSS version 27 was used for analysis.

Results: Bivariate Pearson correlations indicated greater use of emotion suppression was significantly associated with increased depressive symptoms ( $r(64) = 0.255, p < .05$ ), and increased anxiety symptoms ( $r(64) = 0.365, p < .01$ ). Cognitive reappraisal was not significantly correlated with either depressive ( $r(64) = -0.194, p > .05$ ) or anxiety symptoms ( $r(64) = -0.223, p > .05$ ). Using two linear regression models, emotion suppression and cognitive reappraisal accounted for 14.2% of the variance in depressive symptoms ( $F(2, 61) = 5.042, p < .01, R^2 = 0.142$ ) and 24.8% of the variance in anxiety symptoms ( $F(2, 61) = 10.059, p < .01, R^2 = 0.248$ ). Use of emotion suppression ( $\beta_1 = 0.336, p < .01$ ) and cognitive reappraisal ( $\beta_2 = -0.289, p < .05$ ) were both significant predictors of depression, using a two tailed test  $\alpha = 0.05$ . Use of emotion suppression ( $\beta_1 = 0.464, p < .01$ ) and cognitive reappraisal ( $\beta_2 = -0.353, p < .01$ ) were also both significant predictors of anxiety, using a two tailed test  $\alpha = 0.05$ .

Conclusions: This study underscores the role of emotion regulation in the manifestation of internalizing symptoms in autistic young adults. These findings indicate that greater usage of emotion suppression and less usage of cognitive reappraisal are predictive of increased symptomatology for both depression and anxiety. These findings expand upon the current literature by exploring a range of internalizing symptoms in relation to emotion regulation during the critical transition period of young adulthood. This research aids in the development of more targeted treatments to better support autistic young adults during this pivotal time.

**515.026** (Virtual Poster) Language and Social Cognitive Profiles of 7 Autistic Bilingual Adults Who Were Minimally-Speaking in Childhood  
**B. G. Digard<sup>1</sup>**, Z. Blair<sup>2</sup>, A. Sorace<sup>3</sup>, A. C. Stanfield<sup>4</sup> and S. Fletcher-Watson<sup>4</sup>, (1)Division of Psychiatry, University of Edinburgh, Edinburgh, United Kingdom, (2)Edinburgh Medical School, University of Edinburgh, Edinburgh, United Kingdom, (3)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom, (4)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom

---

Background: Bilingualism, an increasingly common experience in our hypermobile and multicultural society, has been demonstrated to have positive language and cognitive effects in autistic and non-autistic people alike. However, data available with the autistic population mostly focuses on children, and almost exclusively represents speaking people. As around 40% of autistic children are non- or minimally-speaking, it is essential to better understand the developmental trajectory of autistic bilingual people who were non- or minimally-speaking in childhood.

Objectives: This multiple case study seeks to explore the language and social-cognitive profiles of bilingual autistic adults who self-reported being non- or minimally-verbal in childhood.

Methods: This is an exploratory secondary descriptive data analysis of 7 autistic bilingual adults (overall group  $n=39$ ), who self-reported being non- or minimally-verbal in childhood. Measures included a Demographic & Language Questionnaire, the Wechsler Abbreviated Scale of Intelligence 2nd Edition, and the Adult-Theory of Mind-extended test. The 7 participants were UK residents, but were born in different countries around the world (located in Asia, Africa, Europe, North and South America, and Oceania).

Results: The seven participants were aged 24-61 years ( $M=44, SD=14.9$ ), with an age at autism diagnosis of 3- 56 years ( $M=29, SD=21.6$ ), and a mean non-verbal IQ (Perceptual Reasoning Index) of 113.9 ( $SD=4.3, 107-121$ ). Visual representation (Figure 1) of their language profiles (i.e. proficiency in their languages) and cognitive skills (i.e. non-verbal IQ and sociocognitive skills) showed they did not differ from their autistic bilingual peers who were verbal in childhood ( $n=32$ ).

Conclusions:

This study is the first to explore the language profiles of bilingual autistic adults who were non- or minimally-verbal in childhood. It revealed diversity in the language and social-cognitive skills and profiles of autistic people, whether or not the development of their expressive language skills followed a typical trajectory in childhood.

The late age of diagnosis of some of the participants despite their expressive language skills in childhood could be linked with the discrepancies in diagnosis practices across time and countries of birth. Indeed, while autism recognition has significantly increased over the past decades in most high-income countries, there are still delays in many lower-income countries.

This study supports the literature regarding the ability of autistic people to learn multiple languages, and seeks to provide a basis for more research and changes in clinical practice.

**515.027** (Virtual Poster) The Influence of Bilingualism on Cognitive and Affective Perspective-Taking Abilities in Autistic and Neurotypical Adults  
**B. G. Digard<sup>1</sup>**, A. Sorace<sup>2</sup>, A. C. Stanfield<sup>3</sup> and S. Fletcher-Watson<sup>3</sup>, (1)Division of Psychiatry, University of Edinburgh, Edinburgh, United Kingdom, (2)Department of Linguistics, University of Edinburgh, Edinburgh, United Kingdom, (3)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom

---

Background: Research in neurotypical children found a positive influence of bilingualism on cognitive perspective-taking. However, findings in adulthood are inconsistent, potentially due to varying binary definitions of bilingualism. Crucially, an understanding of the sociocognitive influence of bilingualism in autism is still lacking, especially regarding perspective-taking, a recognized source of challenge for autistic people.

Objectives: This study aims to describe the influence of bilingualism on cognitive and affective perspective-taking skills in autistic and neurotypical adults, focusing on whether the sociocognitive influence of bilingualism is similar across neurotypes.

Methods:

We recruited 39 autistic and 96 neurotypical adults living in the U.K., who knew more than one language. Participants completed a language history and demographics questionnaire, an executive function task, a non-verbal IQ test (Perceptual Reasoning Index - PRI), and the Adult-Theory of Mind – extended (AToMe) task.

The AToMe involved 6 social videos each followed by 5 questions (general, level 2 cognitive and affective, level 1 cognitive and affective), and 6 control videos, each followed by a non-social question. The videos lasted 30 to 60 sec, and participants had 30 sec to answer each question orally. Answers were scored 0, 1, or 2 points by two coders, based on their accuracy. Points were summed to obtain the following 9 scores: Control, Overall Social, General, Cognitive, Affective, Cognitive Level 1, Cognitive Level 2, Affective Level 1, Affective Level 2. Further details are available at <https://osf.io/vjfnh>.

Stepwise multiple linear regressions were conducted on each AToMe outcome score, independently between autistic and neurotypical participants, to identify their more influential predictors from bilingualism (number of languages, age of acquisition (AoA) and proficiency of the 2<sup>nd</sup> language (L2), language switching habits) and control (age, PRI, sustained attention, switching, inhibition) variables.

#### Results:

Autistic participants (41% female, mean age = 33.2 years, mean PRI = 119.8) had a wide range of AoA (i.e. L2 AoA: 0 to 58 years, M = 7.5 years, SD = 6) and proficiencies in all their languages.

Neurotypical participants (72% female, mean age = 28.5 years, mean PRI = 109.2) had a wide range of language profiles (i.e. L2 AoA: 0 to 14 years, M = 4.7 years, SD = 3.7) as well.

Across the final regression models (except the control score), the bilingualism variable consistently selected was L2 AoA, negatively predicting perspective-taking scores above and beyond the other control variables.

#### Conclusions:

This study is the first to chart the influence of bilingualism on the cognitive and affective perspective-taking skills of autistic adults. It describes a long-lasting developmental stimulating influence of early bilingualism on social cognition in autistic and neurotypical adults alike, above and beyond the role of other individual differences such as non-verbal IQ or executive skills.

This deepens our understanding of the ability of the developing autistic mind to approach and respond to language learning, in terms of non-linguistic social processes. This contributes to an evidence base to support autistic people in their language learning journey.

#### **515.028** (Virtual Poster) Predictors of Sustainable Autism Employment: An 8-Year Longitudinal Study.

**S. M. Bury<sup>1</sup>, S. Begeer<sup>2</sup>, D. Hedley<sup>3</sup>, X. Li<sup>4</sup>, M. Uljarevic<sup>5</sup> and M. A. Stokes<sup>6</sup>,** (1)Olga Tennison Autism Research Centre, School of Psychology and Public Health, La Trobe University, Melbourne, VIC, Australia, (2)VU University Amsterdam, Amsterdam, Netherlands, (3)Olga Tennison Autism Research Centre, La Trobe University OTARC, Melbourne, VIC, Australia, (4)La Trobe University, Melbourne, VIC, Australia, (5)School of Psychological Sciences, University of Melbourne, Stanford, CA, Australia, (6)Deakin University, Burwood, VIC, Australia

Background: Autistic individuals are significantly underrepresented in employment, with low employment rates across the globe (Australian Bureau of Statistics, 2019, Roux et al., 2017; Zwicker et al., 2017), however, around one quarter of autistic individuals achieve good employment outcomes (Hedley et al., 2019; Howlin et al., 2004). Thus, much is to be gained from understanding what factors lead to some individuals having better employment outcomes than others. Previous research suggests household income, gender, parental and individual education level, as well positive parental attitude to employment (Chiang et al, 2013; Ohl et al., 2017, Holwerda et al., 2013) predict employment for autistic people. However, previous studies tend to have small samples or are cross-sectional. Firm findings in large, well-characterized, longitudinal cohorts are essential in order to better understand the underlying mechanisms and predictors of sustainable autism employment (Hedley et al., 2019, Howlin, 2000).

Objectives: The present study aimed to capitalize on the availability of a large longitudinal cohort with comprehensive participant characterization to identify factors that predict changes in employment status of autistic people over time.

Methods: Participants were 2449 adults (1077 men, 1352 women, 20 other) with a mean age of 42.25 years ( $SD=14.24$ ) at their most recent wave, recruited through the Netherlands Autism Register (NAR) – an annual online survey recruiting autistic adults, parents, and legal representatives. Data represents eight annual waves (2013-2021), with participants with a reported autism diagnosis aged 16 years and above included in the study. Participants indicated involvement in 18 daily activities (Table 1), from this an employment score was calculated (0 = no reported employment, 1 = reported employment). Mixed-effects multinomial logistic regression models (MMLR) were used to investigate the impact of fixed factors (i.e., Autism Quotient [AQ]), age, gender, age of diagnosis, parent and participant highest education, importance of employment to parents, co-occurring conditions, urbanicity) and time variant factors (i.e., household income, presence of coaching) on employment status.

Results: Table 1 shows the frequencies of participation in 18 daily activities, with chi-square suggesting that overall reports of participation in more structured daily activities (e.g., employment) remain relatively stable over time, with greater variability in less structured activities (e.g., hobbies). However, the Sankey plot (Figure 1) shows significant transition between employment status across time. MMLR models were carried out to explore the potential factors related to the employment/unemployment transitions. After coding changes in employment status between waves to different transitions (-1 = transition to unemployment; 0 = no change in employment status; 1 = transition to employment), any related factors were put into

the model. After dropping all the non-significant variables ( $p > 0.05$ ) step by step, five variables were found significant in the final model (age, urbanicity, importance of work for parents, guidance/coaching, time) using *transition to unemployment* as reference level.

Conclusions: Despite consistent overall levels of structured daily activities across time, employment status changed for participants across waves. While analysis is ongoing, current results suggest that age, urbanicity, importance of work for parents, guidance/coaching and time are predictors of employment status over time.

#### **515.029** (Virtual Poster) Sensory Sensitivity and Sexual Motivation in Autistic Adults

**A. B. Choi<sup>1</sup>**, **N. Nadwodny<sup>1</sup>**, **D. Thakkar<sup>1</sup>**, **D. W. Pantalone<sup>2</sup>** and **S. Faja<sup>1</sup>**, (1)Boston Children's Hospital, Boston, MA, (2)Psychology, University of Massachusetts Boston, Boston, MA

---

##### Background:

Many autistic people are interested in romantic and sexual relationships. One potentially critical factor influencing motivations for dating and sex is sensory sensitivity, which is common in individuals with autism spectrum disorder (ASD). A growing number of qualitative studies have described how sensory features potentially affect romantic and sexual experiences and interests of autistic individuals (Gray et al., 2021; Lewis et al., 2020). However, we could identify no studies examining whether, and to what extent sensory sensitivity relates to sexual motivation and self-efficacy in romantic relationships of autistic individuals.

##### Objectives:

Using a quantitative approach, this work aims to determine whether and to what extent sensory features of ASD are related to sexual motivation and self-efficacy in romantic relationships of autistic adults.

##### Methods:

Data were collected as part in an ongoing study to examine motivation, knowledge, and behavior concerning dating experiences and sexual health of adults with ASD (age: 18-26 years). Sensory sensitivity was measured using the Glasgow Sensory Questionnaire (GSQ), which has seven subscales: visual, auditory, gustatory, olfactory, tactile, vestibular, and proprioceptive (Robertson & Simmons, 2013). Sexual motivation for dyadic and solitary activities was assessed based on the Sexual Desire Inventory (Spector et al., 1998). Relationship self-efficacy was measured using the Self-efficacy in Romantic Relationships (Riggio et al., 2011). For this preliminary data analysis, data were included from 14 participants (8 male, 6 female) who completed all three questionnaires.

##### Results:

Pearson correlations indicated that the total sensory score on the GSQ was significantly, negatively correlated with dyadic sexual desire ( $r = -.585$ ,  $p = .028$ ), but not solitary sexual desire. To determine whether any GSQ specific subscales were driving the significant correlation with dyadic sexual desire, we ran separate Pearson correlations for each GSQ subscale. Results showed that the sensory scores on the tactile and gustatory subscales were significantly, negatively correlated with dyadic sexual desire (tactile:  $r = -.695$ ,  $p = .006$ ; gustatory:  $r = -.728$ ,  $p = .003$ ). In addition, the total sensory score was negatively, yet non-significantly, related to self-efficacy in romantic relationships ( $r = -.38$ ,  $p = .16$ ).

##### Conclusions:

These results suggest that autistic adults, who experience higher frequencies of difficulties to sensory stimuli, report lower desire for dyadic sexual activities and potentially lower self-efficacy in romantic relationships. With more data to be collected in our ongoing study, findings of this work have the potential to add to the growing evidence suggesting that ASD-specific features (e.g., sensory sensitivity) affect sexual motivation and self-efficacy in adults with ASD. By uncovering what contributes to sexual motivation in autistic individuals, we can better identify ways to support autistic people to have fulfilling sexual relationships and healthy sexual behaviors.

#### **515.030** (Virtual Poster) We Need Less of That and More of This: Autistic Researchers on Autism Research

**S. C. Jones**, Australian Catholic University, Melbourne, VIC, Australia

---

##### Background:

Autism research continues to expand exponentially; Google Scholar shows more than 60,000 papers were published in 2020, compared to 37,000 in 2010 and less than 8,000 in 2000. As autism awareness and research proliferates, the role of autistic people in autism research has evolved from a position of subjection, to participation, into collaboration. Despite these advances, the majority of autism research is conceptualized and conducted by non-autistic researchers.

##### Objectives:

The aim of this study was to explore autistic academics' perspectives on autism research, including their views on what constitutes potentially beneficial and/or harmful research. In addition, this study sought to investigate and collate ideas for future research agendas from autistic academics.

#### Methods:

This qualitative study involved autistic adults working in academia (n=29); including nine who had completed, and 11 who were completing, a doctorate. Participants completed a written reflection on autism research and data were entered into NVivo, coded and analysed inductively, identifying and grouping themes.

#### Results:

Autistic academics identified autism research aiming to establish the 'cause of' or 'cure for' autism as the most likely to be harmful, positioning autism as a fundamental flaw in the human genome that needs to be isolated and eradicated. Research attempting to 'fix' or 'train' autistic people to think or act like the neuro-majority was perceived as having more potential to do harm than good. Other approaches viewed as potentially harmful were research that positions autism as a deficit, pathologizing and stigmatizing autistic characteristics; and research that is non-participatory and does not take into account the perspectives and needs of autistic people.

Autistic academics highlighted autism research that seeks to improve the lives of autistic individuals regardless of age, through the identification of appropriate supports, as being the most beneficial.

This was followed by an appreciation for genuine participatory research that involves autistic people from inception to dissemination. Other topics of interest were addressing stereotypes and misperceptions, highlighting the strengths of autistic people, and managing common co-occurring conditions.

Areas of autism research noted as not inherently good or bad, but over-researched in comparison to other areas, included genetics, animal models and cognitive autism theories. Participants' suggestions regarding research areas that remain largely unexplored – and specific topics that could form part of an autism research agenda – will be outlined during the presentation.

#### Conclusions:

If autism research is striving to meaningfully improve autistic people's lives, non-autistic autism researchers must engage and collaborate with the autistic community to gauge their needs and priorities. Research questions posed by autistic academics are more likely to yield results that are valuable to autistic individuals, their families and wider communities. Autistic academics offer insights that integrate their lived experience and understanding of research methods. Developing a research agenda with 'real-world benefits' for autistic people is more likely to be successful if researchers establish ongoing collaborative relationships with autistic academics.

## Animal Models

### PANEL — ANIMAL MODELS

#### 218 - Sleepless in the Spectrum: Insight from Animal Models

**Panel Chair:** Lucia Peixoto, *Sleep and Performance Research Center, Washington State University, Spokane, WA*

**218.001** (Panel) Shank3 Modulates Sleep across Postnatal Development

**L. Peixoto**, *Sleep and Performance Research Center, Washington State University, Spokane, WA*

Background: Sleep problems are prevalent in Autism Spectrum Disorder (ASD), can be observed before diagnosis, and are associated with increased restricted and repetitive behaviors. Therefore, sleep abnormalities may be a core feature of the disorder. Given the conserved nature of mammalian sleep, mouse models provide a unique opportunity to understand sleep in ASD. Previously we showed that adult mice with a truncation in the high-confidence ASD gene *Shank3* (*Shank3<sup>ac</sup>*) recapitulate the clinical ASD sleep phenotype and are the only mouse model shown to recapitulate problems falling asleep frequently observed in ASD individuals. Sleep is important for brain development and its amount and regulation change considerably during the postnatal period. Nonetheless, sleep ontogenesis in ASD remains unexplored.

Objectives: The objective of this study was to use the *Shank3<sup>ac</sup>* mouse model to characterize, for the first time, the developmental trajectory of sleep from the early post-weaning period into adulthood.

Methods: In this study we used intra-cortical longitudinal electro-encephalographic (EEG) and electro-myographic (EMG) recordings to define changes in sleep amount, states, quality and response to sleep loss from weaning to young adulthood in an ASD mouse model.

**Results:** We show that Shank3<sup>ac</sup> mice sleep less overall throughout their lifespan and have increased rapid eye movement (REM) sleep early in life despite significantly reduced non-rapid eye movement (NREM) sleep. Mutants have abnormal responses to increased sleep pressure (sleepiness) that emerge during a specific developmental period. We show that the ability to fall asleep quickly in response to being sleepy develops normally between 24 and 30 days in mice (transition between 70% and 80 of maximal brain volume, 10-16 months in a human infant). Shank3<sup>ac</sup> mice are unable to achieve this developmental milestone and maintain an immature response to sleep loss regardless of age. This phenomenon seems independent of homeostatic NREM sleep slow-wave dynamics. Shank3<sup>ac</sup> mice also develop a progressive deterioration of NREM sleep spectral power (quality) starting at postnatal day 30.

**Conclusions:** Overall, our study recapitulates both preclinical models and clinical studies showing that reduced sleep is consistently associated with ASD and may be a core symptom of the disorder. Our study also suggests that problems falling asleep may reflect abnormal post-natal development of sleep and arousal mechanisms that could be amenable to early intervention.

**218.002 (Panel) Translational Studies into Sleep Disturbance in Neurodevelopmental Disorders – of Mechanisms and Treatment Strategies**  
*M. Coll-Tané<sup>1</sup>, L. V. van Renssen<sup>1</sup>, N. N. Gong<sup>2</sup>, B. van Reijmersdal<sup>1</sup>, S. J. Belfer<sup>2</sup>, E. C. Kurtz-Nelson<sup>3</sup>, C. M. Hudac<sup>4</sup>, T. Nowakowski<sup>5</sup>, R. K. Earl<sup>1</sup>, S. Pillen<sup>6</sup>, E. E. Eichler<sup>7</sup>, M. S. Kayser<sup>7</sup>, T. Kleefstra<sup>1</sup> and A. Schenck<sup>1</sup>*, (1)Radboud university medical center, Nijmegen, Netherlands, (2)Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)Center for Youth Development and Intervention, Department of Psychology, University of Alabama, Seattle, AL, (5)University of California San Francisco, San Francisco, CA, (6)Kempenhaghe, Heeze, Netherlands, (7)Department of Genome Sciences, University of Washington, Seattle, WA

**Background:** Sleep disturbances in autism and related neurodevelopmental disorders are common and adversely affect quality of life in patients and families, yet the underlying mechanisms are understudied.

**Objectives:** Our research aims to establish a translational pipeline to characterize sleep defects in these disorders, dissect their origin, and identify treatment approaches.

**Methods:** We quantitatively assess sleep in individuals with neurodevelopmental syndromes and their preclinical models. To maximize our efficiency, we take advantage of the fruitfly *Drosophila* as a model organism.

**Results:** In a recent study, we found that individuals with mutations in *CHD8*, among the highest-confidence autism risk genes, or in *CHD7* suffer from disturbed sleep maintenance. These defects are recapitulated in *Drosophila* mutants affecting *kismet*, the sole *CHD8/CHD7* orthologue. We show that Kismet is required in glia, but not neurons, for early developmental and adult sleep architecture. This role localizes to subperineurial glia constituting the blood-brain barrier. Moreover, we show that glial loss of Kismet leads to hyperserotonemia, a well-established but genetically unsolved autism endophenotype. Using a number of pharmacological, thermogenetic and genetic approaches, we demonstrate that increased serotonin levels during development underlie Kismet's sleep problems. Importantly, we find that Kismet-related sleep defects, despite their developmental origin, can be reversed in adulthood by a behavioral regime resembling human sleep restriction therapy, the first line treatment for insomnia. I will present our ongoing efforts to translate our findings back to individuals with mutations in *CHD8* and *CHD7* and to move on to the next disorders.

**Conclusions:** This study provided fundamental insights into glial regulation of sleep and proposed a causal mechanistic link between the CHD8/CHD7/Kismet family, the blood-brain barrier glia, developmental hyperserotonemia, and autism-associated sleep disturbances. It provided proof of principle for the utility of our translational pipeline and a potentially widely applicable strategy to improve sleep in neurodevelopmental disorders.

**218.003 (Panel) Circadian Mechanisms As Bidirectional Modulators of Neurodevelopmental Disorders**  
*J. O. Lipton, Neurology, Boston Children's Hospital, Boston, MA*

**Background:** Dysfunction of sleep and circadian rhythms are among the most common manifestations of autism spectrum disorders like the Tuberous Sclerosis Complex but are poorly understood at the mechanistic level.

**Objectives:** To probe the mechanistic interactions between ASD and the circadian timekeeping, we have used animal and cellular models of the neurodevelopmental disorder (NDD) Tuberous Sclerosis Complex (TSC) to investigate fundamental biochemical, cell biological, and neurobiological connections between the mechanistic target of rapamycin (mTOR) signaling pathway and the circadian clock.

**Methods:** We used mouse and cellular models of TSC, cell biology, biochemistry, neurobiology, physiology, electron microscopy, and animal behavior

**Results:** TSC results from the unbridled activity of the mTOR signaling pathway, a crucial cellular arbiter of growth, stress responses, and metabolism. TSC models demonstrated abnormal circadian timekeeping at both cellular and behavioral levels. We attributed this finding to a biochemical dysregulation of the circadian clock protein BMAL1, an essential component of the timekeeping mechanism. Modulation of BMAL1 was capable of rescuing abnormal circadian behavior and other TSC-related phenotypes suggesting that the circadian clock is an important

downstream component of the TSC disease pathway. We will present our ongoing work linking BMAL1 to TSC-dependent protein synthesis in mammalian neurons and synaptic function

**Conclusions:** Our goal is to show how investigation of circadian timekeeping in models of a human NDD has disclosed fundamental bidirectional interactions between ASD-related mechanisms and biological timekeeping thereby nominating unexpected avenues toward mitigating NDDs.

**218.004 (Panel) Translational Modulation By Isrib Alleviates Synaptic and Behavioral Phenotypes in Fragile X Syndrome**

**P. Mourrain**, *Stanford University, Palo Alto, CA*

---

**Background:** Fragile X syndrome (FXS) is caused by the functional loss of Fragile X mental retardation protein (FMRP), a translational regulator that binds the transcripts of many proteins involved in synaptic function and plasticity. Abnormal synaptic density and wiring are common defects observed across animal models of FXS, including drosophila, zebrafish, mice and rats. These synaptic phenotypes are observed early during development when sleep dominates and has a critical role on protein biosynthesis, synaptic connectivity, and normalization, suggesting an aggravating/causal role for sleep disruptions in the etiology of FXS.

**Objectives:** Dysregulated protein synthesis is a central effect of FMRP loss and to date direct translational modulation has not been leveraged in the treatment of FXS. Thus, we examined the effect of the novel small molecule translational modulator ISRIB in treating synaptic and behavioral symptoms of FXS.

**Methods:** Using a combination of innovative population-level single synapse analysis, *in vivo* two photon microscopy and behavioral analysis, we revealed a new mechanism for the appearance of dense and immature dendritic spines in human FXS patients and *Fmr1* knockout (KO) mice.

**Results:** Our data suggest that FMRP loss at the synapse dysregulates synaptic translational programs such that spines are disproportionately stabilized through increased PSD-95 expression but prevented from maturing through reduced synaptic accumulation of glutamate receptors. The translational modulator ISRIB rescues this molecular and synaptic deficit in FXS, which results in improved social behavior in *Fmr1* KO mice.

**Conclusions:** These findings highlight the novel therapeutic potential of targeting core translational mechanisms linking cellular and behavioral phenotypes in FXS and neurodevelopmental disorders more broadly. We debate these results in the context of sleep intervention to alleviate synaptic and behavioral deficits in genetic and idiopathic autism spectrum disorder.

**218.005 (Panel) Sleep in Dravet Syndrome: Insights from Preclinical Models**

**H. de la Iglesia**, *University of Washington, Seattle, WA*

---

**Background:**

Dravet syndrome (DS) is an intractable epilepsy associated with autism spectrum disorder and caused by heterozygous loss-of-function mutations in the *SCN1A* gene coding for the Nav1.1 sodium channel, which is the primary voltage-gated sodium channel in GABAergic neurons throughout the brain. Clinical evidence suggests that daily sleep timing is disrupted in DS patients, but the neural basis for the sleep phenotype remains unknown.

**Objectives:**

Using the deletion of the *Scn1a* gene in mice, both in a global and a region-specific strategy, our first objective is to identify the neural basis of comorbidities of DS, including disordered sleep.

Because of the severe disruption of circadian rhythmicity in the global *Scn1a*<sup>-/-</sup> mice, a second objective of our work is to assess the effect of environmental changes that improve circadian rhythmicity on symptomatology of DS.

**Methods:**

We have used two transgenic mouse models for all our studies. First, a global *Scn1a*<sup>-/-</sup> mouse that represents a genocopy of DS and presents virtually all symptoms of the disease. Second, an *SCN1A*<sup>fl/fl</sup> mouse that we use to target the hetero- or homozygous mutation to different brain regions either through genetic crosses with Cre mouse lines or through injections of Cre-expressing viruses.

**Results:**

Our results have shown that the sleep disorder comorbidity in DS mouse emerges from deficits in both the circadian and homeostatic regulation of sleep. Furthermore, mice in which *Scn1a*<sup>-/-</sup> mutation is targeted to the forebrain but spares the suprachiasmatic nucleus—the site of a master circadian clock—exhibit the full repertoire of epileptic and autistic symptoms but relatively normal circadian rhythms. Complementary approaches that target the *Scn1a* deletion specifically to the suprachiasmatic nucleus fail to emulate the full array of circadian deficits observed in global *Scn1a*<sup>-/-</sup> mouse.

We have also shown that changes in the 24-h temporal structure of the environment, specifically an ambient temperature cycle superimposed to the light-dark cycle, improve circadian rhythmicity of *Scn1a*<sup>+/-</sup> mice. We are currently assessing if this treatment also leads to improvement on the core symptoms of DS, namely epilepsy and deficits in social behavior.

#### Conclusions:

Our studies show that the DS mouse represents a powerful model to understand the neural basis of different symptoms of the disease. Specifically, they demonstrate that the sleep disorder comorbidity in DS may be generated by decreased Nav1.1 channel activity in sleep regulatory centers, and not merely by seizure-related neural damage or sleep disruption. Together, our studies suggest that the sleep disorder phenotype could be treated independently, and in turn lead to improvement in core symptoms of DS.

## PANEL — ANIMAL MODELS

### 220 - Translational Models for Autism Spectrum Disorders (ASD) and Neurodevelopmental Disorders (NDDs)

**Panel Chair:** Jill Silverman, *Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA*

**220.001 (Panel)** Neural Circuitry of Social Play: Involvement of Oxytocin and Vasopressin

**A. Veenema**, *Michigan State University, E Lansing, MI*

**Background:** Playing with peers in children and young animals is essential for the development of lifelong social competence and social skills. Children with autism spectrum disorder (ASD) have difficulties with this social play which contributes to their lifelong social dysfunction. ASD is more prevalent in males than in females, suggesting sex differences in the etiology of ASD.

**Objectives:** Developing effective means to restore social play in ASD children is expected to improve their lifelong social functioning, but this requires understanding of the neural basis of social play and potential sex differences herein.

**Methods:** In this talk I will discuss the neurobiological mechanisms driving social play behavior with specific emphasis on the involvement of the neuropeptides vasopressin and oxytocin.

**Results:** Our research demonstrates that vasopressin originating in the medial amygdala and bed nucleus of the stria terminalis and acting on vasopressin 1a receptors in the lateral septum and ventral pallidum has opposing effects on the expression of social play behavior in male and female juvenile rats. We further demonstrated that oxytocin originating in the paraventricular nucleus and acting on oxytocin receptors in the nucleus accumbens facilitates social play behavior in both sexes, but it more potent in males than in females.

**Conclusions:** These findings may have implications for the sex-specific use of therapeutic drugs targeting the vasopressin and/or oxytocin systems in aiming to improve social play engagement in ASD children.

**220.002 (Panel)** Advancing Research in Gastrointestinal Dysfunction in People with Neurodevelopmental Disorders

**M. Gareau**, *University of California Davis, Davis, CA*

**Background:** The role of the microbiota-gut-brain (MGB) axis in maintaining overall health and well-being is now well established. Host-microbe interactions are paramount for maintaining normal physiology, including the brain and behavior. Stress, bacterial infection, and inflammation all detrimentally impact host-microbe interactions in the gastrointestinal (GI) tract causing gut dysbiosis and pathophysiology. Cognitive deficits occur in (1) germ-free (GF) conditions (2) following oral antibiotic (Abx) administration or (3) after infection with enteric bacterial pathogens, suggesting a critical role for the gut microbiota in regulating behavior. Nevertheless, mechanisms by which gut microbes communicate with the brain, impacting a wide variety of behaviors are poorly understood. Since colonization by the gut microbiota begins at birth, and maturation of the GI tract and brain development continue during neonatal life, identifying pathways of establishment of communication between these organs during development is critical to maintaining health across the lifespan. GI complications in children and adults with neurodevelopmental disorders (NDDs) have drawn attention to gaps in understanding their causes and treatment. GI dysfunction is particularly common in individuals with autism spectrum disorder (ASD), Phelan-McDermid and Rett syndromes. GI disorders in these conditions can include GI malformations present at birth (such as pyloric stenosis or Hirschsprung disease) but also functional issues such as feeding problems, gastro-esophageal reflux disease (GERD), cyclic vomiting, delayed gastric emptying, diarrhea, bloating, and constipation leading to incontinence, and stool impaction. These GI issues may be associated with severe nutritional deficiencies, weight loss, failure to thrive and lack of seizure control. Unfortunately, mechanisms to accurately diagnose GI conditions in specific rare genetic NDDs are limited, and tailored treatments to address them are nonexistent, since clinical trials are rare, to date.

**Objectives:** Describe GI pathophysiology and behavioral impacts following dysbiosis of the gut microbiota in neonatal mice and identifying mechanisms of gut-brain communication.

**Methods:** Neonatal mouse models of gut dysbiosis including infection with an enteric bacterial pathogen and antibiotic administration. Ussing chambers are used to assess GI physiology and 16S sequencing of the gut microbiota is used to determine dysbiosis.

**Results:** Infection with a bacterial pathogen and administration of antibiotics in neonatal mice both result in significant dysbiosis of the gut microbiota, which persists into adulthood and is coupled with altered GI physiology and behavioral impairments including cognitive deficits.

**Conclusions:** Disruption of colonization of the gut microbiota in neonatal life can lead to persistent impairments in gut-brain communication into adulthood in mice, although precise mechanisms of action need to be determined in future studies. Identification of these mechanisms would allow better treatment of GI symptoms in NDD patients and may improve behavioral impairments.

**220.003 (Panel)** Development of a Rhesus Monkey Model of Naturally Occurring Social Impairment  
**K. J. Parker, Psychiatry and Behavioral Sciences, Stanford University, Stanford, CA**

---

**Background:** Autism spectrum disorder (ASD) is a poorly understood brain disorder of early childhood onset. There are no laboratory-based diagnostic tests to detect ASD, nor are there any disease-modifying medications that effectively treat ASD's core behavioral symptoms. Scientific progress in identifying robust ASD biomarkers and therapeutic targets has been impeded, in part, by overreliance on model organisms that fundamentally lack the sophisticated social and cognitive abilities essential for modeling ASD. We therefore saw significant value in studying naturally low-social rhesus monkeys to model human social impairment, taking advantage of a large outdoor-housed colony for behavioral screening, biomarker identification, and pharmacological testing.

**Objectives:** This talk will describe key criteria for developing a valid animal model and will discuss behavioral, biomarker, and pharmacological findings from low-social rhesus monkeys and people with ASD.

**Methods:** We optimized an ASD screening tool to facilitate rapid identification of socially impaired rhesus monkeys, performed targeted biomarker discovery for low sociality, and tested the efficacy of a medication to improve social cognition abilities in low-social rhesus monkeys. We next used this preclinical information to evaluate putative biomarkers in three ASD case-control cohorts, and performed a pharmacological treatment trial in children with ASD.

**Results:** Careful development and validation of our animal model, combined with a strong commitment to evaluating the translational utility of our preclinical findings directly in people with ASD, yielded a robust neurochemical marker (cerebrospinal fluid vasopressin concentration) of trans-primate social impairment and a medication (intranasal vasopressin) that improved social abilities in low-social monkeys and in a small pediatric ASD cohort.

**Conclusions:** This unique translational research approach has enabled us to move fluidly and bidirectionally across preclinical and clinical research components, to deliver advances in ASD detection and treatment, in a manner not readily achievable with existing animal models. Findings from this research program suggest that vasopressin concentration may be useful for detecting ASD (either alone or in combination with other neurochemical measurements), and that intranasal vasopressin may hold promise for treating ASD's core features.

**220.004 (Panel)** Reconsidering Animal Models Used to Study Autism Spectrum Disorder: Optimizing for Successful Translation  
**J. L. Silverman, Department of Psychiatry and Behavioral Sciences, UC Davis MIND Institute, Sacramento, CA**

---

**Background:** Findings from a workshop held by the Autism Science Foundation on Neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD) and intellectual disability (ID) will be disseminated by Dr. Silverman. Our workshop goal was to highlight strengths and weaknesses in current behavioral approaches to animal modeling of ASD, since with no established biological markers, diagnoses are still solely defined by behavioral criteria. Thus, preclinical *in vivo* animal models of NDDs must be optimally utilized.

**Objectives:** To identify the maximal utility of construct and/or face validity. To provide recommendations for phenotyping animal models. To offer guidelines on how *in vivo* models should be used and reported reliably and rigorously while acknowledging their limitations.

**Methods:** We utilized a tailored literature review and summary of discussion over a two-day workshop and highlighted areas on which the experts agreed.

**Results:** We concluded by recommending minimal criteria for reporting in manuscripts going forward. Dr. Silverman will also discuss examples of behavioral and biomarker assessments that meet these more stringent criteria, recommended from the workshop, being applied in her laboratory using a variety of genetic mouse and rat models of NDDs. Tasks include fine grained assessments of motor skills, various cognitive touchscreen assays with and without co-occurring EEG signatures. EEG and whole-body plethysmography to measure brain seizures, sleep stages and signatures, apneas and respiration during sleep.

**Conclusions:** We ask that attention be paid to minimum reporting requirements. These include: type and description of behavioral test used, sample sizes, statistical tests, utilization of more than one measure of core behaviors, reporting of background strains, and, above all, constant collaboration with behavioral neuroscientists, who are trained not only to design but also to help interpret the results and suggest further experiments before premature publication. We also agreed on the above sample outcomes as translatable between preclinical models and human studies, making these indices extremely useful in a clinical trial.

**401.001** (Poster) Chronic Effects of Manipulating Dietary Tryptophan on Social Preferences and Central Serotonin Neurotransmission in Male Mice  
**G. G. Gould**, *Cellular & Integrative Physiology, The University of Texas Health Science Center at San Antonio, San Antonio, TX*

**Background:** Social interaction deficits are a prominent core symptom of autism spectrum disorders (ASD). Few pharmacological interventions effectively ameliorate these deficits for the majority of affected individuals. Clinical and basic research indicates serotonin (5-HT) system dysfunction, including excessively high or low 5-HT availability in brain, may contribute to the etiology of some forms of autism and underlie social deficits. This led to the hypothesis that altering dietary tryptophan (Trp), the essential amino acid precursor of 5-HT, could improve sociability by modulating serotonergic tone. In a prior acute study, 24 h of enhanced dietary Trp increased social interaction preferences of adult male BTBR T<sup>+</sup>/Itpr3<sup>+</sup>/J (BTBR) mice. To clarify how dietary Trp influences brain 5-HT and sociability chronically, in this study adult male mouse dietary Trp was manipulated in three inbred strains with different social preferences for a month to show behavioral and brain 5-HT<sub>1B</sub> receptor and 5-HT transporter (SERT) effects.

**Objectives:** To establish chronic modulatory effects of dietary Trp content on social preferences and on serotonin transporter (SERT) and brain 5-HT<sub>1B</sub> receptor (R) expression via quantitative autoradiography.

**Methods:** Eight litters each of BTBR, 129S1/SvImJ (129S) and C57BL6/J (C57) were bred for this study. To control for litter effects and reduce cage-mate fighting, at weaning littermate males were placed in different cages so litters were spread across three treatment groups with 8-9 mice per group. Sample size was determined by a-priori Power analysis. At 64 weeks old mice were administered open source purified custom diets (Research Diets, New Brunswick, NJ) containing either 0 g/kg Trp (Trp depleted), 2.1 g/kg Trp (control) or 12.6 g/kg Trp (1% Trp supplement) for 28 days. Mice were weighed and diets refreshed weekly. Social interaction and novelty preference was measured six at a time in three chamber test arenas under low (16 lx) red light with novel 129S males used as strangers for BTBR and C57 tests and novel BTBR used as strangers for 129S tests. Mice were euthanized after tests and blood and brain were collected for serum corticosterone and oxytocin measurements by enzyme-linked immunosorbent assays, and cortical 5-HT levels, SERT and 5-HT<sub>1B</sub>R density measurements by autoradiography. Data were analyzed for each strain by analysis of variance and Sidak's post-hoc tests.

**Results:** In BTBR mice typically lacking social interaction preference, Trp depleted diet improved social interaction preference ( $F(2, 22) = 5.6, P = 0.01$ ) relative to control diet. No other Trp diet-induced changes in social interaction preference occurred in socially deficient 129S mice ( $F(2, 27) = 2.0, P = 0.16$ ) or in gregarious C57 mice ( $F(2, 27) = 2.0, P = 0.16$ ). TRP-depleted mice lost weight, despite high to normal food consumption. Serum corticosterone and oxytocin, and 5-HT<sub>1B</sub>R density in frontal cortex were higher in Trp depleted BTBR, while SERT density was 20% reduced versus BTBR controls.

**Conclusions:** While no chronic diet treatments worsened social behaviors, only Trp depletion was able to improve BTBR social interaction preference. This corresponded with increased serum hormones, 5-HT<sub>1B</sub> expression and global reduction in brain SERT and body weight.

**401.002** (Poster) Distinct Patterns of Cerebellar-Cerebral Structural Correlation Differences Are Present in ASD Mouse Model Clusters  
**F. Morgado<sup>1</sup>, C. Hammill<sup>1</sup>, J. Ellegood<sup>2</sup> and J. P. Lerch<sup>1</sup>**, (1)University of Toronto, Toronto, ON, Canada, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Mouse Imaging Centre, The Hospital for Sick Children, Toronto, ON, Canada, (4)Wellcome Centre for Integrative Neuroimaging (WIN), University of Oxford, Oxford, ON, United Kingdom

**Background:**

The cerebellum is a locus of regulation for motor, vestibular, and cognitive processes. Multiple genes strongly associated with autism spectrum disorder (ASD) have elevated expression in the cerebellum (Menashe et al 2013; Wilsey et al. 2013). Mouse models allow us to probe the structural and functional effects of mutations in these ASD-associated genes. For instance, changes in regional brain volume correlations in mutant (MUT) mice relative to wild-type (WT) controls can provide insight into underlying brain connectivity differences spurred by mutations (Yee et al. 2018). Given the polygenic nature of ASD's etiology, comparing structural correlation differences between ASD mouse models may provide key insights into which ensembles of genes may be responsible for certain brain connectivity differences in ASD.

**Objectives:**

To characterize cerebellar-cerebral structural correlation differences in a wide range of ASD mouse models and determine which models are phenotypically similar.

**Methods:**

4563 mice were imaged on a 7-Tesla MRI scanner with a T2-weighted sequence. After excluding non-ASD models, models without publication permission, and scans that failed imaging registration quality control, 2115 mice remained (758 female, 81 models). A 40um isotropic atlas with 52 cerebellar and cerebral structures (Steadman et al. 2014) was registered to the scans using ANTS (Avants et al., 2010). Sex and brain volume were regressed out of normalized volumes. Study-wise differences in WT mice were also regressed against volumes, and the fitted parameters were used

to calculate residual volumes across all mice. Pearson correlation matrices were calculated separately for each model's MUT and WT mice, and MUT-WT correlation differences were calculated using Fisher's transformation and degrees-of-freedom correction.

Using protein expression data from the Allen Brain Institute, mouse models were clustered together if normalized expression in the cerebellum was at least two-fold greater than in other regions. A second cluster was derived for enrichment in the cerebrum. "Negative control" clusters of models with low cerebellar or cerebral protein expression were also analyzed. Regions were tested for enrichment among statistically significant correlation differences (False Discovery Rate-corrected  $P < 0.05$ ) using Fisher's Exact Test. To investigate broader patterns, analysis was repeated at a coarser parcellation (anterior, posterior, or flocculonodular cerebellar lobe, and sensorimotor or supramodal cerebrum).

#### Results:

Across mouse model clusters, mutant mice exhibited reduced cerebellar-cerebral volume correlations relative to wild-types (Figure 1A). Figures 1B and 1C show the negative-log probability of each brain region contributing by chance to more  $P_{FDR} < 0.05$  correlation differences than observed. In the ABI cerebellum enrichment cluster (Nhs (-/-), Chd7 (+/-), Nexmif (-/-)), most significant correlation differences involved the posterior cerebellum ( $P_{Fisher} = 4.11 \times 10^{-4}$ ) and supramodal cerebrum ( $P_{Fisher} = 0.012$ ). Lobule VII, Crus 2, prelimbic cortex, agranular insula, and the frontal pole regions were over-represented in significant correlation differences ( $P_{Fisher} < 0.05$ ). In the cerebrum enrichment cluster, vermis X ( $P_{Fisher} = 4.01 \times 10^{-8}$ ) and right primary sensory cortex ( $P_{Fisher} = 0.045$ ) were over-represented.  $P_{Fisher} > 0.10$  for all regions in the negative control clusters.

#### Conclusions:

Mutations in ASD-associated genes expressed locally in the cerebellum induce cerebellar-cerebral structural correlation differences, particularly between the posterior cerebellum and supramodal isocortex.

#### **401.003 (Poster)** Early Life Antibiotic Exposure Alters Postnatal Neurogenesis in 16p11.2 Neurodevelopmental Disorder Mice

**C. R. McDermott<sup>1</sup>, X. Zhang<sup>2</sup>, X. Zhou<sup>3</sup>, J. H. Millonig<sup>2</sup>, M. J. Blaser<sup>4</sup> and E. DiCicco-Bloom<sup>5</sup>,** (1)Neuroscience & Cell Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ, (2)Center for Advanced Biotechnology & Medicine, Rutgers University, Piscataway, NJ, (3)Neuroscience & Cell Biology, Rutgers University Robert Wood Johnson Medical School, Piscataway, NJ, (4)Center for Advanced Biotechnology & Medicine, Rutgers University, Piscataway, NJ, (5)Neuroscience and Cell Biology, Rutgers Robert Wood Johnson Medical School, Piscataway, NJ

**Background:** Neurodevelopmental disorders (NDDs) affect the lives of >17% of children and caregivers in the United States and result from the combination of genetic risk variants and exposure to environmental factors. The clinical heterogeneity of NDDs suggests that environmental factors may act on certain genetic susceptibilities, making a Gene x Environment model warranted. A recently identified environmental factor that appears to be linked to increased NDD risk is exposure to cephalosporin antibiotics during the first 2 years of life. Extensive evidence indicates that antibiotic exposure decreases gut bacterial diversity (antibiotic-induced dysbiosis) which may consequently alter adult brain structure and behavior. However, little is known about its effects on developmental neurogenesis, which has been implicated in human genetic, postmortem, and animal model studies as a point of convergence in NDD pathogenesis.

**Objectives:** Our studies use a novel Gene x Environment model to determine how exposure to cephalosporin, a commonly used antibiotic in childhood, alters postnatal neurogenesis in the genetically vulnerable 16p11.2 microdeletion (16pDel) mouse. This mouse models one of the most frequently observed CNVs that accounts for ~1% ASD and also results in other NDD phenotypes.

**Methods:** To model early human life antibiotic exposure, wildtype (WT) and 16pDel littermates were exposed to water (control) or to cefdinir, from postnatal (P) days 5-9 and sacrificed on P13 for analyses. Our preliminary studies examined the cerebellum and hippocampus, two regions that undergo postnatal neurogenesis throughout the first year of human life and are implicated in NDDs.

**Results:** Using immunoblot analysis, we found sex- and genotype-dependent effects of cefdinir exposure on cerebellar neuronal differentiation and hippocampal neurogenesis. Cefdinir-exposed WT mice had a 50% reduction in levels of hippocampal intermediate precursor marker, Tbr2, compared to controls. In genetically vulnerable 16pDel mice, cefdinir-exposed males had decreased hippocampal Cyclin E (mitosis marker) and increased doublecortin (differentiation marker) compared to controls, while cefdinir-exposed females had reduced levels of cerebellar doublecortin compared to controls. Thus, cefdinir effects were dependent on sex and genotype.

**Conclusions:** These results collectively suggest that early life exposure to a cephalosporin alters postnatal neurogenesis in WT and genetically vulnerable 16pDel mice. Ongoing work will assess effects on the microbial community. Ongoing work will assess effects on microbial community composition and function, neurodevelopmental gene expression, and behavioral outcomes related to NDDs.

#### **401.004 (Poster)** Effect of Neonatal Status Epilepticus in Microglial Activation and Complement Pathway.

**D. Santana Coelho, D. Narvaiz, S. Chilukuri and J. N. Lugo, Psychology and Neuroscience, Baylor University, Waco, TX**

**Background:** The developing brain is uniquely susceptible to seizures. Studies have demonstrated that seizures during the early postnatal period can have deleterious consequences to brain development leading to behavioral outcomes such as deficits in communication and increased anxiety. Additionally, status epilepticus in early life is a risk factor for autism spectrum disorder. However, the mechanisms by which neonatal seizures

disrupt neurodevelopment are unclear. Microglia are resident brain immune cells that respond to insults and exhibit important roles in development such as synapse pruning, which is a process that is altered in developmental disorders such as autism.

**Objectives:** Considering the detrimental roles of microglia during development, we aimed to assess microglial response to status epilepticus and the potential effect that these seizures can have in pruning by altering the complement system pathway.

**Methods:** To investigate the temporal response of microglia to status epilepticus, we treated mice with 2 mg/kg kainic acid at postnatal day 10. Following seizures, hippocampal microglia activation was assessed at 1, 2, 3, 4, and 5 days, two weeks and 1 month post seizures. Additionally, we measure the expression of complement proteins to identify a possible mechanism by which synaptic pruning could be altered in these mice. Analysis of microglial activation was done using flow cytometry to quantify MHCII+ myeloid cells and complement system proteins expression was measured using qPCR.

**Results:** Preliminary data demonstrated that microglia activation was significantly increased by status epilepticus and this activation is higher at 1 and 2 days post status epilepticus

**Conclusions:** Our characterization of microglial response suggests that the first 48 hours after status epilepticus can be a critical window where the use of therapeutic interventions might prevent the deleterious consequences that status epilepticus during early life can have on neurodevelopment.

#### **401.005 (Poster) Genetic Mouse Models of Autism Spectrum Disorder Present Subtle Heterogeneous Cardiac Abnormalities**

**S. Assimopoulos<sup>1,2,3</sup>, C. Hammill<sup>2,3</sup>, D. J. Fernandes<sup>2,3</sup>, T. L. Spencer Noakes<sup>2,3</sup>, Y. Q. Zhou<sup>2,3</sup>, L. M. Nutter<sup>2,4</sup>, J. Ellegood<sup>2,3</sup>, E. Anagnostou<sup>5</sup>, J. G. Sled<sup>2,3,6</sup> and J. P. Lerch<sup>7</sup>,** (1)Department of Medical Biophysics, Mouse Imaging Centre, Toronto, ON, Canada, (2)The Hospital for Sick Children, Toronto, ON, Canada, (3)Mouse Imaging Centre, The Hospital for Sick Children, Toronto, ON, Canada, (4)The Centre for Phenogenomics, Toronto, ON, Canada, (5)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (6)Department of Medical Biophysics, University of Toronto, Toronto, ON, Canada, (7)Wellcome Centre for Integrative Neuroimaging (WIN), University of Oxford, Oxford, ON, United Kingdom

---

**Background:** Autism Spectrum Disorder (ASD) and Congenital Heart Disease (CHD) are strongly linked on a functional and genetic level. Most work has been focused on the neurodevelopmental abnormalities in CHD, whereas the investigation of cardiac abnormalities (CHD or not) in ASD has been more limited.

**Objectives:** In this work we investigate the prevalence of cardiac comorbidities relative to genetic contributors of ASD.

**Methods:** Using high frequency ultrasound imaging, we screened 9 mouse models with ASD-related genetic alterations (*Arid1b*<sup>+/Δ</sup>, *Chd8*<sup>+/Δ</sup>, 16p11.2 (deletion), *Sgsh*<sup>+/Δ</sup>, *Sgsh*<sup>+/Δ</sup>, *Shank3* Dexon 4-9<sup>+/Δ</sup>, *Shank3* Dexon 4-9<sup>+/Δ</sup>, *Fmr1*<sup>+/Δ</sup>, *Vps13b*<sup>+/Δ</sup>), along with pooled wild-type littermates (WT). Using a standardised imaging protocol, the cardiac morphological and functional parameters measured were thickness and thickening of the left-ventricular (LV) anterior and posterior walls, LV chamber diameter, LV fractional shortening, heart rate (HR), aorta diameter (AoD), LV stroke volume and cardiac output.

**Results:** Small-scale alterations in cardiac structure and function were found in the mutant groups compared to WT. When mutant groups were compared to each other, a greater number of significant differences was observed than when mutant groups were compared to WT controls. Mutant groups differed primarily in measures of structure (LV chamber diameter and anterior wall thickness, HR, AoD), while when compared to WT controls, they differed in both structure and function (LV anterior wall thickness and thickening, LV chamber diameter and fractional shortening, HR). The mutant groups with most differences to WT controls are 16p11.2 (deletion), *Fmr1*<sup>+/Δ</sup>, *Arid1b*<sup>+/Δ</sup>. Among mutant groups, the groups differing most from the others were 16p11.2 (deletion), *Sgsh*<sup>+/Δ</sup>, *Fmr1*<sup>+/Δ</sup>. Our results recapitulate the clinical findings associated with each genetic mutation and broadly with ASD, to the extent that a direct comparison is possible. Additionally, our protocol was verified as an effective screening protocol capturing various dimensions of cardiac function.

**Conclusions:** The characteristic heterogeneity of ASD was recapitulated in the cardiac phenotype of ASD-models. However, determining whether certain mutant groups differ in morphological or functional measures (as a general category) can offer insight regarding common underlying mechanisms. Clinically, knowledge of cardiac abnormalities in ASD can be essential as even non-lethal cardiac abnormalities can impact normal development.

#### **401.006 (Poster) Microglial Mutation Affects Auditory and Somatosensory Perceptions**

**L. Gray<sup>1</sup>, G. S. Shelton<sup>2</sup> and M. Gabriele<sup>3</sup>,** (1)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA, (2)James Madison University, Harrisonburg, VA, (3)Biology, James Madison University, Harrisonburg, VA

---

**Background:** Deficits in microglial cell (MGC) signaling are thought to be an underlying cause of autism as MGCs are responsible for pruning an initial excess of connections during early critical periods of development. Fractalkine signaling (CX3CL1-CX3CR1) appears to be of particular importance in the shaping of several unimodal systems. Preliminary data from our lab suggests similar mechanisms influence the refinement of multisensory maps in the inferior colliculus, a midbrain structure known to mediate startle responses.

**Objectives:** The present study measures responsiveness to auditory and somatosensory stimuli in control and fractalkine signaling mutants to assess behavioral effects of unrefined multisensory midbrain networks.

**Methods:** Forty-two mice (WT, hetero-, and homozygous CX3CR1-GFP mutants) were tested twice. Each test included 172 measurements of an acoustic-startle response with and without various auditory and somatosensory pre-pulses. The dependent variable was pre-pulse inhibition, PPI, a reflexive response where startle is less if preceded by a non-startling stimulus. One of two auditory pre-pulses (70 dB SPL broad-band noises, 10 or 20 ms in duration) or twelve somatosensory pre-pulses (240, 360, 480 Hz, at two intensity levels, and 10 or 20 ms long) were presented alone or in multimodal combinations. These pre-pulses were presented (or not, for controls) 200 ms before the startle-eliciting stimulus (SES): 15 ms of 110 dB SPL broadband noise. Root-mean-square voltage (Vrms) from the accelerometer was measured over 100 ms following the onset of the SES. The accompanying figure shows the testing apparatus and various voltages (stimuli and response) for a multimodal trial.

**Results:** First, homozygous mutant and male mice were more responsive ( $>PPI$ ) to the unimodal auditory and somatosensory pre-pulses. Second, homozygous mutant mice had more disparate responses to some vibrations compared to the sounds produced by those vibrations. Third, responses of wild-type and heterozygous mice to the multimodal stimuli equaled the sum of their responses to unimodal stimuli, while responses of homozygous mutant mice to multimodal pre-pulses were significantly less than the sum of their responses to unimodal stimuli.

**Conclusions:** Perturbations of MGC-neuronal crosstalk affect the salience of cues that influence unconditioned startle responses in several ways relevant to underlying neural mechanisms for autism (and likely ADHD and PTSD). First, mutant mice had greater PPI to unimodal pre-pulses. This increased responsiveness from the compromised fractalkine signaling is relevant to increased defensive reactions to unanticipated noises and touches in ASD and PTSD. Second, mutant mice responded differently to some vibrations compared to the sounds those vibrations produced, suggesting that altered MGC functioning impairs an ability to ignore extraneous details and respond to 'the big picture'. This is relevant to models of autism, as children on the spectrum often 'miss the forest for the trees'. Third, mutants' responses to simultaneous auditory and somatosensory pre-pulses were less than the sum of responses to each modality alone. This again is relevant to models of autism; the 'whole' being perceived as less than its individual pieces. These results show the value of multimodal psychophysics in MGC mutants as a way to explore underlying causes of multiple perceptual disorders.

#### **401.007 (Poster) Phenotyping Mouse Models of Angelman Syndrome with Multidimensional Behavioral Analysis**

J. K. Tanas<sup>1</sup>, J. M. Wolter<sup>2</sup>, Y. Elgersma<sup>3</sup> and M. S. Sidorov<sup>1</sup>, (1)Center for Neuroscience Research, Children's National Hospital, Washington, DC, (2)The University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)ENCORE Expertise Center for Neurodevelopmental Disorders, Erasmus Medical Center, Rotterdam, Netherlands

---

**Background:** Angelman syndrome (AS) is a single-gene neurodevelopmental disorder caused by loss of function mutations in the maternal copy of the paternally imprinted UBE3A gene. Individuals with AS have a multifaceted behavioral phenotype consisting of deficits in motor function, epilepsy, cognitive impairments, sleep abnormalities, as well as other comorbidities.

**Objectives:** Effectively modeling this behavioral profile and measuring behavioral improvement will be crucial for the success of ongoing and future clinical trials. Foundational studies have defined an array of robust and reliable behavioral phenotypes in the AS mouse model. However, no single behavioral test is able to fully capture the complex nature of AS - in mice, or in children.

**Methods:** Here, we use a multidimensional analysis approach comprised of principal component analysis (PCA) and k-means clustering to quantify the combined performance across eight behavioral domains in a mouse model of AS (Ube3a m-/p+).

**Results:** Multidimensional analysis can successfully predict the genotype of mice based on their behavioral profile with approximately 95% accuracy, and typically achieves  $>90\%$  accuracy with an "n" of ~10 to 15 mice per genotype. We confirmed that multidimensional analysis has the necessary sensitivity to detect behavioral improvement following treatment to increase Ube3a expression in Ube3am-/p+ mice.

**Conclusions:** This approach can be applied to related neurodevelopmental disorders, and may be particularly valuable for disorders where individual behavioral tests are less reliable than in AS and a combinatorial approach is required to determine a phenotype.

---

**Background:**

Disruptions in embryonic brain development can manifest as altered postnatal brain structure and function, leading to neuropsychiatric illness. One such disruption is mutation in *Chromodomain helicase DNA binding protein 8 (Chd8)*; a gene that encodes an ATP-dependent chromatin remodeler. Heterozygous *Chd8* loss of function mutations result in macrocephaly in both humans and mouse models, and autism in humans. However, how *Chd8* haploinsufficiency impacts brain structure across cortical development is unknown. Importantly, previous work demonstrated that increases in brain volume are observed across several brain regions including the cortex, requiring a whole brain imaging approach to study the mutation's effects.

## Objectives:

We employ magnetic resonance imaging (MRI), tissue clearing technology, and light-sheet microscopy to acquire MRI and 3D cellular resolution images in intact whole brains from a mouse model with a single heterozygous point mutation in *Chd8* leading to truncated protein. Our goal is to quantify neural progenitors and neuronal cell-types within annotated areas of the developing neocortex in both WT and *Chd8*<sup>-/-</sup> mice to determine the cell types that drive this ASD associated cortical hyper-expansion.

## Methods:

Four pairs of mouse postnatal day 4(P4) littermate brains were perfused, harvested and fixed overnight with 4% paraformaldehyde. The brains were then incubated in 3% gadolinium for 23 days to improve contrast in MRI. Following the incubation, the brains were then imaged on a 9.4T MRI scanner at 60µm×60µm×60µm. Additionally, we generated 3D cellular high resolution (0.75µm×0.75µm×4µm) images from 6 littermate pairs at P4 labeled with upper- (*Brm2*) and lower- (*Ctip2*) layer neuronal markers following tissue clearing using the iDISCO+ protocol (Renier et al., 2016). Using NuMorph, a suite of image analysis tools developed in our lab, we have registered one of these images to the Allen Developing Brain Atlas and quantified all the nuclei in the cortex.

## Results:

From our MRI analysis, we found increased cortical volume in *Chd8*<sup>-/-</sup> mice (~10%) relative to WT littermate controls in both males and females, replicating previous work. Additionally, we quantified all the nuclei in the cortex using NuMorph from one of the 3D cellular resolution images and detected about 13.8 million cortical nuclei comprised of 21% each of upper- and lower-layer neurons. These results suggest that roughly about 42% of all cells in the cortex of P4 mouse brain may be excitatory neurons. Ongoing experiments will permit comparison to an age-matched WT littermate control.

## Conclusions:

These results demonstrate cortical volume increases in *Chd8*<sup>-/-</sup> mouse brains. Moving forward, we aim to perform similar analyses for 9 biological replicates per sex and per genotype at P4 and other early developmental timepoints to elucidate the cellular basis and spatial localization of brain overgrowth in our mouse model, leading to a better understanding of how genetic variation can affect cortical development and alter risk for neurodevelopmental disorders.

### 401.009 (Poster) Shared and Distinct Effects of Autism-Associated Tbr1 Mutations on Cortical Development

M. Co<sup>1,2</sup>, S. Grindstaff<sup>1</sup>, J. N. Jahncke<sup>2</sup>, R. A. Barnard<sup>1</sup>, L. Fedorov<sup>3</sup>, K. M. Wright<sup>2</sup> and B. J. O'Roak<sup>1</sup>, (1)Molecular and Medical Genetics, Oregon Health & Science University, Portland, OR, (2)Vollum Institute, Oregon Health & Science University, Portland, OR, (3)Transgenic Mouse Models Core, Oregon Health & Science University, Portland, OR

Background: Over 50 pathogenic or likely pathogenic variants affecting *TBR1* have been identified in patients with neurodevelopmental disorders (NDDs) such as autism. As a transcription factor, TBR1 directly regulates the expression of other high-confidence autism risk genes in the developing cerebral cortex. While mouse genetic studies have established *Tbr1* as essential for cortical development, their interpretation in the context of NDDs is somewhat limited. Most studies used homozygous *Tbr1* knock-out mice, while human *TBR1* patients are heterozygous for mutations ranging in type (e.g. missense, nonsense, frameshift) and location within the gene. Thus, *TBR1* patient mutations may cause distinct functional effects ranging from haploinsufficiency, *de novo* gain-of-function, or dominant-negatives. Little is currently known about how patient-specific mutations alter TBR1 function and downstream cortical development *in vivo*.

Objectives: We aim to identify the shared and distinct effects of patient-specific *TBR1* mutations on TBR1 function and mammalian cortical development, focusing on an early-truncating frameshift mutation (p.A136PfsX80) and a missense mutation in the T-box DNA-binding domain (p.K228E).

Methods: Using CRISPR/Cas9, we generated patient mutant mouse lines *Tbr1*<sup>A136PfsX80</sup> and *Tbr1*<sup>K228E</sup> and compared them to a published *Tbr1* knock-out line (*Tbr1*<sup>ko</sup>). All experiments were conducted on mixed sex cohorts and compared heterozygous and homozygous mutants to wild-type littermate controls. We assessed *Tbr1* expression in neonatal and adult mice using Western blot, quantitative PCR, and immunohistochemistry (IHC) (n=3 mice/genotype). We also examined brain morphology using IHC markers and DiI axon labeling (n=3-7 mice/genotype). Groups were statistically compared using unpaired t-tests (two groups) or one-way ANOVA with Tukey's multiple comparisons test (three groups).

Results: We identified p.A136PfsX80 as a loss-of-function *Tbr1* mutation, as TBR1 protein was completely absent from homozygous mutant cortex and reduced by ~40% in heterozygotes. Furthermore, *Tbr1*<sup>A136PfsX80</sup> homozygotes phenocopied the developmental defects previously observed in *Tbr1*<sup>ko</sup> homozygotes. In contrast, homozygous p.K228E mutation caused a ~3.5-fold upregulation of *Tbr1* transcript, and a ~5-fold increase and misexpression of TBR1 protein throughout the cortical layers. In *Tbr1*<sup>K228E</sup> heterozygotes, TBR1 was upregulated by ~2-fold but distributed normally in deep-layer cortex. Despite this upregulation, the p.K228E mutation caused severe cortical defects when homozygosed and failed to genetically complement the *Tbr1*<sup>ko</sup> allele in a complementation cross, indicating limited protein functionality. Nonetheless, p.K228E retained sufficient activity to prevent the substantial cortical apoptosis seen in perinatal *Tbr1*<sup>ko</sup> homozygotes. Common phenotypes present in heterozygotes of all three mutant lines were downregulation of deep-layer cortical marker CTIP2 in adults and reduction of the anterior commissure, suggesting shared defects in cortical neuronal identity maintenance and interhemispheric axon development.

Conclusions: *Tbr1* p.A136PfsX80 is a loss-of-function mutation *in vivo*, suggesting that *TBR1* haploinsufficiency underlies NDDs in patients carrying early-truncating *TBR1* mutations. In contrast, p.K228E may act as a strong hypomorph and/or dominant-negative, as *in vitro* studies suggest the mutant protein can homodimerize with wild-type TBR1. Moreover, upregulation of *Tbr1* transcript in *Tbr1*<sup>K228E</sup> mutants suggests that TBR1 may normally repress its own expression. Further characterization of these mutations, including shared and distinct transcriptional effects, will identify a core TBR1-regulated pathway that may be targeted therapeutically for *TBR1*-related disorders.

**401.010 (Poster)** Utilizing Vagus Nerve Stimulation to Reverse Maladaptive Plasticity in the Inferior Colliculus in a Rat Autism Model

---

## Background:

Individuals with autism often exhibit delayed and weak neural responses to sounds. Prenatal exposure to valproic acid (VPA) alters the development of both subcortical and cortical auditory areas in both humans and animal models. These neural changes have been observed in VPA-exposed rats, which display significantly delayed and weak responses to sound in the auditory cortex. Recent studies in VPA exposed animals have also observed brainstem anatomical alterations, specifically the early processing areas for auditory pathways such as the superior olivary complex and the inferior colliculus. Therefore, developing a method to improve these neural deficits throughout the auditory pathway is needed. We have developed a new approach to drive robust, specific plasticity that substantially enhances recovery after neurological damage. This strategy uses brief bursts of vagus nerve stimulation (VNS) paired with a sound presentation.

## Objectives:

The aims of this study are to 1) document differences in the multi-unit inferior colliculus (IC) response to sounds in VPA exposed rats in comparison to saline exposed control rats, and 2) investigate the ability of vagus nerve stimulation (VNS) paired with speech sounds to reverse the maladaptive plasticity in the inferior colliculus in VPA exposed rats. In these experiments, we test the hypothesis that VNS paired with the speech sound 'dad', 300 times per day for 20 days, will reverse maladaptive plasticity and restore neural responses to sounds in VPA-exposed rats.

## Methods:

The experimental groups included: 1) control rats who were prenatally exposed to saline, 2) VPA-exposed rats who did not undergo therapy, and 3) VPA-exposed rats who underwent VNS-sound pairing therapy. Following the last day of VNS-sound pairing, neural recordings in response to tones, speech sounds, and noise burst trains were collected from the inferior colliculus in each of the experimental groups. Statistical analysis was completed using MATLAB software and SPSS version 27.

## Results:

Our results suggest that VPA animals displayed weaker responses to speech sounds in the IC, and VNS-sound pairing significantly enhanced the IC response strength in VPA-exposed rats ( $F(2, 599) = 6.344, p < 0.01$ ). Interestingly, in response to tones, no significant differences were observed in response rate across the three experimental groups ( $F(2, 315) = 0.1, p = 0.91$ ).

## Conclusions:

VPA animals responded weaker to speech sounds compared to the control animals in the IC. This strengthening effect of VNS was not specific to the paired sound, and was also strengthened in novel speech sounds differing in initial consonant or vowel. This indicates that the VNS-paired plasticity was not specific to paired sound but generalizes to broadband sounds that are acoustically similar to the paired sound. Insights derived from this study may influence the development of new behavioral and sensory techniques to treat communication impairments that result in part from a degraded neural representation of sounds.

**401.011 (Poster)** microRNA As a Potential Biomarker in Autism: Prenatal Stress and SERT Gene Interaction Model  
**T. Woo<sup>1</sup>**, C. King<sup>2</sup>, C. Bloomer<sup>3</sup>, N. Kibiryeva<sup>4</sup>, Z. Talebizadeh<sup>5</sup> and D. Q. Beversdorf<sup>6</sup>, (1)Interdisciplinary Neuroscience Program, University of Missouri, Columbia, MO, (2)Biological Science, University of Missouri, Columbia, MO, (3)University of Kansas Medical Center, Kansas City, KS, (4)Children's Mercy Hospital, Kansas City, MO, (5)Children's Mercy Hospital, Kansas City, MO, (6)Department of Radiology, Neurology, and Psychological Sciences, University of Missouri, Columbia, MO

---

Background: Prenatal stress is critical in neurodevelopment and many studies suggest it increases risk for autism spectrum disorder (ASD), particularly in those genetically susceptible to stress. In animal models, we demonstrated that aberrant social behavior was observed in offspring of heterozygous serotonin transporter knock-out (SERT-het) mice exposed to stress during pregnancy, and restricted social interaction was associated with epigenetic changes in the embryonic brains. Two independent clinical studies have shown that the higher incidence of ASD in prenatally stress-exposed mothers is associated with maternal presence of the SERT short-allele (deletion in promoter region). Recently, we have reported differential expression (DE) of microRNAs (miRNAs) in blood samples of prenatally stress-exposed mothers carrying the SERT short allele who have children with ASD, which may serve as a potential blood biomarker of the gene x environment (G x E) interaction in ASD.

Objectives: To further investigate the role of miRNAs as a potential biomarker during pregnancy in this G x E interaction model.

Methods: We profiled the miRNA expression in blood from dams in the mouse model of SERT-het/stress dams at embryonic day 21 (E21) and postnatal day 60 (PD60) and compared with that of wild-type mice at the same time window.

Results: More than three thousand mature miRNAs were examined, and the ANOVA analysis detected several DE miRNAs. However, there were no common DE miRNAs between E21 and PD60, which suggested a transition in miRNA profiles in SERT-het/stress dams after delivery. One of the upregulated miRNAs at PD60 (miR-149-3p) and E21 (miR-762) were also found in the DE miRNAs of human samples from our previous study.

Conclusions: These miRNAs could be biomarker candidates for G x E interactions in ASD, and are highly dynamic over time. Our study provides evidence for epigenetic alterations associated with the gene x environmental interaction which we hope will lead to better understanding of the causes and treatments of ASD, resulting from prenatal stress exposure in genetically stress susceptible individuals.

## VIRTUAL POSTER SESSION — ANIMAL MODELS

### 501 - Animal Models --- (V)

#### **501.001** (Virtual Poster) Microbial Dysbiosis and Increased Gut Permeability in a *Cntnap2* Knock-out Rat Model of Autism

R. Mittal<sup>1</sup>, I. Memis<sup>1</sup>, L. Cavalcante<sup>1</sup>, E. Furar<sup>1</sup>, R. S. Eshraghi<sup>2</sup>, F. Wang<sup>1</sup>, J. Mittal<sup>1</sup> and A. A. Eshraghi<sup>2</sup>, (1)University of Miami Miller School of Medicine, Miami, FL, (2)Otolaryngology, Neurological Surgery and Pediatrics, University of Miami Miller School of Medicine, Miami, FL

Background: Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social communication and restricted, repetitive behaviors. Although pathophysiology of ASD is multifactorial, mutations in *CNTNAP2* have been implicated in the genetic etiology of autism. *CNTNAP2* is a gene within the neurexin family which codes for Contactin-associated protein-like 2 (CASPR2). Neurexins plays a crucial role in the development of the nervous system, synapse formation and cell adhesion properties. Previous studies have shown that *Cntnap2* knock-out (KO) rats exhibit ASD associated behavior abnormalities and can serve as a powerful tool to understand the mechanisms underlying autism. Besides behavior abnormalities, gastrointestinal (GI) complications are a common co-morbidity observed in individuals with ASD. It has been proposed that this association regarding behavior abnormalities and GI complications is related to the concept of the gut-brain axis, which suggests a bidirectional communication between the brain and the gut microbiota. There is a need to characterize the gut microbiota and GI abnormalities utilizing preclinical animal models such as *Cntnap2* KO rats that will pave the way to develop novel treatment modalities for ASD.

Objectives: As *Cntnap2* KO rats provide a preclinical model of ASD with strong face and predictive validity, the objective of the present study was to characterize gut microbiome profile of *Cntnap2* KO and wild-type (WT) littermate rats by 16S rRNA sequencing. In addition, we investigated GI parameters such as gut motility and permeability as indicators of gut function.

Methods: Heterozygous breeders of *Cntnap2* KO rats were obtained from Envigo company. The model contains a five base pair deletion in exon six of the *Cntnap2* gene, created using the zinc finger nuclease target site CAGCATTTCGCACC|aatgga|GAGTTTGACTACCTG. All experimental animals were obtained from heterozygous crossings. Both male and female rats were used in each experiment. Gut microbiota of *Cntnap2* KO and WT littermate control rats was characterized using 16s RNA sequencing followed by determination of alpha and beta microbial diversity. Gastrointestinal transit time was determined using the nonabsorbable red dye Carmine red whereas gut permeability was determined using FITC-dextran assay.

Results: We observed gut dysbiosis and distinct microbial composition in *Cntnap2* KO rats compared to WT littermate control rats. There was a significant difference in gut microbial beta diversity in terms of Bray-Curtis and unweighted UniFrac distances in *Cntnap2* KO and WT littermate control animals. In addition, there was decreased GI motility and increased gut permeability in *Cntnap2* KO animals compared to WT littermate control rats.

Conclusions: The gut dysbiosis observed in *Cntnap2* KO is in agreement with the findings observed in individuals with ASD. Thus, this model provides a tool to explore the role of gut dysbiosis and microbiota-gut-brain axis in predisposition to ASD. Our new findings of gut dysbiosis in *Cntnap2* KO will provide opportunities to develop novel therapeutic strategies based on restoration of gut microbiome.

#### **501.002** (Virtual Poster) Understanding the Development of ASD Trajectory in Offspring Following Exposure to Maternal and Postnatal Immune Activation Using a Rat Model

F. Wang<sup>1</sup>, I. Memis<sup>1</sup>, J. Mittal<sup>1</sup>, E. Furar<sup>1</sup>, R. Mittal<sup>1</sup> and A. A. Eshraghi<sup>2</sup>, (1)University of Miami Miller School of Medicine, Miami, FL, (2)Otolaryngology, Neurological Surgery and Pediatrics, University of Miami Miller School of Medicine, Miami, FL

Background: Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by three core features, repetitive behavior, impaired social interactions, and difficulty with communication. Increasing evidence suggests that maternal immune activation (MIA) ("single hit") resulting from maternal viral infection may be involved in predisposition to ASD in the offspring. This is a worldwide concern, especially during this pandemic of COVID-19. In addition, studies have shown that offspring exposed to MIA may be more susceptible to gram negative bacterial infections during birth leading to postnatal immune activation (PIA) ("double hit"). However, it is not known when the offspring exposed to MIA and PIA start exhibiting the core symptoms of ASD. There is a need to understand the trajectory of ASD development in offspring following exposure to MIA and PIA using animal models that will provide opportunities for early intervention and hence better clinical outcomes.

**Objectives:** The objective of this study was to determine when the offspring exposed to MIA and PIA start exhibiting the core symptoms of ASD. We also determined whether the effects of MIA and PIA in exhibiting behavioral abnormalities are limited to juvenile stage or they have long lasting effects till the adult stage.

**Methods:** The animals were divided into five groups as shown in Table 1. MIA was induced in pregnant dams using intraperitoneal injection of double-stranded RNA polyinosinic-polycytidylic acid [poly(I:C)] (20mg/kg) at embryonic day 12.5 (E12.5). PIA was induced by giving oral gavage of lipopolysaccharide (LPS) (10 mg/kg) on postnatal day 9. Animals in all groups were subjected to behavior tests such as juvenile play during ages from postnatal day 21 to day 30. In addition, the animals were subjected to a comprehensive battery of behavior tests during adult stage upto six months. These behavior tests include three-chamber test, locomotor and repetitive/stereotypic-like activity, open-field, marble burying and determination of sensory stimuli response using prepulse inhibition and acoustic startle reflex.

**Table 1: Experimental animal groups**

| Group | Pregnant Dam (Mother) | Offspring            |
|-------|-----------------------|----------------------|
| 1     | No treatment (Naïve)  | No treatment (Naïve) |
| 2     | Vehicle (PBS)         | Vehicle (PBS)        |
| 3     | MIA                   | No treatment         |
| 4     | No treatment          | LPS (PIA)            |
| 5     | MIA                   | LPS (PIA)            |

**Results:** The offspring exposed to MIA or PIA alone exhibited behavioral abnormalities that were further exacerbated following exposure to MIA and PIA together compared to control group. The behavior abnormalities were observed as early as during juvenile stage that continued till the adult stage.

**Conclusions:** The result of the present study suggests that MIA or PIA have long lasting effects on the developmental trajectory of offspring. In addition, the findings are highly relevant in the current situation of pandemic given that COVID-19 will lead to MIA or PIA and potentially affect the neurological functioning of future children. Our findings provide novel insights regarding the effect of MIA and PIA in predisposition to ASD and will pave the way for development of novel preventive and therapeutic modalities.

**501.003 (Virtual Poster)** Effects of a Gut-Selective Integrin-Targeted Therapy in a Mouse Model for Autism Spectrum Disorders  
*R. De Simone<sup>1</sup>, A. Butera<sup>1</sup>, R. Potenza<sup>1</sup>, M. Armida<sup>1</sup>, F. Trenta<sup>2</sup>, M. Boirivant<sup>1</sup> and L. Ricceri<sup>2</sup>, (1)CNRVF, Istituto Superiore di Sanità, Rome, Italy, (2)CSCSM, Istituto Superiore di Sanità, Rome, Italy*

*Background:*

Inflammatory and immune changes are recognized as pivotal mechanisms in ASD, particularly the ones involving the microbiota-mucosal immune response development. Few data are so far available concerning the primary contribution of mucosal immune dysfunction to behavioral and neuroinflammatory profiles in ASD mouse models.

*Objectives:*

To clarify the role of gut mucosal immunity on behavioral and neuroinflammatory profile in ASD, we used the early-life immune activation (EIA) mouse model. As double-hit model, it includes both prenatal (Poly I:C, mimicking a gestational viral infection) and postnatal (LPS mimicking a bacterial infection) immune challenges

*Methods:*

In male C57BL6/J EIA adult offspring we evaluated the effects of a two-week ip treatment with a monoclonal antibody (DATK-32) directed against the integrin alpha4 beta7 (anti- $\alpha 4 \beta 7$  Ab), responsible for lymphocyte trafficking in the gut mucosa. The anti-  $\alpha 4 \beta 7$  Ab causes a selective blockade of gut-experienced lymphocyte traffic to intestinal lamina propria. The effects of the treatment are assessed on EIA behavioral and neuroinflammatory profile, and immune-inflammatory changes.

*Results:*

The integrin targeted treatment counteracts selected EIA changes in anxiety and exploratory profiles (detected in the open field and marble burying tests), but did not significantly affect the social deficits shown by EIA male mice in the three-chamber tests (both social responsiveness and social novelty). EIA behavioral effects are associated with a proinflammatory phenotype in the hippocampus of male offspring, as reflected by a significant increase in the mRNA expression of the proinflammatory cytokine IL-6 and a concomitant reduction of microglia-associated protective genes such as arginase-1, TGF- $\beta$ 1 and CD-68. Treatment with anti- $\alpha 4 \beta 7$  Ab in EIA mice re-established the expression of arginase-1, CD-68 and TGF- $\beta$ 1, whereas it did not modify IL-6 mRNA.

Cytofluorimetric analyses of lymphocytes isolated from gut associated lymphoid tissue show in EIA mice increased percentage of IL-17+ or IFN-g+ lymphocytes in Mesenteric Lymph Nodes (MLN) or colonic lamina propria, respectively. Treatment with anti- $\alpha$ 4 $\beta$ 7 Ab was associated with percentage of IL-17+ and IFN-g+ lymphocytes comparable to control mice (saline +Isotype Ab).

#### Conclusions:

Treatment with anti- $\alpha$ 4 $\beta$ 7 Ab counteracts some of the behavioral abnormalities in the EIA mouse model of ASD. We suggest that preclinical interventions on gut mucosal immune-system could have beneficial effects on selected ASD neurobehavioral features.

**501.004 (Virtual Poster)** Vorinostat, a Histone Deacetylase Inhibitor, Ameliorates the Sociability and Cognitive Memory in an Ash1L-Deletion-Induced ASD/ID Mouse Model

**J. He**, Biochemistry and Molecular Biology, Michigan State University, East Lansing, MI

#### Background:

ASH1L is an epigenetic factor that facilitates gene expression through modifying chromatin. Previous genetic studies reported that *ASH1L* is a high ASD risk gene. Our recent study used a mouse model to demonstrate that loss of *ASH1L* in the mouse brain was sufficient to cause core autistic-like behaviors and impaired cognitive memory, confirming that the disruptive *ASH1L* mutations are the causative drivers leading to ASD/ID genesis.

#### Objectives:

Since histone acetylation and *ASH1L*-mediated histone modification have synergistic effects in facilitate gene expression, in this study we examined whether vorinostat (SAHA), a histone deacetylase inhibitor (HDACi), could ameliorate the ASD/ID-like behavioral and cognitive memory deficits in the *Ash1L*-deletion-induced (*Ash1L*-Nes-cKO) ASD/ID mouse model.

#### Methods:

Low dose of SAHA (5mg/kg/day) was administrated to the *Ash1L*-Nes-cKO from postnatal day 5 to 60. Three-chamber tests, novel object recognition (NOR) tests, and open field assays were used to assess the sociability, social novelty, recognition memory, and anxiety-like behaviors of *Ash1L*-Nes-cKO mice.

#### Results:

The behavioral tests showed that low dose of SAHA administration for 50 days largely enhanced the discrimination index of sociability ( $p = 0.0412$ ) as well as reduced the hair grooming episodes ( $t = 3.733$ ,  $df = 18$ ,  $p = 0.0015$ ) and time ( $t = 3.20$ ,  $df = 18$ ,  $p = 0.005$ ) in the *Ash1L*-Nes-cKO mice, suggesting that SAHA treatment ameliorated the core ASD-like deficits in sociability and repetitive behaviors. Furthermore, the NOR tests revealed that the SAHA treatment significantly increased the discrimination index for the novel object ( $p < 0.0001$ ), suggesting that SAHA treatment ameliorated the cognitive memory. However, the SAHA treatment did not show positive effects to ameliorate postnatal growth retardation, anxiety-like behaviors, and paw clasping in the *Ash1L*-Nes-cKO mice. Blood biochemical analysis and peripheral blood cell counting showed that the mice treated with SAHA had normal liver and renal functions as well as normal blood cell counts, suggesting that the low dose of SAHA did not induce severe side effects and was well tolerated by animals.

#### Conclusions:

Our current study provides experimental evidence to show that the postnatal administration of low-dose SAHA significantly ameliorates the sociability, repetitive behaviors, and cognitive memory in the *Ash1L*-deletion-induced ASD/ID mouse model, indicating that SAHA is a promising reagent for the pharmacological treatment of core ASD/ID behavioral deficits caused by disruptive *ASH1L* mutations.

## Brain Function (fMRI, fcMRI, MRS, EEG, ERP, MEG)

### PANEL — BRAIN FUNCTION (FMRI, FCMRI, MRS, EEG, ERP, MEG)

#### 202 - Pupillometry As a Neuroimaging Tool during Naturalistic Behavior – New Avenues for Biomarker Research, Etiological Mechanisms, and Prognostic Risk Assessment

**Panel Chair: Nico Bast**, Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany

**202.001 (Panel)** Attentional Strengths and Weaknesses in Autism Spectrum Disorder: The Role of the Locus Coeruleus – Norepinephrine System

**Background:** Infants at elevated risk for autism spectrum disorder (ASD), as well as children, adolescents, and adults diagnosed with ASD excel at visual search compared to their typically developing (TD) peers. Paradoxically, slowed attentional disengagement has also been found across the lifespan in those at risk for, or diagnosed with, ASD. However, whether these two paradoxical states co-exist within the same individuals and the neurofunctional mechanism(s) associated with these strengths and weaknesses remains to be determined.

**Objectives:** To examine the relationship between enhanced visual search and impaired disengagement, and assess the role that the locus coeruleus – norepinephrine (LC-NE) system, as indexed by pupil diameter, plays in the manifestation of atypical attentional processes.

**Methods:** Participants were 28 children with ASD and 30 age- and non-verbal IQ-matched TD children. The study consisted of separate visual search, gap-overlap, and resting eye-tracking paradigms. For the visual search paradigm, participants were instructed to find the target (vertical line) embedded within an array of tilted (10°) distractor lines. The target was present on 50% of trials, and displayed within set sizes of 18, 24, and 36 items. In the gap-overlap task, participants were instructed to fixate on a central crosshair and then move their eyes to a peripheral target once it appeared. Each trial began with a crosshair presented alone. Next, a target could appear with either the crosshair remaining on the screen (overlap) or 200ms after the crosshair disappeared (gap). For the resting eye-tracking, participants were instructed to relax, remain still, and to look at the central crosshair. Saccadic latency and pupil diameter were monitored using an EyeLink 1000 Plus eye-tracking system.

**Results:** For the visual search paradigm, groups did not differ significantly for RT or accuracy. However, there was a significant interaction between group and target presence; while the groups were equivalent for target present (ASD=1541ms; TD=1525ms), there was an ASD advantage in the target-absent condition (ASD=2323ms; TD=2928ms). Children with ASD showed faster, albeit a non-significant difference in, search efficiency (ASD=12ms/item; TD=20ms/item). For the gap-overlap paradigm, groups did not differ on saccadic RT. Gap effect scores (overlap – gap) were marginally larger for children with ASD ( $p<.1$ ; ASD=66ms; TD=34ms); step effect scores (overlap – baseline) were significantly larger in ASD ( $p<.05$ ). Resting pupil diameter was significantly larger in the ASD group ( $p<.05$ ). Correlations between gap effect and search efficiency measures showed that, for the ASD group (but not the TD group), slower disengagement was associated with better search efficiency, and that larger pupil size was related to slower disengagement and more efficient visual search ( $ps<.05$ ).

**Conclusions:** Similar to previous reports, children with ASD exhibited a target-absent search advantage and slower attentional disengagement. For the ASD group, greater search efficiency was associated with slower attentional disengagement. Importantly, increased tonic activation of the LC-NE system (i.e., larger resting pupil size) was associated with greater search efficiency and poorer attentional disengagement. The present findings suggest attentional strengths and weaknesses co-occur in individuals with ASD, and may be linked to atypical activation of the LC-NE system.

## **202.002 (Panel) Sensory Salience Processing and Associated Pupillary Responses Modulate Attenuated Social Attention in Autism Spectrum Disorder**

**N. Bast, Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany**

---

**Background:** Visual exploration is defined by an interactive evaluation of sensory salience (stimulus-driven) and semantic content (goal-directed). Attenuated social attention is a key marker of autism spectrum disorder (ASD) that has been explained by an altered processing of semantic content like attenuated social motivation. In contrast, neuroimaging findings emphasized altered sensory processing of salience. The Locus-Coeruleus Norepinephrine (LC-NE) system has been established as a neurophysiological modulator of sensory processing. Recent findings revealed altered LC-NE functioning in ASD, which indicates altered sensory processing as an underlying mechanism of altered social attention.

**Objectives:** We aim to investigate sensory salience processing with LC-NE functioning as neurophysiological modulator as a predictor of social attention during naturalistic visual exploration.

**Methods:** We assessed a sample of heterogenous individuals (AIMS-2-TRIALS study) with ASD and neurotypical development (TD:  $n = 164$ , ASD:  $n = 164$ ) that were matched in age ( $m/SD = 16.3/5.8$  years, range = 6–30 years), IQ ( $m/SD = 103/17$ , range = 60–140), and sex distribution (female:  $n = 95$ , male:  $n = 233$ ). During eye tracking, participants watched a series of movie scenes that either depicted humans or did not depict humans. Eye tracking data contained pupillary response information as an index of LC-NE phasic activity. We further applied computer vision algorithms to extract physical and motion salience information of the movie scenes (see figure). This sensory salience information was related to corresponding gaze behavior and pupillary responses to retrieve estimates of gazes on and reactivity to sensory salience, which were then applied as predictors of social attention as measured by gazes on eye regions (definition of areas-of-interest). We applied linear mixed models that controlled for data quality, comorbid psychopathology, and scene duration by a polynomial effect of time. Significant and standardized effects are presented as marginalized coefficients ( $\beta$ ) or contrasts ( $\Delta M$ ) with 95% confidence intervals.

**Results:** Across groups, higher pupillary responses were associated with lower gazes on sensory salience during early phases ( $\beta = -0.04 [-0.05, -0.02]$ ) and higher gazes on sensory salience during intermediate phases of the movie scenes ( $\beta = 0.05 [0.03, 0.07]$ ). In ASD compared to TD, pupillary responses were lower during human movie scenes ( $\Delta M = -0.09 [-0.15, -0.02]$ ) and higher during non-human movie scenes ( $\Delta M = 0.07 [0.02, 0.14]$ ). Importantly, we found lower social attention in ASD ( $\beta = -0.08 [-0.15, -0.02]$ ) that was moderated by gazes on and reactivity to sensory salience. In ASD, lower pupillary responses predicted lower social attention ( $\beta = -0.04 [-0.06, -0.02]$ ).

In a secondary analysis, the pupillary response signal across scenes was decomposed into an early response component (PR1) and a late pupillary response component (PR2). Across groups, PR1 was negatively associated with social attention ( $\beta = -0.04 [-0.05, -0.01]$ ), while PR2 was positively associated with social attention ( $\beta = 0.01 [0.00, 0.03]$ ).

**Conclusions:** We provide the first empirical support of altered sensory processing in ASD during naturalistic visual exploration. Different LC-NE phasic activity is emphasized as a basic neurophysiological mechanism in ASD that contributes to attenuated social attention and altered sensory salience processing.

#### **202.003 (Panel) Pupil Size and Pupillary Light Reflex in Early Infancy: Heritability and Associations with Polygenic Liability for Neuropsychiatric Conditions**

**A. M. Portugal<sup>1</sup>, M. Taylor<sup>2</sup>, C. Viktorsson<sup>3</sup>, P. Nyström<sup>4</sup>, D. Li<sup>5</sup>, K. Tammimies<sup>6</sup>, A. Ronald<sup>7</sup> and T. Falck-Ytter<sup>8</sup>,** (1)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research, Department of Women's and Children's Health, Karolinska Institute, Stockholm, Sweden, (2)Karolinska Institutet, Stockholm, Sweden, (3)Development and Neurodiversity Lab, Department of Psychology, Uppsala University, Uppsala, Sweden, (4)Uppsala University, Uppsala, Sweden, (5)Center for Psychiatry Research, Region Stockholm, Stockholm, Sweden, (6)Center for Neurodevelopmental Disorders at Karolinska Institutet (KIND), Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (7)Birkbeck College, London, United Kingdom of Great Britain and Northern Ireland, (8)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden

---

**Background:** The pupillary light reflex (PLR, a sudden constriction response to retinal or attended stimulus luminance serving to regulate the amount of light reaching the retina) and the baseline pupil diameter are measures based on pupil tracking that reflect physiological responses linked to specific neural circuits (both parasympathetic function and sympathetic activity linked to the locus coeruleus-norepinephrine system) that have been implicated as atypical in some psychiatric and neurodevelopmental conditions, particularly autism and schizophrenia.

**Objectives:** We investigated the contribution of genetic and environmental factors to individual differences in early life baseline pupil size and the PLR, and whether there were shared or distinct genetic etiologies between these measures. We also tested its associations with common genetic variants associated with neurodevelopmental (autism spectrum disorder and attention deficit hyperactivity disorder) and mental health (bipolar disorder, major depressive disorder, and schizophrenia) conditions using genome-wide polygenic scores (GPSs).

**Methods:** Our study included 510 infant twins assessed at 5 months of age (281 monozygotic and 229 dizygotic pairs) in the lab, using a Tobii TX300 eye-tracker to record pupil size over 12 PLR trials interspersed with other audio-visual tasks. Zygosity and GPSs were estimated based on DNA samples. The analysis plan for this study was pre-registered in OSF (<https://osf.io/5kzh2>).

**Results:** Univariate twin modelling showed high heritability at 5 months for both pupil size ( $h^2 = .64$ , CI: .54-.72) and constriction in response to light ( $h^2 = .62$ , CI: .51 to .70), and bivariate twin modelling indicated substantial independence between the genetic factors influencing each ( $r_G = .38$ ). When analyzing genome-wide polygenic scores, we found a statistically significant positive association between infant tonic pupil size and the GPS for schizophrenia ( $\beta = .15$ ,  $p = .024$ ). There was no significant association with the GPS for autism ( $p > .25$ ) or any other GPSs, and no associations between constriction response and the GPSs.

**Conclusions:** This study shows that individual differences in some measures based on pupillometry are highly heritable in early infancy, although substantially independent in their genetic etiologies. It also provides initial evidence that pupil size may share some links with common genetic variants linked to schizophrenia. It illustrates how genetically-informed studies of infants may help us understand early physiological responses associated with psychiatric disorders which emerge much later in life.

#### **202.004 (Panel) Capturing the Pupillary Light Reflex As Part of Medical Appointments in a Neurodevelopmental Clinic Using Automated Pupillometry**

**V. Troiani<sup>1</sup>, A. DiCriscio<sup>1</sup>, S. Dickey<sup>2</sup> and A. Beck<sup>2</sup>,** (1)Geisinger Autism & Developmental Medicine Institute, Lewisburg, PA, (2)Geisinger, Lewisburg, PA

---

**Background:**

We and others have previously found that the pupillary light reflex (PLR) and pupil response captured using infrared eye tracking are atypical in autism spectrum disorder (ASD) and individual differences in pupil responses are associated with core diagnostic traits of ASD. However, widespread assessment of the PLR in clinical settings has been limited using infrared eye trackers, which can be expensive, require time consuming calibration for each participant, and domain-specific knowledge for data analysis and export. The PLR can also be captured using hand-held pupillometers, such as the NeuroOptics NPi 200 pupillometer. The NPi 200 is a validated, hand-held optical scanner that captures pupil reactivity and pupil size (see Figure, Part A). The device captures and records a PLR waveform (pupillogram), which can be output for analysis, along with summary metrics, including a normalized pupil response estimate (NPi), pupil size, constriction and dilation velocity, amongst others (See Figure, Part B). The device allows for standardized data capture in clinical settings, but to date, has primarily been used in critical care settings, rather than within the context of neurodevelopment.

**Objectives:** The purpose of this study was to evaluate a process to capture automated pupillometry within a clinical setting to assess the feasibility of using hand-held pupillometers in populations with neurodevelopmental concerns and a wide range of ability and functioning, including ASD. We also aim to confirm reliability of PLR capture with the NPi 200 across timepoints. Future analyses will compare PLR metrics from successful captures in children with and without ASD.

## Methods:

We developed a process that included 1) generating and monitoring a clinical appointment list, 2) using existing electronic health record data to identify eligible participants, 3) calling participants to gauge interest in research participation as an add-on to their clinical appointment, and 4) rapid PLR assessment using the NeuroOptics NPi 200 pupillometer. In a subset of participants, we captured data at 2 timepoints to confirm reliability of the PLR.

## Results:

To date, we have assessed N=60 children (study ongoing), with successful capture completed on N=46 children (n=36 of 46 with a clinical diagnosis of ASD; n=10 with other neurodevelopmental diagnoses). Age of participants currently ranges from 3 to 17, FSIQ from 42 to 144, and SRS Total T-score ranging from 53 to 91. Preliminary results indicate that internal consistency of measures across multiple timepoints is high (Cronbach's alpha ranging from 0.86 to 0.98; Figure, part C). When the target pediatric sample is reached, we will perform planned analyses to determine specificity and sensitivity of the PLR metrics to discriminating between ASD and other neurodevelopmental diagnoses.

## Conclusions:

These results indicate that hand-held, automated pupillometers, such as the NeuroOptics NPi 200, can be used for successful capture (77% success rate) of PLR in children with a large range of ability and functioning. Thus, hand-held pupillometers show promise for use in neurodevelopmental populations as part of furthering our understanding of PLR differences in ASD, presymptomatic detection, identifying clinically meaningful subgroups with differing severity or treatment response, and monitoring treatment efficacy.

**228.001 (Panel)** Aberrant Acoustic and Tactile Sensory Sensitivity and Integration at Specific Developmental Stages in the *Cntnap2* and *Nrxn1* Mouse Models for Autism Spectrum Disorders

**I. W. Riemersma,** *R. Havekes and M. Kas, University of Groningen, Groningen, Netherlands*

## Background:

Sensory information processing is key for normal functioning in daily life. Sensory abnormalities are a frequent feature of neurodevelopmental disorders (NDD). In autism spectrum disorders (ASD) sensory abnormalities are reported in up to 90% of patients. Moreover, these symptoms are reported as early as 6 months of age while diagnosis generally takes place at 3 years of age or later. This suggests that deficits in sensory processing could underlie other symptoms found in NDD.

## Objectives:

It is unclear which biological mechanisms underlie these sensory symptoms and when during development these changes could contribute to a behavioural phenotype. Therefore, the aim of this research was to perform a longitudinal screening of the behavioural sensory phenotype in genetic mouse models of NDD.

## Methods:

We assessed acoustic and peripheral tactile sensory sensitivity by measuring startle responses to single auditory and tactile stimuli. In addition, prepulse inhibition (PPI) of paired auditory and auditory-tactile stimuli was measured to assess sensory gating. These tests were performed in two genetic models associated with NDD: *Nrxn1*<sup>-/-</sup> and *Cntnap2*<sup>-/-</sup> mutant mice with their respective WT littermates serving as controls. This multi-model approach was used with the aim of finding convergence in possible underlying biological mechanisms of NDD. In addition, sensory phenotypes were monitored at three different developmental timepoints (TP1 6-8 weeks, TP2 12-14 weeks and TP3 18-20 weeks) with the goal of identifying possible sensitive time windows. Significance was ascertained by repeated measures ANOVA with corrections for multiple comparisons.

## Results:

A significant main effect of genotype and a genotype x sound level interaction was found for acoustic sensory sensitivity in both the *Nrxn1* and *Cntnap2* mice (*Nrxn1*: p=0.0013; *Cntnap2* p=0.0371, interaction: *Nrxn1*: p=0.0095 *Cntnap2* p=0.0013). Both gene knockout models showed a decrease in acoustic sensitivity for higher dB acoustic pulses (110-120dB). In addition, the *Cntnap2*<sup>-/-</sup> mice showed decreased peripheral tactile

sensitivity. Moreover, for the acoustic and tactile-acoustic sensory gating a main effect of both age and genotype was found for both mouse models (Age  $p < 0.001$ , acoustic *Cntnap2*:  $p < 0.001$ ; *Nrxn1*  $p = 0.0133$ , tactile-acoustic *Cntnap2*  $p = 0.0018$ ; *Nrxn1* n.d.). *Nrxn1*<sup>-/-</sup> and *Cntnap2*<sup>-/-</sup> mice showed increased levels of PPI indicating aberrant sensory gating. Interestingly, the decreased acoustic sensitivity and increased sensory gating effects were not yet visible during the first timepoint at 6-8 weeks. Conversely, peripheral tactile hyposensitivity in the *Cntnap2* was most prominent at the earliest timepoint at 6-8 weeks.

#### Conclusions:

Here, we show that tactile and acoustic sensory sensitivity and gating is affected in two mouse models for NDD, specifically at later developmental stages (early and late adulthood), but not yet during early adolescence. Interestingly, the peripheral tactile phenotype was specifically clear at the first time point, while the central acoustic sensory phenotypes were most apparent at later stages. To further determine the origin of the behavioural deficits observed in these mice, our next step is to identify changes in brain markers related to sensory processing during these time points. Ultimately to further unravel underlying biological mechanisms as well as identifying optimal developmental time windows for new therapeutic strategies for NDD.

**228.002 (Panel)** Variance in Motor Functioning in Autistic Children Is Explained By Low-Level Tactile Perception and Brain GABA Levels  
**J. L. He<sup>1</sup>**, G. Oeltzschner<sup>2</sup>, E. Wodka<sup>3</sup>, R. A. Edden<sup>4</sup>, S. H. Mostofsky<sup>3</sup> and N. A. Puts<sup>1</sup>, (1)Department of Forensic and Neurodevelopmental Sciences, Sackler Institute for Translational Neurodevelopment, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, UK, King's College London, London, United Kingdom, (2)Russell H. Morgan Department of Radiology and Radiological Science, The Johns Hopkins University School of Medicine, Baltimore, MD, (3)Center for Autism and Related Disorder, Kennedy Krieger Institute, Baltimore, MD, (4)Russell H. Morgan Department of Radiology and Radiological Science, Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK, Baltimore, MD, United Kingdom

**Background:** Altered sensory processing and motor functioning are some of the earliest signs of autism. While the sensory and motor signs of autism have been studied and reported on separately, few studies have investigated how these sensory and motor signs might co-occur in autism. This is perhaps surprising since the development of motor competency is well-known to depend on sensory functioning. Moreover, with increasing evidence of altered excitatory-inhibitory (E-I) balance in cortical and thalamic brain regions, and an important role of E-I in sensorimotor integration, it is of interest whether motor competency in autism is also explained by differences in GABA and glutamate levels.

**Objectives:** We explored associations between low-level tactile perception and motor functioning in autistic children and typically developing controls (TDC), 8-12 years of age. We also conducted exploratory analyses to see whether and how brain GABA and glutamate levels in relevant brain regions contribute to tactile perception and overall motor functioning.

**Methods:** 144 autistic children ( $M_{Age} = 10.39$ ,  $SD_{Age} = 1.35$ ) and 216 neurotypical controls ( $M_{Age} = 10.17$ ,  $SD_{Age} = 1.23$ ) participated in this study. Low-level tactile perception was assessed using a well-established vibrotactile psychophysical battery. Two-alternative force choice staircasing procedures were used to estimate each participant's tactile detection, discrimination and temporal order judgement thresholds. Motor functioning was assessed using the Movement Assessment Battery for Children – Second Edition (MABC-2) and the Physical and Neurological Examination of Subtle Signs (PANESS). A subset of children ( $N_{ASD} = 44$ ,  $N_{TDC} = 58$ ) also underwent edited magnetic resonance spectroscopy (MRS), where GABA+ (GABA + macromolecules) and Glx (glutamate + glutamine) levels of the primary sensorimotor cortex (SM1) and thalamus (Thal) were quantified (~27 ml voxels, 10 min acquisition (320 transients)). Data were analysed using Gannet and metabolite levels expressed as tissue-corrected water-scaled estimates. Due to different acquisition phases with slightly different parameters, data shown are shown as residuals.

**Results:** When collapsing across groups, both static detection and temporal order judgement thresholds were associated with MABC-2 total percentile ranking ( $R = 0.38$ ,  $p < 0.001$ ) and PANESS total ( $R = 0.33$ ,  $p < 0.001$ ) scores. These associations also held at the group-level. See Fig. 1. SM1 GABA+ levels were associated with MABC Total Percentile Rank scores in autism ( $R = 0.54$ ,  $p = 0.002$ ) but not TDCs ( $R = 0.23$ ,  $p = 0.15$ ). See Fig. 2.

**Conclusions:** Our results suggest that low-level tactile perception is associated with motor functioning in both autistic and non-autistic children. Children who were better able to detect and judge the temporal order of tactile stimuli were also those who had higher overall motor functioning. Additionally, the results suggest that motor functioning is associated with SM1 GABA+ levels in autism, a finding that is broadly consistent with the suggestion that motor functioning may be associated with excitatory-inhibitory balance. A limitation of these findings is that they are cross-sectional. Future investigations through a longitudinal design beginning in early childhood would help us better understand how tactile perception (and perception in other domains) relates, and potentially contributes, to motor functioning.

**228.003 (Panel)** Reduced Inhibition of Stimulus Temporal Segregation Associated with Sensory Hyperresponsiveness in ASD  
**T. Atsumi<sup>1</sup>**, M. Ide<sup>1</sup> and Y. Terao<sup>2</sup>, (1)Department of Rehabilitation for Brain Functions, Research Institute of National Rehabilitation Center for Persons with Disabilities, Tokorozawa, Saitama, Japan, (2)Department of Medical Physiology, Faculty of Medicine, Kyorin University, Mitaka, Tokyo, Japan

#### Background:

Individuals with autism spectrum disorder (ASD) often exhibit sensory hyperresponsiveness. Ide et al. (2019) reported individuals with ASD and severe sensory hyperresponsiveness exhibited finer temporal resolution in the temporal order judgment task (TOJ). Our fMRI study on an ASD patient with sensory hyperresponsiveness and ultra-high temporal resolution of TOJ revealed the neural circuit related to the excessive performance (Ide et al., 2020). Using MR spectroscopy, we also demonstrated that individuals with ASD and reduced gamma-aminobutyric acid (GABA) in the part of the circuit for TOJ exhibited increased sensory hyperresponsiveness (Umesawa et al., 2020). Stimulus temporal resolution in TOJ often does not differ from neurotypical controls (Ide et al., 2019), but we have reported the specific condition that task-irrelevant visual stimulus preceding

target stimuli for performing TOJ enhanced the temporal resolution in ASDs (Chakrabarty et al., 2021). We hypothesized that GABA-related E/I imbalance in the neural circuits which regulates stimulus temporal resolution may relate to sensory hyperresponsiveness.

#### Objectives:

We sought to determine whether individual sensory hyperresponsiveness associates with the regulation of temporal resolution (TR) in visual TOJ with multiple task-irrelevant stimuli encouraging perceptual integration. We examined how impairment of TR relates to sensory hyperresponsiveness in adults with ASD.

#### Methods:

Participants observed 4 successive sets of the left and right stimuli of C-shaped line segments. One out of the 4 sets were formed by asynchronous stimuli (target) while the others involved synchronous stimuli (distractors). Twenty-two ASD and 19 typically developed (TD) participants reported which stimulus (L/R) of the target set was presented later. Participants performed the task with observing the two stimuli configured to encourage perceptual grouping or those without that configuration. Such grouping condition with C-shaped line segments might impair TR (just noticeable difference) in TOJ task (Nicol and Shore, 2007). We also evaluated individual sensory hyperresponsiveness by using the Adolescent/Adult Sensory Profile (Brown et al., 2001; Dunn, 1997).

#### Results:

In line with the previous study, the configuration for perceptual grouping worsened the TR of the target set without preceding distractors in ASD and TD groups. Comparisons of the finest TR of all the sets for each participant revealed no difference between ASD and TD groups, but the ASD group showed significant improvement of TR. Reduced effect of the perceptual grouping on the finest TR was associated with enhancement of sensory hyperactivity (Sensory Sensitivity + Sensation Avoiding score) in ASD group.

#### Conclusions:

The present data suggested the reduced inhibitory function for over-processing of successive stimuli resulting in heightened TR of individuals with ASD. We speculate that spatial integration of stimuli may reduce mental loads induced by overflow of sensory information, and its dysfunction would lead to sensory hyperresponsiveness. Further study is necessary to reveal whether neural E/I imbalance affects such regulatory function or temporal processing itself.

#### Background:

Efficient brain function depends on coordinated Excitatory (E) glutamate and Inhibitory (I) GABA signalling. E-I regulation is thought to be altered in autism. However, in living humans, investigation of E-I is constrained by methods which lack temporal resolution (Magnetic Resonance Spectroscopy) or are invasive (Positron Emission Tomography). In contrast, electroencephalography (EEG) has good temporal resolution and is safe.

#### Objectives:

We tested the hypothesis that EEG markers extracted from an auditory oddball paradigm are sensitive to E-I modulation with the GABAB receptor agonist arbaclofen; and whether E-I responsivity (to a pharmacological challenge) is altered in autism. Two types of EEG markers which may capture different aspects of E-I were considered: task-dependent (including event-related potentials (ERPs) and event-related spectral perturbation (ERSP)) response to auditory signals and task-independent (aperiodic 1/f).

#### Methods:

EEG data was available from 66 adults with (n = 38) and without autism (n = 28). Repetitive standard tones (1066 trials) were interrupted with intermittent deviant tones that differed from the standard in terms of frequency (78 trials), duration (78 trials) or both (78 trials). Data were collected following a single dose of either placebo, low (15mg) dose or high (30mg) dose arbaclofen. The order of administration was randomized and double-blind. We looked at latency and amplitude in two ERPs: the P3a (elicited by novelty) and the mismatch negativity (MMN; elicited by the auditory odd-ball paradigm). We then used ERSP analysis to measure dynamic, time-locked changes to theta. Finally, we looked at the aperiodic 1/f exponent which quantifies the arrhythmic activity contained in the power spectrum. Here, spectral densities were extracted from epochs of four standard tones only, and parameterised to quantify aperiodic activity separate from periodic.

#### Results:

ERP: Across groups, there was a significant drug effect on P3a latency to frequency deviants ( $p=0.01$ ); P3a latency after 30mg of arbaclofen was longer than the placebo condition. There was also a significant drug-group interaction ( $p=0.04$ ) in P3a latency to combined deviants: Arbaclofen reduced P3a latency in the non-autistic group ( $p=0.001$ ) only. Arbaclofen had no effect on P3a amplitude, nor MMN amplitude or latency ( $p>0.05$ ). ERSP: There was a significant drug-group interaction in theta power to combined deviants ( $p=0.002$ ): Arbaclofen depressed theta band perturbation

in the autistic group ( $p < 0.001$ ) only.

Aperiodic 1/f: Across groups, there was a significant effect of drug- Aperiodic exponents after 30mg of arbaclofen were larger than those at placebo. There was no significant effect of group ( $p = 0.082$ ) and no significant drug-group interaction ( $p = 0.194$ ).

#### Conclusions:

We provide direct evidence that EEG markers extracted from an auditory oddball paradigm are sensitive to GABAergic drug challenge. Arbaclofen altered task-dependent brain signalling, but the response profile was different in people with and without autism. Arbaclofen also altered task independent E-I signalling, but response was similar in both groups. We discuss how these findings may further knowledge of sensory processing in autism. We consider whether individual responses to pharmacological challenge could help identify individuals who may (or may not) be responsive to this intervention in a clinical setting.

## ORAL SESSION - 3A — BRAIN FUNCTION (FMRI, FCMRI, MRS, EEG, ERP, MEG)

### 303 - Neurodevelopmental Processes Associated with Sensory Functions in ASD

#### 303.001 (Oral) Atypical Integration of Sensory-to-Transmodal Functional Systems Mediates Symptom Severity in Autism

**S. Park<sup>1</sup>**, K. V. Haak<sup>2</sup>, H. B. Cho<sup>1</sup>, M. P. Milham<sup>3</sup>, B. Bernhardt<sup>4</sup>, A. Di Martino<sup>3</sup> and S. J. Hong<sup>1,3,5</sup>, (1)Center for Neuroscience Imaging Research, Institute for Basic Science, Suwon, Korea, Republic of (South), (2)Radboud University Medical Center Nijmegen, Donders Institute for Brain, Cognition and Behaviour, Department of Cognitive Neuroscience, Nijmegen, Netherlands, (3)Child Mind Institute, New York, NY, (4)Neurology and Neurosurgery, Montreal Neurological Institute, Montreal, QC, Canada, (5)Department of Global Biomedical Engineering, Sungkyunkwan University, Suwon, Korea, Republic of (South)

**Background:** Autism spectrum disorder is characterized by co-occurring deficits in low-level sensory processing and high-order social cognition. Despite evidence that suggest cascading effects of sensory abnormalities on the development of high-order transmodal functional systems, only few studies have investigated biological substrates underlying atypical interactions across the cortical hierarchy and how it is associated with ASD symptoms.

**Objectives:** To assess the functional organisation of sensory and motor areas, and their relationship with subcortical and high-order transmodal systems.

**Methods:** We applied connectopic mapping on primary sensory/motor areas, along with targeted seed-based intrinsic functional connectivity (iFC) analyses in a multi-site resting-state fMRI dataset of 107 ASD and 113 neurotypical controls (NT). The connectopic map represents how the functional connectivity between the targeted sensory/motor area and the rest of neocortex vary topographically within the given ROI. We first investigated group differences in these connectopic maps and then further projected the vertex-wise correlations of the gradient clusters showing group differences onto the neocortex to examine differences in whole brain connectivity. For the seed-based connectivity analysis, individual iFC matrices were constructed by correlating the functional time-series across predefined parcels within a hierarchically stratified brain system: (i) within sensory/motor areas, (ii) between sensory/motor and subcortical areas, and (iii) within high-order transmodal areas.

**Results:** We observed robust evidence of atypical functional gradient profiles in primary sensory/motor regions and disrupted macroscale cortical hierarchies that underlie phenotypic symptoms in ASD. Specifically, connectopic mapping showed topological gradient abnormalities (i.e., excessively more segregated iFC) in the motor and visual areas, the former of which was associated with restricted and repetitive behaviors, one of the key symptoms of ASD. Different patterns of cortical projections from regions showing gradient abnormalities indicate an overall atypical functional organization in ASD. Notably, the atypical motor gradient showed stronger connectivity with other low-level sensory areas (i.e., visual and auditory) as well as high-order transmodal areas such as the medial prefrontal cortex in ASD compared to NT. Meanwhile, cortical projections from the peripheral visual gradient to the angular gyrus and orbitofrontal cortex were comparably weaker in ASD (**Figs A, B**). Seed-based iFC analyses revealed mosaic patterns of abnormalities: hypoconnectivity within the low-level and high-order functional networks but hyperconnectivity between subcortical and primary sensory/motor regions. Moreover, the proportion of hypoconnectivity in high-order functional networks tends to increase along the cortical hierarchy, suggesting a less integrated high-order system in ASD (**Figs C, D**). Finally, a series of mediation analyses showed that the association between low-level sensory/motor iFCs and clinical symptoms of ASD was mediated by high-order transmodal systems, suggesting pathogenic functional interactions along the cortical hierarchy (**Fig E**).

**Conclusions:** Together with that the findings were largely replicated in an independent dataset; our results collectively suggest the critical role of atypical integration of sensory-to-high-order systems in the complex ASD symptomatology.

#### 303.002 (Oral) Atypicalities in Salience Network Connectivity at 9 Months Relate to Sensory Sensitivity in Infants with a Family History of Autism

**L. E. Wagner<sup>1</sup>**, M. Banchik<sup>1</sup>, T. Tsang<sup>1</sup>, N. J. Okada<sup>2</sup>, K. K. Cummings<sup>3</sup>, J. Jung<sup>4</sup>, N. M. McDonald<sup>5</sup>, S. Y. Bookheimer<sup>4</sup>, S. A. Green<sup>6</sup> and M. Dapretto<sup>4</sup>, (1)University of California, Los Angeles, Los Angeles, CA, (2)Harvard Medical School, Harvard University, Boston, MA, (3)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (5)UCLA Center for Autism Research and Treatment, Los Angeles, CA, (6)Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA

**Background:** Individuals with Autism Spectrum Disorder (ASD) show atypical connectivity in the Salience Network (SN; Uddin et al., 2013), a functional brain network involved in orienting attention to relevant stimuli (Uddin 2015). In particular, in youth with ASD, sensory over-responsivity

(SOR) is related to hyperconnectivity between the SN and sensory cortices (Green et al., 2016), suggesting that SOR may arise from over-attribution of salience to extraneous sensory stimuli. Previous work in our group has demonstrated differences in SN connectivity with sensorimotor and social regions in infants at high vs. low familial risk for ASD by 6 weeks of age (Tsang et al., 2021). However, it remains unknown whether aberrant SN connectivity persists later in development and how it may relate to early atypical sensory reactivity.

**Objectives:** This study aimed to further characterize early atypicalities in SN connectivity and their relationship to sensory reactivity in infants at high familial risk for ASD.

**Methods:** Sixty-six 9-month-old infants underwent an 8-minute resting-state fMRI scan during natural sleep on a 3T MRI scanner. Participants with an older sibling with an ASD diagnosis were deemed to be at high risk (HR, n=45) for ASD, whereas infants with no familial history of ASD were deemed to be at low risk (LR, n=21). The fMRI data were preprocessed and analyzed with FSL using ICA-AROMA to remove signal components attributable to motion. The right anterior insula – the hub of the salience network – was used in seed-based analyses of SN connectivity across the whole brain. Infants' sensory sensitivity was assessed via parental reports on the Infant Sensory Profile (ISP) at 6 months of age, and the Infant-Toddler Social and Emotional Assessment (ITSEA) at 12 months of age. These sensory sensitivity scores were used as regressors in whole-brain analyses to examine how sensory processing atypicalities related to SN connectivity. Here, we report on regression results involving sensory assessment measure within the HR sample. Since the majority of HR infants are expected to not receive an ASD diagnosis (Ozonoff et al., 2011), subsequent analyses will stratify the entire sample by diagnostic outcome to test for group differences in SN connectivity.

**Results:** Within the HR group, heightened sensory sensitivity on the ISP at 6 months of age was significantly correlated with stronger connectivity between the hub of the SN and bilateral primary auditory and somatosensory cortices, thalamus, and amygdala. Interestingly, greater SN connectivity with left somatosensory and auditory cortices, thalamus, and amygdala at 9 months was also predictive of higher sensory sensitivity scores on the ITSEA at 12 months of age.

**Conclusions:** In HR infants, increased SN connectivity with sensory cortices and subcortical regions was related to heightened sensory sensitivity across the first year of life. These results corroborate and extend our prior findings in 6-week-old infants at high risk for ASD (Tsang et al., 2021). As early as 9 months, prior to autism diagnosis, infants already demonstrate hyperconnectivity in the SN that relates to early sensory sensitivity, which may have downstream effects on later development of core autism symptoms.

### **303.003 (Oral) Resting-State Functional Connectivity of the Sensorimotor Cerebellum in ASD**

**M. E. Cakar<sup>1</sup>, J. Jung<sup>2</sup>, N. J. Okada<sup>3</sup>, K. K. Cummings<sup>4</sup>, G. Patterson<sup>5</sup>, S. Y. Bookheimer<sup>6</sup>, M. Dapretto<sup>2</sup> and S. A. Green<sup>6</sup>,** (1)Interdepartmental Neuroscience Program, University of California, Los Angeles, Los Angeles, CA, (2)Dept of Psychiatry and Biobehavioral Sciences, University of California, Los Angeles, Los Angeles, CA, (3)Harvard Medical School, Harvard University, Boston, MA, (4)The University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)University of Denver, Denver, CO, (6)Dept of Psychiatry and Biobehavioral Sciences, UCLA, Los Angeles, CA

**Background:** The cerebellum is involved in sensorimotor processing and continues to develop through adolescence (Bernard et al. 2015). In youth with autism spectrum disorder (ASD), the cerebellum shows structural and functional atypicalities (Rogers et al., 2013; Khan et al., 2015). Many individuals with ASD have sensory processing differences (Leekam et al. 2007), however, there is limited research on how the sensorimotor cerebellum is functionally connected in the typically developing (TD) brain and how the connectivity is different in ASD vs. TD youth. Furthermore, while subparts of the sensorimotor cerebellum are thought to be associated with different aspects of sensory processing, there is little research on their distinct connectivity patterns.

**Objectives:** To examine resting-state functional connectivity (rsFC) with Lobules I-IV and Lobules V-VI of the sensorimotor cerebellum in TD compared to ASD youth.

**Methods:** We collected functional magnetic resonance imaging (fMRI) data to examine rsFC in 54ASD (16F,38M) and 45TD (12F,33M) children and adolescents (age 8-18). Participants were age- and sex-matched. IQ was significantly different between groups and was included as a covariate in analyses. A whole-brain connectivity analysis was conducted using two sensorimotor cerebellar regions-of-interest (ROIs): lobules I-IV (associated specifically with sensorimotor processing) and lobules V-VI (associated with sensorimotor, visual, and auditory processing) (Khan et al. 2015; Leggio and Olivito, 2018). Results were thresholded at  $z > 2.3$  and cluster corrected for multiple comparisons at  $p > 0.05$ .

**Results:** In examining rsFC across groups and lobules, we found that the sensorimotor cerebellum is functionally connected with a wide-range of regions associated with sensorimotor processing (e.g. precentral gyrus, postcentral gyrus, lingual gyrus, thalamus), as well as the limbic system (i.e. hippocampus, amygdala, cingulate gyrus), basal ganglia (i.e., pallidum) and higher-order cognitive function (e.g. precuneus, temporal pole). Lobules I-IV and V-VI showed distinct connectivity with regions associated with the mesolimbic and limbic systems; and with regions related to sensory and emotion processing, respectively.

The ASD group had higher connectivity than the TD group between Lobules I-IV and visual regions, precuneus, brainstem and cerebellum (Figure 1), and reduced connectivity with auditory-language cortical regions and posterior cingulate gyrus. Lobules V-VI showed similarly increased connectivity with the brainstem and within the cerebellum in ASD, and reduced connectivity with inferior frontal gyrus and precentral gyrus, regions known to play a role in social and motor function, respectively.

**Conclusions:** The sensorimotor cerebellum is functionally connected with brain regions including the basal ganglia, limbic and higher-order cognitive systems as well as sensorimotor areas at rest. In the ASD group, both Lobules I-IV and V-VI show elevated short-range rsFC characterized by connectivity within the cerebellum and with the brainstem. Lobules I-IV showed atypically increased connectivity with visual regions and decreased connectivity with regions associated with higher-order language, social, and regulatory functions. Lobules V-VI showed decreased connectivity with

regions related to motor and social function in the ASD group. Overall, these findings suggest that atypical cerebellar connectivity may play a role in increased sensory reactivity and decreased language, social, and regulatory skills often seen in ASD.

**303.004 (Oral) Relationship between GABA, Glutamate and Social and Sensory Processing in Children with Autism Spectrum Disorder**

**A. Johnson<sup>1</sup>, E. Shankland<sup>2</sup>, T. L. Richards<sup>3</sup>, N. Corrigan<sup>2</sup>, A. M. Estes<sup>3</sup>, T. St. John<sup>2</sup>, S. R. Dager<sup>4</sup> and N. Kleinhans<sup>3</sup>,** (1)University of Washington, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Speech and Hearing Sciences, University of Washington, Seattle, WA, (4)Radiology, University of Washington, Seattle, WA

**Background:** Theories of altered inhibitory/excitatory signaling in autism spectrum disorder (ASD) suggest that gamma amino butyric acid (GABA) and glutamate (Glu) abnormalities may underlie social and sensory challenges in ASD.

**Objectives:** The present study investigated GABA and Glu concentrations in the amygdala and cerebellum, brain regions implicated in ASD, and related them to individual differences in social and sensory processing. We hypothesize that a greater imbalance of the GABA/Glu ratio in the amygdala will be related to olfactory performance and social impairment.

**Methods:** Age- and sex- matched children with ASD (n=51), a clinical control group with sensory abnormalities (SAs) but not ASD (SA;n=50), and children with typical development (TD;n=50) were enrolled. Single-voxel MRS data were acquired from the left amygdala and right cerebellum at two echo times (TE=30 and 80ms) using a MEGA-PRESS pulse sequence (TR 2000, 2048 complex time points, spectral width 2000 Hz, 32 averages, voxel size 30x30x30mm). A similar sequence, with a modification for GABA-editing, was acquired from the same voxel locations (TR/TE 2000/68ms). All participants were assessed using the Social Responsiveness Scale-2 (SRS-2), Autism Diagnostic Interview-Revised (ADI-R), and Autism Diagnostic Observation Scale (ADOS). Individual sensory processing profiles were characterized using the Child Sensory Profile-2 (CSP-2). Odor identification and detection thresholds were evaluated using the University of Pennsylvania Smell Identification Test (UPSIT) and two odorants via Sniffin' Sticks Threshold Test (phenylethyl alcohol, vanillin), respectively.

**Results:** Significantly increased cerebellar Glu levels were observed in ASD compared to TD ( $p<.05$ ). No other significant group differences for GABA or Glu levels were observed in either region of interest. Children with ASD and SAs had more difficulty with odor detection and odor identification than TD children, but did not perform significantly different from each other. Additionally, there were no significant group differences between children with ASD and SAs on parent-reported sensory processing measures (CSP-2). The ASD group demonstrated a negative correlation between the ratio of amygdalar GABA/Glu and vanillin odor detection ( $r=-.519$ ,  $p<.01$ ), while the SA group exhibited a positive correlation between cerebellar GABA/Glu and vanillin odor detection ( $r=.532$ ,  $p<.01$ ). Lastly, a greater imbalance of cerebellar GABA/Glu was correlated with increased social impairment in the ASD group measured using the ADOS-2 Social Affect Calibrated Severity Score ( $r=-.443$ ,  $p<.05$ ).

**Conclusions:** Our results provide insight into ASD-specific relationships between neurotransmission and odor identification and detection impairments. Despite limited phenotypic differences between children with ASD and SA across all measures of sensory processing, behavioral and parent-reported sensory challenges were related to GABA and Glu levels in the amygdala in the ASD group, while these same measures were related to cerebellar GABA and Glu in the SA group. Further, the relationship between a greater imbalance in the ratio of cerebellar GABA/Glu and social impairment appears specific to individuals with ASD. Our findings provide preliminary evidence that an imbalance in excitatory and inhibitory neurotransmission is associated with some clinical features of ASD. These neural markers may also aid in parsing out disorder-specific neurochemical and sensory profiles and subtypes of ASD.

**ORAL SESSION - 9A — BRAIN FUNCTION (FMRI, FCMRI, MRS, EEG, ERP, MEG)**

**315 - Functional Brain Network Variation Across Autism and Related Neurodevelopmental Disorders**

**315.001 (Oral) Cerebellar Functional Connectivity Profiles Are Shared Among Children with Autism Spectrum Disorder and Other Neurodevelopmental Disorders**

**Background:**

The cerebellum plays an integral role in regulating cognitive and affective processes, and its deregulation can lead to behavioural differences (Limperopoulos et al. 2009). For instance, perinatal cerebellar injury bears one of the highest increased likelihoods for development of autism spectrum disorder (ASD) among non-genetic causes (Wang et al. 2014). Symptoms due to cerebellar injury can also reflect behaviours relevant to other neurodevelopmental disorders (NDDs), like attention-deficit hyperactivity disorder (ADHD) (Makris et al. 2015) and obsessive-compulsive disorder (OCD) (Sha et al. 2020).

Investigating shared features of cerebellar functional connectivity (FC) between ASD, other NDDs, and typically developing (TD) children can provide insight into which patterns of cerebellar dysfunction in ASD or ASD subgroups are shared with NDDs.

#### Objectives:

To characterize the extent to which behaviour-correlating patterns of cerebellar FC in ASD are shared among typically developing (TD) children and those with diagnoses of ADHD and OCD.

#### Methods:

913 participants were recruited through the Province of Ontario Neurodevelopmental Disorders Network. 422 passed imaging quality control and had complete scores on the behavioural measurements for attentional problems, social communication, and obsessive-compulsive traits (Figure 1) (142 ADHD, 129 ASD, 86 TD, 45 OCD; 73% male; age =  $12.3 \pm 3.1$  (mean  $\pm$  standard deviation)). Resting-state functional MRI data were collected using T2\*-weighted echo planar imaging with one of two 3-Tesla Siemens scanners. Viewing condition was a movie (pre-upgrade) or Inscapes (post-upgrade) and included as a confounder in the analyses. Pre-processing was performed using FMRIPREP; scans were excluded if framewise displacement  $>0.5\text{mm}$  or DVARS  $>0.5\%$  in more than 1/3 of volumes.

Signal was averaged over regions-of-interest (ROIs) from the Yeo and Buckner et al. functional atlases (2011). FC was quantified per participant using partial correlation matrices from the ROI-averaged signals. Canonical correlation analysis (CCA) was performed to identify maximally correlated components (canonical variates (CV)) of the behavioural and FC data. CVs were probed for statistical stability and significance via bootstrap resampling and multivariate analysis of variance.

#### Results:

$P_{\text{Permutation}} < 0.05$  for the first two CVs (Figure 1). CV-1 (“attentional/social deficit” CV) loading values strongly correlated with CBCL Attentional Problems score and SCQ score, which bore coefficients opposite in sign to TOCS score. CV-2 (“obsessive-compulsive CV”) loading values trended with TOCS score, which had the largest coefficient (Figure 1). White stars denote  $|z| > 1.6$ , where  $z$  is the ratio of coefficient to standard error measured from bootstrap resampling (this heuristically indicates a stable coefficient).

Figure 2 illustrates stable cerebellar-cerebral FC. For the “attention/social deficit” CV,  $|z| > 1.6$  was observed for FC between lobules VI/VII/VIII to right-lateralized dorsal attention, control, and limbic networks. For the “obsessive-compulsive” CV, FC between bilateral posterior cerebellar lobe to bilateral dorsal attention, control, and visual network ROIs bore stable coefficients.

ASD children had large negative CV-1 loadings and comprised 52% of participants below the 5<sup>th</sup> percentile of loading values. TD children were observed to have low loading values across both CVs.

#### Conclusions:

ASD shares features of cerebellar-cerebral FC, largely involving the posterior cerebellum, with ADHD and OCD along orthogonal attentional/social communication deficit and obsessive-compulsive components of behaviour.

**315.002 (Oral)** Using Optimal Classification Trees to Disentangle the Overlap between Autism Spectrum Disorder and Schizophrenia  
**L. Uscatescu<sup>1</sup>, C. Hyatt<sup>2</sup>, M. Kronbichler<sup>3</sup>, V. Calhoun<sup>4</sup>, S. Corbera<sup>5</sup>, K. Pelphey<sup>6</sup>, B. Pittman<sup>7</sup>, G. Pearson<sup>2,7</sup> and M. Assaf<sup>2,7</sup>**, (1)Olin Neuropsychiatry Research Center, Hartford Hospital/Institute of Living/Olin Neuropsychiatry Research Center, Hartford, CT, (2)Olin Neuropsychiatry Research Center, Institute of Living, Hartford, CT, (3)University of Salzburg, Salzburg, Austria, (4)Tri-institutional Center for Translational Research in Neuroimaging and Data Science (TReNDS) Georgia State University, Georgia Institute of Technology, Emory University, Atlanta, GA, (5)Department of Psychological Science, Central Connecticut State University, New Britain, CT, (6)University of Virginia, Charlottesville, VA, (7)Psychiatry, Yale School of Medicine, New Haven, CT

Background: Significant genotypic and phenotypic overlap between Autism Spectrum Disorder (ASD) and Schizophrenia (SZ) has been widely documented. This can hinder accurate diagnosis. Neural excitation/inhibition (E/I) ratio, a parameter indicating the contribution of excitatory and inhibitory synaptic activity, has shown to be impaired in both ASD and SZ, yet no study to date has directly compared E/I ratio between SZ and ASD thus the degree of its overlap and differentiation between the groups is not known. To this extent, E/I can be quantified using the Hurst exponent. Additionally, machine learning approaches can aid in increasing the accuracy of differential diagnosis.

Objectives: We had two main objectives: (1) to quantify group differences in the E/I ratio between HC, ASD and SZ, and (2) to assess the discriminant ability of the E/I ratio, both alone and combined with phenotypic measures, in distinguishing between ASD and SZ.

Methods: We collected resting state fMRI (rsfMRI) data from 55 healthy controls/HC (mean age  $24 \pm 3.73$ ; 29 females), 30 ASD (mean age  $22 \pm 3.74$ ; 5 females), and 39 SZ (mean age  $26 \pm 3.58$ ; 8 females) as well as phenotypic data from both patient groups: the Positive and Negative Syndrome Scale (PANSS), the Autism Diagnostic Observation Schedule module 4 (ADOS-T), the Bermond-Vorst Alexithymia Questionnaire (BVAQ), the Empathizing Quotient (EQ), and the Intelligence Quotient (IQ) based on the Wechsler Adult Intelligence Scale (WAIS-III). We ran independent component analysis (ICA) with Neuromark templates on the rsfMRI data to identify 53 components. On the resulting 53 time-courses

from each participant we subsequently computed the Hurst exponent, an indicator of the E/I ratio. Finally, using Optimal Classification Trees (OCT), we ran a classification analysis on the two clinical groups using five incremental feature sets (i.e., models): (1) PANSS and ADOS only; (2) PANSS; ADOS, BVAQ, EQ and IQ; (3) Hurst only; (4) Hurst plus PANSS and ADOS; (5) Hurst plus PANSS; ADOS, BVAQ, EQ and IQ.

Results: Using ANCOVAs, we observed significant group differences in Hurst exponent of the cerebellum and the Sensorimotor, Visual and Cognitive Control networks ( $F > 3.0$ ,  $p < .05$ ). In all of these areas, there was a persistent decrease in E/I ratio in ASD and SZ compared to HC, with SZ showing the lowest values. OCT analyses showed a consistent increase in classification accuracy over the five models: (1) 50%; (2) 64%; (3) 78%; (4) 78%; and (5) 85%.

Conclusions: Our analyses demonstrated that incorporating the E/I ratio alongside phenotypic data results in the best accuracy when disentangling the overlap between ASD and SZ. Using standardized measures and analysis methods will allow expanding these results to new samples, further clarifying the documented heterogeneity in both SZ and ASD.

### **315.003** (Oral) Challenging Diagnostic Boundaries in ASD, ADHD and OCD Using fMRI Resting-State Networks

Background: Autism spectrum disorder (ASD), attention-deficit/hyperactivity disorder (ADHD), and obsessive-compulsive disorder (OCD) are neurodevelopmental conditions that have distinct behaviour-based diagnostic criteria. However, the behavioural manifestations are highly heterogeneous within disorder and overlap across disorder, supporting trans-diagnostic approaches to studying these conditions. Topographical differences in the brain's functional connectome, particularly differences in the integration and segregation between resting-state networks, have frequently been described in these conditions compared to typically developing (TD) individuals, and there is increasing evidence that these differences are shared across conditions.

Objectives: The objective of this study is to use functional magnetic resonance imaging (fMRI)-derived measures of connectome topography to identify data-driven subgroups. These subgroups may map to underlying biological mechanisms and may better differentiate on their clinical and cognitive characteristics than the current diagnostic labels.

Methods: fMRI resting-state data were acquired on 612 participants (173-ADHD, 250-ASD, 123-TD, 66-OCD; 438-males, 174-females) between 4-19 years of age through the Province of Ontario Neurodevelopmental Disorders (POND) network. Functional connectomes were constructed using parcels that were categorized into eight resting-state networks (visual, somatomotor, dorsal attention, ventral attention/salience, limbic, frontoparietal control, default, and subcortical). Distance matrices were constructed that quantified the dissimilarity of pairs of participants on the integration and segregation of these networks. Similarity Network Fusion was used to fuse the distance matrices from which subgroups were identified using spectral clustering to obtain a solution for a particular set of parameters. This procedure was performed across a wide range of parameters, retaining solutions that were stable across the parameter space. A participant co-assignment matrix was constructed that quantified the probability that pairs of participants were clustered in the same subgroup across the retained solutions, and hierarchical clustering was performed to identify subgroups. To remain agnostic to the number of subgroups identified from the co-assignment matrix, hierarchical clustering was performed to identify subgroups across a range of number of clusters.

Results: The Davies-Bouldin index pointed to four being the optimal number of clusters, and the proportion of each diagnoses did not differ between the clusters. The first cluster was characterized by decreases in IQ and adaptive functioning as well as increases in repetitive behaviours; this contrasted with a second cluster with relatively high performance in these behavioural domains. The third cluster was distinguished by increased repetitive behaviours and obsessive-compulsive traits. Finally, the fourth cluster was comprised of two subgroups that emerged from the hierarchical clustering that differed in their attention abilities. Segregation of the default mode network and integration of the visual, dorsal attention, and subcortical networks were the most significant contributors in determining the subgroups. While the first subgroup demonstrated decreased segregation of the default mode yet increased integration of the visual, dorsal attention, and subcortical networks compared to the remaining subgroups, the third subgroup demonstrated the opposite pattern of segregation and integration, with the remaining subgroups falling in between.

Conclusions: Measures of the brain's functional segregation and integration can be used to identify subgroups of children and adolescents with neurodevelopmental conditions that reflect behavioural differences that span diagnostic boundaries.

### **315.004** (Oral) Neural Correlates of Face Processing in Children with Autism, Fragile X Syndrome, Unaffected Siblings of Children with Autism, and Typical Development

**M. W. Guy<sup>1</sup>**, J. E. Richards<sup>2</sup>, A. L. Hogan<sup>3</sup>, C. J. Black<sup>3</sup> and J. Roberts<sup>3</sup>, (1)Loyola University Chicago, Chicago, IL, (2)University of South Carolina, Columbia, SC, (3)Department of Psychology, University of South Carolina, Columbia, SC

**Background:** Atypical neural responses to face stimuli have been well-documented in children with autism spectrum disorder (ASD). However, much of this research excludes additional participant groups that are also impacted by varying degrees of ASD symptoms. In the current study, we investigated neural correlates of social information processing among children with ASD, as well as children with fragile X syndrome (FXS) and unaffected siblings of children with ASD (ASIBs). FXS is single gene disorder often characterized by intellectual impairment. Approximately 60% of preschoolers with FXS also meet diagnostic criteria for ASD (Roberts et al., 2020). Additionally, ASIBs are often impacted by the broader autism phenotype, in which they display higher rates of subclinical ASD symptoms than observed in the general population (e.g., Ozonoff et al., 2014).

**Objectives:** To examine differences in neural responses to social and non-social stimuli in heterogeneous groups of participants impacted by ASD, including children with ASD, children with FXS, and unaffected ASIBs.

**Methods:** Participants included children with ASD ( $N = 36$ , 35 males, age  $M = 5.6$  years), children with FXS ( $N = 19$ , 13 males, age  $M = 6.2$  years), and non-ASD younger siblings of children with ASD ( $N = 23$ , 16 males, age  $M = 5.5$  years). A group of children with typical development were also included ( $N = 28$ , 23 males, age  $M = 5.2$  years). Event-related potentials (ERPs) were measured in response to photographs of upright and inverted faces and houses. A behavioral support protocol was utilized to promote successful data collection (Guy, Black, et al., 2021). The P1, indicative of stimulus orienting, and N170, reflecting specialized face processing, ERP components were examined.

**Results:** There was a difference in the amount of useable data collected across groups: ASD (trials  $M = 159$ ), FXS (trials  $M = 127$ ), ASIB (trials  $M = 221$ ), TD (trials  $M = 206$ ). As presented in Figure 1, there was a main effect of group on P1 amplitude,  $F(3, 6696) = 37.00, p < .01, \eta^2 = .02$ . As presented in Figure 2, there were main effects of stimulus type,  $F(1, 159) = 6.26, p = .01, \eta^2 = .03$ , and group,  $F(3, 6675) = 90.35, p < .01, \eta^2 = .04$ , on N170 amplitude.

**Conclusions:** Neural responses to face and house stimuli differed across groups at both the P1 and N170 components. Children with FXS demonstrated the greatest amplitude P1 and N170 responses, possibly reflecting hyper-responsivity to the stimuli. The ASIB and TD groups showed similar patterns of responses across both ERP components. Participants in the ASD group showed statistically similar P1 amplitude responses to TD and ASIB participants, however, their N170 amplitude responses were decreased relative to other participant groups. While this may be indicative of atypical face processing in ASD, all groups showed evidence of specialized face processing, based on the main effect of stimulus type at the N170. The results of the current study indicate that heterogeneous participant groups impacted by ASD demonstrate unique patterns of neural responses to visual stimuli.

## POSTER SESSION — BRAIN FUNCTION (fMRI, fCMRI, MRS, EEG, ERP, MEG)

### 416 - Brain Function (fMRI, fCMRI, MRS, EEG, ERP, MEG)

#### 416.040 (Poster) Evaluation of EEG Biomarkers for Angelman Syndrome during Overnight Sleep

N. S. Hosamane<sup>1</sup>, Y. Levin<sup>1</sup>, T. E. McNair<sup>2</sup>, S. S. Kunnam<sup>1</sup>, B. D. Philpot<sup>3</sup>, Z. Fan<sup>4</sup> and M. S. Sidorov<sup>1,5</sup>, (1)Center for Neuroscience Research, Children's National Hospital, Washington, DC, (2)UNC, Chapel Hill, NC, (3)University of North Carolina Chapel Hill, Chapel Hill, NC, (4)Neurology, UNC, Chapel Hill, NC, (5)Pediatrics, George Washington University, Washington, DC

**Background:** Angelman syndrome (AS) is a neurodevelopmental disorder caused by loss of function mutations in the *UBE3A* gene. AS is characterized by intellectual disability, impaired speech and motor skills, epilepsy, and impaired sleep. Multiple treatment strategies to re-express functional *UBE3A* were successful in rodent models of AS and have now moved to early stage clinical trials in children.

**Objectives:** Developing reliable and objective AS biomarkers is essential to guide the design and execution of current and future clinical trials. Our prior work quantified short clinical EEGs to define promising biomarkers for AS. Here, we asked whether overnight sleep is better suited to detect AS EEG biomarkers.

**Methods:** We retrospectively analyzed EEGs from twelve overnight sleep studies from individuals with AS with age and sex-matched Down syndrome and neurotypical controls, focusing on low-frequency (2-4 Hz) delta rhythms and sleep spindles.

**Results:** Delta EEG rhythms were increased in AS during all stages of overnight sleep, but overnight sleep did not provide additional benefit over wake in the ability to detect increased delta. Abnormal sleep spindles were not reliably detected in AS during overnight sleep, suggesting that delta rhythms represent a more reliable EEG biomarker.

**Conclusions:**

Overall, we conclude that periods of wakefulness are sufficient, and perhaps ideal, to quantify delta EEG rhythms for use as AS biomarkers.

#### 416.041 (Poster) Age-Related Changes in Insular Cortical Functional Connectivity in Autism Spectrum Disorder

L. Kupis<sup>1</sup>, N. A. Kathrein<sup>2</sup>, Z. T. Goodman<sup>2</sup>, S. Hoang<sup>3</sup>, L. Kircher<sup>2</sup>, J. S. Nom<sup>3</sup> and L. Q. Uddin<sup>1</sup>, (1)University of California Los Angeles, Los Angeles, CA, (2)University of Miami, South Miami, FL, (3)University of Miami, Coral Gables, FL

**Background:** Insular function is implicated in generally all cognitive processes such as social cognition, attention, speech, language, and executive function (Uddin et al., 2017). This multifaceted cortical region can be further divided into at least three functional subdivisions: a dorsal anterior, ventral anterior, and posterior insula (Deen et al., 2011). Altered functional connectivity of the insular cortices has been demonstrated in autism spectrum disorder (ASD; Nomi et al., 2019) and is linked with several behavioral characteristics of ASD (Green et al., 2016; Neufeld et al., 2018; Uddin et al., 2013). However, little is known regarding insular functional connectivity (FC) changes across development and into adulthood in ASD.

**Objectives:** To characterize age-related differences in insular subdivision FC strength between individuals with ASD and typically developing (TD) individuals from childhood to middle age.

**Methods:** Using a large multi-site resting-state fMRI dataset from the Autism Brain Imaging Data Exchange (ABIDE; 9 sites; 758 participants; TD: N = 405 (mean age: 15 years); ASD: N = 353 (mean age: 15 years); Age: 5-50 years), we investigated age-related differences in insular FC strength between individuals with ASD and TD individuals. The right (R) and left (L) ventral anterior (vAI), dorsal anterior (dAI), and posterior insula (PI) were identified as regions of interest (ROIs; Deen et al., 2011; **Figure 1**). Individual time courses were extracted and averaged across insula voxels for each subdivision. Time courses were correlated with every other cerebral voxel to identify FC strength between insular subdivisions and other brain regions. Linear regression models were used to identify age x group (ASD, TD) interactions of insula functional connectivity strength.

**Results:** An age x group (ASD, TD) interaction revealed that younger individuals with ASD had weaker functional connections with the cerebellum, lateral occipital cortex, and temporal fusiform cortex than typical individuals but older individuals with ASD had stronger functional connections with these same brain areas compared to typical individuals (voxel (uncorrected),  $p < .001$ ; cluster (corrected),  $p < .05$ ; **Figure 2**). Specifically, age-related functional connections that changed with age were observed between the R dAI and the cerebellum and lateral occipital cortex (**Figure 2A and 2B**); the L dAI and the L cerebellum (**Figure 2C**); the R PI and the temporal fusiform cortex (**Figure 2D**); and the L PI and the temporal occipital fusiform cortex, lingual gyrus, and L cerebellum (**Figure 2E and 2F**).

**Conclusions:** In all insula subdivisions examined, the general trend was that functional connectivity with the whole-brain increased with age in ASD and decreased with age in TD. The findings suggest individuals with ASD undergo altered age-related FC with the insula and cerebellum, occipital cortex, and temporal cortex, potentially underlying disturbed sensory integration processing commonly experienced in ASD.

**416.042 (Poster)** Association between the Visual Evoked Potential and autistic symptoms in children with and without Tuberous Sclerosis Complex  
*C. C. Clements<sup>1</sup>, C. L. Wilkinson<sup>2</sup>, L. Gabard-Durnam<sup>3</sup>, C. E. Mukerji<sup>4</sup>, C. Ochi<sup>5</sup>, M. Hartney<sup>6</sup>, C. Hyde<sup>7</sup>, H. Tager-Flusberg<sup>8</sup>, S. Jeste<sup>9</sup> and C. A. Nelson<sup>2</sup>*, (1)Labs of Cognitive Neuroscience, Boston Children's Hospital, Brookline, MA, (2)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA, (3)Pediatrics, Harvard Medical School, Boston, MA, (4)Harvard University, Cambridge, MA, (5)UCSF, San Francisco, CA, (6)Developmental Medicine, Boston Children's Hospital, Boston, MA, (7)Semel Institute, UCLA Medical Center, Los Angeles, CA, (8)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (9)University of California, Los Angeles, Los Angeles, CA

**Background:** Tuberous Sclerosis Complex (TSC) results from mutations in *TSC1* or *TSC2* genes. This leads to increased activation of the mammalian target of rapamycin (mTOR) pathway, which in turn causes benign hamartomas in the brain and also impacts neuronal connectivity and function. Approximately 50% of individuals with TSC meet criteria for Autism Spectrum Disorder (ASD). The neural mechanisms underlying ASD in individuals with TSC remain unknown, despite the known underlying gene and resulting disruptions in neuronal pathways. The Visual Evoked Potential (VEP) is a robust neural response to basic visual stimuli. It reflects integrity of lower-level visual pathways and synaptic efficiency, and atypicalities in basic sensory circuitry (e.g., visual processing) could perturb higher-order complex functions (e.g., social cognition) that rely upon it. The VEP can be measured in infants easily using a reversing checkerboard stimulus and EEG. Varcin et al. (2016) found the 12-month VEP was remarkably intact in a pilot sample of infants with TSC, though individual differences likely exist given findings in 'idiopathic' ASD of the altered P100 component of the VEP. We now present data from 12, 18, 24, and 36 months describing the VEP and autism severity in individuals with and without TSC.

**Objectives:** assess the development of the VEP and its relationship to autism severity in individuals with and without TSC.

**Methods:** Pattern reversal VEP and ADOS-2 data were collected at 12, 18, 24, and 36 months from children with TSC and a comparison sample of typically developing children (Table 1). Most data were cross-sectional, though some children participated at multiple time points. We processed VEP data using the HAPPE pipeline (Gabard-Durham et al., 2018) and visually inspected each waveform for drift and evidence of noise (multiple peaks, no prominent peaks, or severe perturbations to morphology or latency). We conducted multiple regressions to predict ADOS-2 calibrated severity score (CSS) with N1 amplitude, P1 amplitude, and TSC case status, while controlling for sex and number of trials. P-values were adjusted for multiple comparisons using the False Discovery Rate.

**Results:** P1 amplitude was significantly increased in infants with TSC compared to typically developing infants at 12 and 18 months ( $p$ 's  $< 0.05$ ), but not 24 and 36 months. No between-group differences were observed in N1 amplitude at any age. With regard to autism severity, no significant relationship emerged between VEP components and ADOS-2 CSS. Future work will include ASD diagnostic data as well as Mullen Visual Reception and Fine Motor raw scores.

**Conclusions:** The VEP appears atypical in younger infants with TSC but normalizes by two years. Interestingly, this pattern appears to be driven by stability in TSC P1 amplitudes across ages, while the sample without TSC shows increasing P1 amplitude. Analysis of available longitudinal data may elucidate whether this pattern of different developmental trajectories holds at the individual level. The absent relationship between ADOS-2 CSS and VEP amplitude suggests that basic visual processing may remain intact, and social atypicalities may be due instead to perturbations in higher

order neural processes.

**416.043 (Poster)** Attentional Influences on Neural Processing of Biological Motion in Typically Developing Children and Those on the Autism Spectrum

**E. J. Knight<sup>1</sup>**, A. I. Krakowski<sup>2</sup>, J. S. Butler<sup>3</sup>, E. G. Freedman<sup>4</sup>, S. Molholm<sup>5</sup> and J. J. Foxe<sup>1</sup>, (1)Developmental and Behavioral Pediatrics, University of Rochester Medical Center, Rochester, NY, (2)City University of New York, New York, NY, (3)Technological University Dublin, Dublin, Ireland, (4)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY, (5)Albert Einstein College of Medicine, Bronx, NY

---

**Background:** Biological motion imparts rich information related to the movement, actions, intentions and affective state of others, which can provide foundational support for various aspects of social cognition and behavior. Given that atypical social communication and cognition are hallmark symptoms of autism spectrum disorder (ASD), many have theorized that a potential source of this deficit may lie in dysfunctional neural mechanisms of biological motion processing. Indeed, synthesis of existing literature provides some support for biological motion processing deficits in autism spectrum disorder, although high study heterogeneity and inconsistent findings complicate interpretation.

**Objectives:** Here, we attempted to reconcile some of this residual controversy by investigating a possible modulating role for attention in biological motion processing in ASD.

**Methods:** We employed high-density electroencephalographic (EEG) recordings while participants observed point-light displays of upright, inverted and scrambled biological motion under two task conditions to explore spatiotemporal dynamics of intentional and unintentional biological motion processing in children and adolescents with ASD (n=27), comparing them to a control cohort of neurotypical (NT) participants (n=35). In the unattended task condition, participants passively viewed the point-light displays and indicated whether they observed a red or green color change in one of the dots. Next, in the attended condition participants indicated whether the point light displays depicted biological (upright or inverted) or non-biological (scrambled) motion.

**Results:** Behaviorally, ASD participants were able to discriminate biological motion with similar accuracy to NT controls (Unattended:  $d'_{ASD}=1.26\pm.78$ ;  $d'_{NT}=1.53\pm.74$ ; Attended:  $d'_{ASD}=1.05\pm.76$ ;  $d'_{NT}=1.44\pm.77$ ). However, electrophysiologic investigation revealed reduced automatic selective processing of upright biologic vs. scrambled motion stimuli in ASD relative to NT individuals in the P1, N1, and P2 components, which was ameliorated when task demands required explicit attention to biological motion. Additionally, we observed distinctive patterns of covariance between visual potentials evoked by biological motion and functional social ability, such that Vineland Adaptive Behavior Scale-Socialization domain scores were differentially associated with biological motion processing in the N1 ( $F(1,18)=9.343$ ,  $R^2=.342$ ,  $p<.007$ ) and P2 ( $F(1,18)=6.601$ ,  $R^2=.223$ ,  $p<.017$ ) periods in the ASD and NT groups, respectively.

**Conclusions:** Together, these data suggest that individuals with ASD are able to discriminate, with explicit attention, biological from non-biological motion but demonstrate diminished automatic neural specificity for biological motion processing, which may have cascading implications for the development of higher order social cognition.

**416.044 (Poster)** Distinct Habituation Patterns of Auditory Social Attention Associated with Disruptive SCN2A and GRIN2B Mutations

**C. M. Hudac<sup>1</sup>** and N. R. Friedman<sup>2</sup>, (1)Center for Youth Development and Intervention, Department of Psychology, University of Alabama, Seattle, AL, (2)Cincinnati Children's Hospital Medical Center, Cincinnati, AL

---

**Background:** Upwards of 30% of autistic individuals carry a *de novo* copy number or single nucleotide variant associated with ASD (Iossifov et al., 2014), including individuals with a genetic disruption to either *SCN2A* (loss of genetic function, specifically) or *GRIN2B* (Pan et al., 2015; Sanders et al., 2018). Autism spectrum disorder (ASD) is a complex neurodevelopmental disorder with heterogeneity across levels of the genotype and phenotype (Lord et al., 2020) associated with sensory information overload and sensory sensitivities (Wilson et al., 2019). Habituation is the mechanism by which sensory information is filtered at the neural level, and it represents a fundamental, evolutionarily conserved form of learning. Atypical habituation patterns are reported in ASD (Hudac et al., 2018; Vivanti et al., 2018), and may underlie cognitive and behavior hallmarks of both ASD. We anticipate that novelty habituation may be a translational biomarker for preclinical drug screening, objective clinical classification, and stratification of human cohorts.

**Objectives:** Our objective is to examine neural attention responses to nonsocial (e.g., tones) and social information (e.g., speech) in youth with disruptive mutations to *SCN2A* and *GRIN2B*.

**Methods:** Over 40 youth (aged 2-22 years) with a known disruptive mutation to *SCN2A* and *GRIN2B* enrolled in the BioGENE study completed mobile electroencephalography (EEG) at off-site locations (participant's home, local hotel room). Preliminary analyses include 14 *SCN2A* and 4 *GRIN2B* youth aged 2-19 years. Two passive auditory oddball EEG experiments measured attention and speed of habituation to (1) nonsocial information (Hudac et al., 2018) and (2) consonant-vowel speech information. Here, we focus on the within-category response differentiation of the P3a (100-350ms). Linear mixed-effects analyses with random effects [R lme() package] tested experiment differences (nonsocial vs social) in condition (i.e., deviant noises vs. frequent/repeated tone or speech) and habituation (i.e., the reduction rate of N1 amplitude).

**Results:** Both *SCN2A* and *GRIN2B* groups exhibited a P3a effect (novel relative to frequent sounds) for both experiments,  $F's>3.71$ ,  $p's<.011$ , however, larger P3a effects were observed for *GRIN2B* ( $p<.001$ ) relative to *SCN2A* ( $p=.06$ ). In addition, the *GRIN2B* group was sensitive to experimental context with larger P3a effects for nonsocial relative to social sounds,  $F(1,512)=10.11$ ,  $p=.002$ . Lastly, a trend indicates potential habituation differences between groups,  $p=.07$ .

**Conclusions:** Group differences in auditory attention may implicate distinct underlying mechanisms of ASD for SCN2A and GRIN2B. For one, the GRIN2B differentiated between social and nonsocial sounds, albeit with an atypical pattern than one may expect from a neurotypical population. Further work to understand individual difference factors associated with auditory attention, such as sex, age, cognition, and ASD severity, will be helpful in clarifying the specificity of this potential biomarker.

**416.045 (Poster)** EEG Frequency Tagging Evidence of Intact Social Interaction Recognition in Adults with Autism

**D. Oomen**<sup>1,2</sup>, **E. Cracco**<sup>1,2</sup>, **M. Brass**<sup>2,3,4</sup> and **J. R. Wiersma**<sup>1,2</sup>, (1)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)Research group EXPLORA, Ghent University, Ghent, Belgium, (3)Berlin School of Mind and Brain, Department of Psychology, Humboldt-Universität zu Berlin, Berlin, Germany, (4)Department of Experimental Psychology, Ghent University, Ghent, Belgium

---

**Background:** To explain the social deficiencies in autism, a large amount of research has been conducted on the neural correlates of social stimuli processing. This research typically uses simple stimuli such as a single agent or body parts such as eyes, faces or hands. Although these simple stimuli provide great experimental control, there is a trade-off with ecological validity. That is, simple social stimuli have the disadvantage of not resembling the complexity of what we encounter in our daily social lives, and as such, the situations people with autism experience difficulties in. This might be the reason why these studies found mixed results so far. Perhaps, anomalies only occur when processing more complex social stimuli that require complex cognitive processes. A particularly relevant process in this respect is the recognition of third-party social interactions, as it is both highly relevant in social life and requires advanced processing. In a previous study, we used EEG frequency tagging to investigate how neurotypical individuals infer social interaction from contextual information. The results revealed increased neural responses over lateral posterior electrodes to social scenes depicting a social interaction than to social scenes not depicting a social interaction.

**Objectives:** To further our understanding of social interaction difficulties in autism, we compared social interaction recognition in adults with and without autism using EEG frequency tagging. We expected to replicate the enhanced response to social interaction scenes in the control group. Importantly, we also expected this effect to be diminished in the autism group.

**Methods:** We administered the EEG frequency tagging task to 24 adults with autism<sup>1</sup>, and a gender- and age-matched group without any diagnoses ( $n = 22$ ). The task included four types of stimuli: images that depict rich social scenes with social interaction, images that depict rich social scenes with no social interaction, and the scrambled versions of both image types (See figure 1). The study design and analyses for this study were pre-registered.

**Results:** Contrary to our expectations, a repeated measures ANOVA revealed an enhanced response to social scenes with social interaction compared to social scenes without social interaction in *both* groups, with no difference between them.

**Conclusions:** We found an enhanced response to social scenes with social interaction, replicating our previous findings. However, this effect was not diminished in adults with autism. This suggests that the process of inferring social interaction from context using static images is not anomalous in adults with autism, and cannot explain the social difficulties adults with autism experience.

<sup>1</sup>We are aware of the ongoing person-first versus identity-first debate. We acknowledge and respect different preferences for language used to refer to a person with a diagnosis of autism spectrum disorder. Our choice of person-first language was based on the preference of our Dutch-speaking autism group.

---

**Background:** Biological motion perception supports successful social function as it allows us to identify social conspecifics in our environments. Because social perception is thought to be different in ASD, biological motion perception has been the topic of much eye-tracking and neuroimaging research, with studies indicating reduced attention or reduced activation to biologically relevant information in ASD. However, there is limited understanding of the neural time course of biological motion perception in ASD. This early activity likely reflects mechanisms guiding how eye-movements are deployed in the environment and represents a meaningful inflection point for understanding differences in social attention.

**Objectives:** Our goals were to (1) use novel functional data analytic methods to characterize brain response to biological motion in participants with ASD and (2) assess whether brain activity to biological motion differed between participants with ASD and a neurotypical (NT) comparison sample.

**Methods:** Data were collected as part of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT); a multisite, naturalistic study of 6-11 year-old children with ASD and NT. Clinical characterization was thorough and included measures of cognitive ability (Differential Ability Scales — DAS-II), ASD symptomology (Autism Diagnostic Observation Schedule — ADOS) and adaptive behavior, (Vineland Adaptive Behavior Scales — VABS3). ERP data were collected (ASD  $n=213$ ; NT  $n=113$ ) using a high-density electrode montage while participants viewed one-second segments of point light animations depicting either humans walking (biological motion) or phase scrambled comparison stimuli (scrambled motion).

Segmented and averaged ERPs for all participants were then processed to estimate principle ERPs (pERP)s. pERPs are a set of maximally independent basis functions, or waveform shapes, shared among all participants, which represent the time courses of distinct sources of neural activity. Subsequent analyses were conducted on individual pERP scores, which represent the activation of a specific neural source for a given participant and experimental condition.

**Results:** Six pERPs were sufficient to explain >80% of the variance in the sample. Of these six, two pERPs showed significantly different activation between biological and scrambled motion at occipitotemporal sites. The first pERP was most prominent at ~200ms ( $t = 4.1$ ,  $p < .05$ ) whereas the second spanned the entire time course ( $t = 2.5$ ,  $p < .05$ ). These pERPs indicated that scrambled motion, relative to biological motion, elicited greater neural activity across all participants. However, an interaction with diagnostic group revealed that NT individuals, relative to ASD, showed increased differentiation between biological and scrambled motion at the pERP impacting activity in the 200ms range ( $t = 2.3$ ,  $p < .05$ ).

**Conclusions:** These data show that biological motion is differentiated from non-biological motion in brain as early as <300ms. This time course is commensurate with facilitating the deployment of eye-movements to socially relevant information in the environment. Individuals with ASD showed reduced neural specialization in this early time range. This finding suggests that reports of reduced attention to biological motion in ASD may be evident in the first milliseconds of perception. Ongoing analyses evaluate whether these patterns of neural activity can explain heterogeneity in clinical presentation or patterns of attention to social information.

#### **416.047 (Poster)** Infant/Toddler Trajectories of Amygdala Development Are Associated with Later ASD Diagnosis and School-Age Anxiety in a Familial High-Risk for ASD Sample

**Background:** Children with autism spectrum disorder (ASD) are at an increased risk for other co-occurring behavioral and mental health problems, including anxiety disorders (Leyfer et al., 2006; Simonoff et al., 2008; Sukhodolsky et al., 2007). Siblings of children with ASD also show increased rates of anxiety, particularly in middle childhood (Shivers, Deisenroth, & Taylor, 2013), making high-risk sibling samples ideally suited to identify precursors of anxiety in ASD. The amygdala is involved in emotion processing and fear regulation (Pine, 2008), and has been implicated in both ASD and anxiety (Amaral, Bauman & Schumann, 2003; Kilgore & Yurgelun-Todd, 2005). No study to date has investigated how amygdala growth in infancy is related to later anxiety symptoms in a sample at high-risk for ASD.

#### **Objectives:**

Examine whether growth trajectories in amygdala volume from 6 to 24 months differ based on later ASD and anxiety outcomes.

#### **Methods:**

This study prospectively examined infants at high- and low-familial-risk (HR, LR) for ASD at 6, 12 and 24 months of age and at one visit during school age (7 to 11 years). Clinical best estimate diagnosis of ASD or no-ASD was made at 24 months. Participants were further classified as having clinically significant symptoms of anxiety or not at school age, based on cutoffs (T-score>65) on the Child Behavior Checklist (CBCL; Achenbach, 1999). This resulted in 4 groups: ASD+anxiety (N=11; 24 developmental samples); ASD only (N=14; 33 developmental samples); Anxiety only (N=19; 45 developmental samples); No ASD or anxiety (N=112; 275 developmental samples). Participants underwent structural MRI scans at 6, 12 and 24 months. Pre-processing included registration to an age-specific multi-atlas, and multi-modality based quantification of amygdala volume. Multi-level models examined trajectories of amygdala volume from 6 to 24 months as predicted by the main effects and interactions between age at imaging, later ASD diagnosis, and school-age anxiety symptoms, controlling for sex and total brain volume at each imaging timepoint.

**Results:** Growth trajectory of the left amygdala in the first 2 years of life was associated with ASD diagnosis ( $t=2.709$ ,  $p=.007$ ) and elevated anxiety symptoms ( $t=4.014$ ,  $p<.001$ ; Figure 1). Both the presence of later ASD diagnosis and anxiety symptoms were associated with increased growth trajectories of amygdala volume over time, but the interaction between the two was not significant. Results were similar in the right amygdala, but left amygdala is presented for ease of interpretation.

**Conclusions:** Amygdala growth differed by presence of later ASD diagnosis and anxiety symptoms, and may serve as an early marker of impaired social and emotional processing. The lack of a significant interaction indicates that the association between early amygdala development and later anxiety symptoms is comparable in children with and without ASD. Understanding early predictors may help identify those most at risk for developing each condition and inform the search for potential intervention targets.

#### **416.048 (Poster)** Late Positive Potential to Emotional Faces in Young Children with Autism: Associations with Sex and Reciprocal Social Interaction

**Background:** Difficulties with emotional face processing have been well-established in the autism spectrum disorder (ASD) literature (Lozier et al., 2014), with electroencephalogram (EEG) research focusing on early-stage perceptual processing using the N170 event-related potential (Kang et al., 2017). The field has begun to examine late positive potential (LPP), which indexes sustained attention to emotional stimuli and elaborative processing at later stages, lending insight into heterogeneity across ASD (Keifer et al., 2019). In autistic adults, ASD symptoms are positively associated with heightened LPP in response to subtler emotional faces, suggesting increased attention due to difficulty with processing (Keifer et al., 2019). Conversely, no significant associations were reported between LPP and ASD symptoms in adolescents (Benning et al., 2016). However, LPP has not yet been examined in younger autistic children. Although sex differences have not been established in ASD, literature in typically-developing (TD) populations suggests larger LPP amplitudes in females than males (Yu et al., 2020; Kato & Takeda, 2017). Examining the effects of ASD symptoms and sex on LPP in this younger developmental period may be an important next step to understanding differences in late-stage emotion processing in ASD.

**Objectives:** We examined the relationship between ASD symptoms and LPP in response to emotional faces in autistic and TD children. We hypothesized that greater ASD symptoms would relate to heightened LPP. We explored potential sex differences in LPP amplitudes.

**Methods:** Eighty participants (N = 45 ASD, 75% male,  $M_{age}=7.94$ ,  $SD_{age}=1.84$ ;  $M_{IQ}=106$ ) participated in this study. Parents completed a measure of autism symptoms (SCQ; Rutter et al., 2003). LPP was indexed from parietal sites during a non-verbal awareness task with cartoon faces with varying emotions. Independent samples *t*-tests were first conducted to examine group differences in LPP, followed by Pearson and point-biserial correlations. Hierarchical linear regressions were conducted to examine the predictive relationships of ASD symptoms or sex on LPP.

**Results:** T-tests revealed no differences in LPP between TD and ASD groups ( $p>.307$ ). However, among ASD children, SCQ Total and Reciprocal Social Interaction subscale were correlated positively with parietal LPP and differed by sex. LPP also differed by sex (Table 1). SCQ predicted heightened LPP above and beyond sex. Upon probing, this effect was more pronounced in the SCQ reciprocal social interaction subscale (Table 2).

**Conclusions:** This is the first study in ASD to examine LPP in childhood. Similar to adults (Keifer et al., 2019), LPP did not differ between ASD and TD children. However, within ASD children, results suggest autistic girls than boys may pay more sustained attention during late-stage emotional processing, similar to TD populations (Yu et al., 2020; Kato & Takeda, 2017). Above and beyond sex, higher levels of ASD symptoms, specifically in the reciprocal social interaction subdomain, may relate to requiring more attentional neural resources to late-stage emotional processing (Keifer et al., 2019). These findings provide insight into developmental trends and specific ASD symptom associations with emotional face processing and can aid in the development of treatments targeting emotional processing in children with ASD.

**416.049 (Poster)** Modulation of the Face-Sensitive N170 Event-Related Potential By Emotional Expression and Visual Attention in Adults with Autism, Schizophrenia, and a Non-Clinical Comparison Group

G. T. Han<sup>1</sup>, A. Naples<sup>1</sup>, J. M. Wolf<sup>1</sup>, J. H. Foss-Feig<sup>2</sup>, V. Srihari<sup>3</sup>, A. Anticevic<sup>4</sup> and J. McPartland<sup>5</sup>, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Program for Specialized Treatment Early in Psychosis (STEP), Department of Psychiatry, Yale University School of Medicine, New Haven, CT, (4)Division of Neurocognition, Neurocomputation, and Neurogenetics (N3), Yale University School of Medicine, New Haven, CT, (5)Child Study Center, Yale Child Study Center, New Haven, CT

---

**Background:** Compared to non-clinical (NC) samples, individuals with autism (ASD) and schizophrenia (SZ) spectrum disorder exhibit atypical brain responses to faces as quantified by the N170, a face-sensitive event-related potential. Features of the N170, such as amplitude and latency, may also relate to emotional valence and patterns of visual attention to faces. Investigations of how neural processing of faces relates to emotional valence and/or visual attention are needed to elucidate processes underlying social difficulties in ASD and SZ.

**Objectives:** Examine relations among emotional valence, visual attention, and neural response to faces in a transdiagnostic sample of ASD, SZ, and NC individuals.

**Methods:** Participants were adults aged 18-35 years (ASD n=28; SZ n=24; NC n=40) with confirmed diagnoses via standardized tools and expert clinician assessment. A novel gaze-contingent and interactive face processing paradigm with co-registration of electroencephalography and eye tracking was used to examine both neural response and visual attention during face viewing. Participants were presented with a fixation cue followed by a neutral face with a direct gaze. Contingent upon gaze to the eyes of the neutral face, the stimulus changed to either a happy or fearful face. Visual attention was defined as percentage of time looking (%looking) to the face and was logit transformed to accommodate distributional assumptions for statistical analyses. Neural response was approximated by N170 peak amplitude and latency extracted from electrodes over right occipitotemporal scalp. Separate linear mixed effects models were conducted to assess the main and interactive effects of diagnostic group, face valence, and %looking on N170 amplitude and latency. Models included the three-way Diagnosis (ASD, SZ, NC) x Emotion (happy, fearful) x Visual Attention (%looking) interaction and all lower order effects.

**Results:** For N170 amplitude, significant effects included the main effects of Diagnosis [ $F(2, 89)=3.51$ ,  $p=0.03$ ] and Emotion [ $F(2, 89)=7.87$ ,  $p<0.01$ ], and the Diagnosis x Emotion x Visual Attention interaction [ $F(2, 89)=10.84$ ,  $p<0.001$ ]. Irrespective of valence and %looking, ASD exhibited reduced N170 amplitude compared to SZ [ $t(83)=-2.10$ ,  $p=0.04$ ] and NC [ $t(83)=-1.98$ ,  $p=0.05$ ]. Greater amplitude was observed for happy [ $M(SE)=-5.44(0.28)$ ] compared to fearful [ $M(SE)=-4.64(0.29)$ ] faces [ $t(83)=4.78$ ,  $p<0.001$ ]. The significant three-way interaction indicated different relationships between %looking and N170 amplitude based on diagnostic group and valence. Specifically for happy faces, there was a positive

association between %looking and amplitude in NC that was not evident in ASD and SZ. For fearful faces, more %looking was positively associated with N170 amplitude across all groups. With N170 latency as the outcome variable, only the main effect of Emotion [ $F(1, 83)=21.2, p<0.01$ ] was significant: slower latencies were observed in response to fearful faces [difference=10.80ms,  $t(83)=4.83, p<0.001$ ].

**Conclusions:** Findings demonstrate the importance of considering both valence and visual attention to faces to clarify mixed findings regarding atypical neural response to faces reported in the ASD and SZ literatures. Between-group differences in the association between visual attention and neural response in happy but not fearful faces suggests shared aberrations in early perceptual processing of particularly prosocial information in ASD and SZ that may underly reduced social approach and/or downstream social difficulties.

**416.050 (Poster) Neurocomputational Mechanisms of Social Decision-Making Impairments in Autism Spectrum Disorder**

**S. M. Banker<sup>1</sup>, S. Na<sup>1</sup>, M. Schafer<sup>1</sup>, S. Barkley<sup>2</sup>, J. Trayvick<sup>1</sup>, C. McLaughlin<sup>3</sup>, E. Isenstein<sup>4</sup>, S. B. Guillory<sup>3</sup>, X. Gu<sup>1</sup>, D. Schiller<sup>1</sup> and J. H. Foss-Feig<sup>3</sup>,**  
(1)Department of Neuroscience, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Seaver Autism Center at the Icahn School of Medicine at Mount Sinai, New York, NY, (4)University of Rochester, Rochester, NY

---

**Background:**

Autism Spectrum Disorders (ASDs) are characterized by impairments in social functioning as well as repetitive behaviors and restricted interests. Perhaps due to deficits in socioemotional reciprocity, individuals with ASD are thought to show alterations in social decision-making. Despite the multitude of neuroimaging studies investigating social dysfunction in ASD, the neural underpinnings of these social impairments remain poorly understood. Prior research is largely limited by the use of passive paradigms (e.g. face perception, emotion recognition) rather than ecologically-relevant, proactive social tasks more akin to the type of interactions with which people with ASD struggle daily.

**Objectives:**

By utilizing tasks that probe dynamic and naturalistic aspects of social decision-making in combination with 7T functional magnetic resonance imaging (fMRI), this study takes an innovative computational psychiatry approach to understanding the neural underpinnings of social deficits in ASD. We hope that by better characterizing impairments in specific aspects of social interaction, both behaviorally and in the brain, we can gain a fuller understanding of the mechanisms involved and inform the development of future interventions.

**Methods:**

In conjunction with fMRI, ASD participants (n=12; mean age: 25.3, age range: 18.1-35.7; 75% male) completed the ultimatum game, a neuroeconomic task in which they accepted or rejected proposed monetary offers from virtual partners. Participants also completed a choose-your-own-adventure game in which they simulated interactions with virtual characters. In this game, each interaction shifted a given character's position in a behind-the-scenes plot of 'social space' framed by axes of social hierarchy and affiliation. Computational modeling approaches extracted parameters of interest based on the trajectory of decision-making in each task. General linear models with parametrically modulated regressors assessed activity in several brain regions in association with model-derived task behavior.

**Results:**

In the ultimatum game, ASD patients showed higher initial offer expectations ( $p=0.03$ ) and impairments in norm adaptation speeds (the degree of offer expectation adjustment based on observations;  $p<0.001$ ) than have been previously reported in typically-developing (TD) individuals (n=45). Neurally, individuals with ASD did not show the encoding of norm prediction errors (the difference between the expected and actual offers) in the anterior insula that is typically present in TD individuals. In the choose-your-own-adventure game, reduced social consistency (more varied character trajectories) was associated with increased ASD symptoms (ADOS;  $p<0.05$ ). Neurally, individuals with ASD did not show hippocampal encoding of the angles of the vectors drawn between the participant's point of view and the characters' locations in social space (which typically represents intact tracking of relationships) that has been previously described in TD individuals. Within the ASD group, this decreased hippocampal encoding was associated with impaired social affect (ADOS;  $p<0.05$ ) and decreased prosocial motivation (EmQue,  $p<0.05$ ).

**Conclusions:**

Together, these results suggest that individuals with ASD show altered social decision-making and do not utilize neural circuits known to support social decision-making to the same extent as TD individuals. Additionally, the observed alterations in both social behavior and neural encoding of social information were associated with increased ASD symptoms, suggesting these results hold clinical relevance.

**416.051 (Poster) Neurophysiological Correlates of the Sensory Gating Inventory in Adults with Autism Spectrum Disorders**

**J. E. Crasta, Physical Medicine and Rehabilitation, The Ohio State University, Baltimore, MD**

---

**Background:** Adults with autism spectrum disorders (ASD) show significant and persistent sensory symptoms. A common sensory symptom in ASD includes impairments in filtering out redundant sensory information, referred to as sensory gating. The paired-click electroencephalography (EEG) paradigm is widely used to examine neural sensory gating.

**Objectives:** This study examined perceptual abnormalities associated with sensory gating using the self-report Sensory Gating Inventory (SGI) and its relationship to event-related potential (ERP) measures from the paired-click EEG paradigm in young adults with and without ASD.

**Methods:** Twenty-four young adults with ASD (range: 18 – 30 years, Mean: 23.3 years) and 24 age-matched neurotypical adults completed the SGI. The SGI is a 36-item self-report questionnaire of perceptual anomalies related to sensory gating. The questionnaire yields 4 factors: Perceptual Modulation (16 items), Distractibility (8 items), Over-Inclusion (7 items), and Fatigue-Stress Vulnerability (5 items). A higher score indicates greater sensory symptoms. EEG data were recorded during the auditory paired-click paradigm wherein participants heard repeated presentations of 80 pairs of click sounds. Each click was 3 ms in length with a 500 ms stimulus onset asynchrony between clicks and an 8-second inter-trial interval between pairs. The study's primary ERP measures included the P50 and N1 amplitude and latency and difference score (Click 2 – Click 1). Group differences on the SGI and ERP measures were examined using univariate analysis of variance and effect sizes are reported using Cohen's *d*. We used Pearson's correlation to examine the relationship between SGI and ERP measures.

**Results:** Compared to controls, adults with ASD had significantly higher scores on all 4 factors of the SGI, Perceptual Modulation ( $d=1.5, p<.0001$ ), Distractibility ( $d=1.3, p<.0001$ ), Over-Inclusion ( $d=1.5, p<.0001$ ), and Fatigue-Stress Vulnerability ( $d=.71, p=.017$ ), as well as the SGI total score ( $d=1.4, p<.0001$ ). On the paired-click EEG paradigm, there was no significant group difference on P50 and N1 amplitudes of Click 1 or 2, and difference scores. There were no group differences on the P50 latencies of either click. However, the ASD group showed significantly delayed N1 latencies of click 1 ( $d=.90, p=.003$ ) and click 2 ( $d=.73, p=.017$ ) compared to controls. Across all participants, there was a positive relationship between click 2 N1 latency and SGI total score ( $r=.32, p=.034$ ), such that longer N1 latencies were associated with greater perceptual sensory gating anomalies.

**Conclusions:** Our results indicate that young adults with ASD show significant perceptual anomalies related to sensory gating. The SGI may serve as an informative tool to assess sensory and perceptual functioning in adults with ASD. While adults with ASD show robust neural sensory gating at the P50 and N1 components, they show delayed processing of simple auditory sounds. Delayed auditory processing has been proposed as a biomarker for ASD, and our results show that longer N1 latencies are associated with greater behavioral sensory gating deficits. These findings support a growing body of literature investigating the clinical correlates of atypical neurophysiologic responses in adults with ASD.

**416.052 (Poster)** Novel Unsupervised Machine Learning Approaches for Understanding Sleep EEG Brain State Dynamics in Rett Syndrome  
**C. Huang<sup>1,2</sup>, A. Mahaf<sup>3,4</sup>, D. G. Glaze<sup>3,4</sup>, M. Maletic-Savatic<sup>1,2,3</sup>, A. Buckley<sup>5</sup> and M. McGinley<sup>1,2,6</sup>**, (1)Neuroscience, Baylor College of Medicine, Houston, TX, (2)Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX, (3)Pediatrics-Neurology, Baylor College of Medicine, Houston, TX, (4)Neurology, Texas Children's Hospital, Houston, TX, (5)National Institute of Mental Health, Bethesda, MD, (6)Electrical and Computer Engineering, Rice University, Houston, TX

**Background:**

Brain activity during sleep is highly dynamic. Conventional description of the sleep process in neurotypical subjects relies on manual scoring of the sleep polysomnography (PSG) into 5 stages (Wake, rapid eye movement (REM), and Non-REM 1-3). These stages represent predictable and discrete transitions of state and reflect various combinations of underlying neurotransmitter influences. However, sleep brain state dynamics may be so significantly altered in developmental brain disorders (DBD), such as Rett syndrome, that the conventional PSG approach may provide an inaccurate and incomplete model. Redefining this altered ultradian rhythm offers insight into underlying neuropathology in DBD.

**Objectives:**

Here we used a Hidden Markov Model (HMM) approach to describe brain activity during sleep as continuous transitions between quasi-stable brain states. We compared differences between the inferred states from healthy subjects and the states from Rett syndrome patients. To validate the model, for a given holdout segment of unlabeled EEG signals, the models trained from healthy and Rett groups were used to predict which group the EEG signals were from.

**Methods:** 51 healthy children (age:  $8.3\pm4.7$  years) and 38 Rett syndrome girls (age:  $11.6\pm5.4$  years) participated in the study. For each subject, we obtained 5-channel (Fp1, F7, C4, O1, T4) electroencephalogram (EEG) and a single lead of chin EMG signals. As the model input, we extracted power spectrum from seven frequency bands (in Hz): slow (0.5–1.5) and fast (1.5–4) delta; slow (4–6) and fast (6–8) theta; alpha (8–12); slow (12–14) and fast (14–16) sigma. Additional features were signal root mean squared (RMS) and per-channel sample entropy and the EMG RMS. We then employed multivariate Gaussian HMM to infer the hidden states, including initial states probability, the state first (mean activity) and second order statistics (covariance matrix), and states transition probabilities.

**Results:**

For control group, 20 inferred states described the sleep EEG statistics well. Some states were highly specific to a PSG stage, while some states appeared to reflect within-state microstructure and apparently novel cross-stage states not captured by conventional PSG staging. The transition matrix showed the patterns of switching between states. For the Rett group, the number of inferred states varied between individuals. No states were highly specific to the REM stage. We observed a high probability of transitioning from NREM-associated states to wake-associated states, which rarely occurred in the control group. The leave-one-out validation showed high accuracy rate when predicting whether a subject is from the healthy group (sensitivity: 96%, precision: 91%) or the Rett syndrome group (sensitivity: 87%, precision: 94%).

**Conclusions:**

Altered sleep-state generation and rhythms, as uncovered here in the proposed HMM framework, can help define brain state pathology in Rett syndrome, such as rapid cycling between states, heterogeneities of state architecture within the Rett group, and important differences between the control and Rett groups. This approach holds promise for diagnosis as well as evaluation of treatment efficacy, particularly when treatments aim to alter early developmental neuromodulatory brain state aberrancies in DBDs.

**416.053 (Poster)** Physical Disgust Processing in Children with Autism Spectrum Disorder (ASD) during Observation of Rotten Foods

**A. Jayashankar<sup>1,2</sup>, E. Kilroy<sup>1,2</sup>, S. Ringold<sup>1,2</sup>, R. W. McGuire<sup>1,2</sup> and L. Aziz-Zadeh<sup>1,3</sup>**, (1)Brain and Creativity Institute, Dornsife College of Letters, Arts and Sciences, University of Southern California, Los Angeles, CA, (2)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (3)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, USC, Los Angeles, CA

---

**Background:** Proper processing of disgust, a primary emotion, is necessary for (i) perception and labelling of stimuli as harmful, (ii) preparing an adequate avoidant or adaptive response to stimuli, and (iii) regulating stress and behavior produced from the experience of disgust. However, children with autism may display difficulties with identifying potentially noxious stimuli and making appropriate withdrawal responses. Aberrant disgust processing in children with ASD may be linked with these issues and could influence inappropriate behavior, like pica.

**Objectives:** Aims included: i) Identifying neural differences associated with disgust processing in youths with ASD during an fMRI food observation task; ii) Characterizing the factors influencing the neural activity during the fMRI task.

**Methods:** Data from 12 participants with ASD (ages 8-16, mean=12.49 ± 2.48) and 14 TD participants (ages 8-17, mean=11.97 ± 1.86) were analyzed. Assessments included: a) Disgust Sensitivity Questionnaire for Children (DSQ-C); b) Body Perception Questionnaire Very Short Form (BPQ-VSF); and c) Sensory Over-Responsivity Inventory (SenSOR). fMRI data was collected while participants observed pictures of disgusting foods (i.e., rotten foods) presented in a block design and analyzed using a standard preprocessing pipeline on FSL. Whole brain comparisons between groups were completed using FSL's FEAT function controlling for age, sex and IQ. Parameter estimates from spherical ROIs in the left and right anterior insula (AI), were extracted. Spearman's correlations and linear regression were used to assess the association between AI activity when observing disgusting foods with food-related disgust above and beyond associations with interoception and sensory overresponsivity.

**Results:** Whole brain comparisons revealed hypoactivity in the left ventral AI for the ASD group compared to TD when viewing disgusting foods ( $Z > 2.3$ , uncorrected). AI activity across groups was significantly positively correlated with disgust sensitivity (DS;  $R = 0.451$ ,  $p = 0.021$ ) and interoceptive ability (BPQ;  $R = 0.445$ ,  $p = 0.023$ ). Stepwise regression between AI activity and DSQ-C while including BPQ and demographic factors (age, IQ, gender) as covariates, indicated that only DS continued to be significantly associated with insula activity ( $p = 0.014$ ). Within-group analysis revealed that this association was driven by the TD group where the association was also significant ( $R = 0.707$ ,  $p = 0.017$ ). However, in the ASD group, there was no significant association ( $R = 0.176$ ,  $p > 0.05$ ). Using prediction models, we identified that only within the ASD group, insula activity towards disgusting foods is strongly influenced by participant age ( $R = 0.741$ ,  $p = 0.004$ ).

**Conclusions:** Our initial findings of insula hypoactivity in the ASD group during the observation of rotten foods (which elicits physical disgust) supports the hypothesis that poor insula activity associated with disgust processing could be a factor in difficulties with contamination and food-related behavior. We also found that AI activity during this task was driven by DS significantly more than interoception or sensory processing. Additionally, the influential factors within each group differed significantly. Disgust processing is influenced by individual DS only in the TD group. However, for the ASD group, disgust processing in the insula was associated with age, which suggests that proper disgust processing may be influenced by development and learning of appropriate behaviors over time.

**416.054 (Poster)** Resting EEG and Language Development in Young Children with Autism Spectrum Disorder

**C. E. Mukerji<sup>1,2,3</sup>, J. Wilson<sup>4</sup>, C. L. Wilkinson<sup>2</sup>, M. A. Krol<sup>4</sup>, C. A. Nelson<sup>2</sup> and H. Tager-Flusberg<sup>4</sup>**, (1)Department of Psychology, Bryn Mawr College, Bryn Mawr, PA, (2)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA, (3)Psychological and Brain Sciences, Boston University, Boston, MA, (4)Department of Psychological and Brain Sciences, Boston University, Boston, MA

---

**Background:** Autism spectrum disorder (ASD) is characterized by core difficulties in language and communication. Recent electroencephalography (EEG) studies suggest that baseline neural activity may be associated with individual differences in language among young children at-risk for language impairment. For example, Wilkinson and colleagues (2019) found that reduced frontal gamma power is associated with better expressive—but not receptive—language in infant siblings of children with ASD (Wilkinson, 2019). However, it remains unclear whether similar neural mechanisms are linked to language abilities in young children who meet clinical criteria for ASD.

**Objectives:** This study aimed to (a) test whether frontal gamma power differs between young children who meet clinical criteria for ASD and TD peers and (b) whether gamma power is associated with individual differences in expressive or receptive language in ASD.

**Methods:** Participants included 49 young children with ASD and 59 age and sex-matched TD children (ages 22-60 months) recruited from ongoing research studies at Boston University and Boston Children's Hospital. Children sat quietly while watching a screensaver while baseline EEG was recorded using a 128-channel Hydrocel Geodesic Sensor Net. Data were pre-processed through BEAPP-HAPPE pipeline. Log-transformed mean power in the gamma frequency range (30-55 Hz) was computed for each electrode and then averaged over a frontal region of interest. Children also completed the Mullen Scales of Early Learning (MSEL), including measures of expressive language and receptive language skill.

**Results:** We did not find significant differences between ASD and TD in frontal gamma power at rest ( $p > .05$ ). Children with ASD scored significantly lower than TD on both expressive and receptive language subscales of the MSEL (all  $ps < .001$ ). Multiple regression analysis predicting expressive language scores revealed significant interactions between diagnostic group and frontal gamma power [ $t = -2.538$ ,  $p = .013$ ]: lower gamma

power predicted higher expressive language in the ASD group only, controlling for the effects of age and sex. In contrast, neither the main effect of gamma power nor the interaction between gamma power and group significantly predicted receptive language scores in a separate multiple regression model (all  $p > .05$ ).

**Conclusions:** Young children with ASD did not differ from age- and sex-matched TD peers on frontal gamma power, in line with prior studies indicating that group differences in resting state power may be most pronounced in the first year of life. However, reduced gamma was associated with better expressive language skills among autistic children, suggesting unique associations between high frequency neural activity and the ability to express oneself through language in ASD. These findings replicate and extend prior research in infant siblings of autistic children in an independent sample of young children who meet clinical criteria for ASD. Our results implicate high frequency neural synchrony in the gamma band in the development of expressive language in ASD, highlighting a potential target for future interventions to support language skills.

**416.055 (Poster)** Robust Sex Differences in Functional Brain Organization and Their Dissociable Links to Clinical Symptoms in Autism  
**K. Supekar**, *Stanford University School of Medicine, Stanford, CA*

---

**Background:**

Autism spectrum disorder (ASD) is a highly heterogeneous neurodevelopmental disorder that affects nearly 1 in 189 females and 1 in 42 males. However, the neurobiological basis of sex differences in ASD is poorly understood, as most studies have neglected females and relied on analytical approaches that are ill-equipped to capture robust neurobiological sex differences.

**Objectives:**

Identify robust and interpretable dynamic brain markers that distinguish between female and male children with ASD and predict clinical symptom severity.

**Methods:**

We leverage multiple brain imaging cohorts (ABIDE, Stanford, CMI-HBN;  $N_{ASD} = 773$ ) and exciting recent advances in explainable artificial intelligence (xAI), to develop a novel multivariate time series deep neural network (stDNN) that extracts informative brain dynamics features that accurately distinguish between female and male children with ASD, and predict clinical symptom severity.

**Results:**

stDNN achieved an accuracy of  $86.0 \pm 1.65\%$  for distinguishing between females and males with ASD from multisite ABIDE/Stanford cohort ( $N_{ASD} = 678$ ). Notably, stDNN also classified data from an independent CMI-HBN cohort ( $N_{ASD} = 95$ ) with an accuracy of  $83.4 \pm 3.67\%$ , without additional training. stDNN trained to distinguish between ASD males and ASD females, however, could not distinguish neurotypical males from neurotypical females, highlighting the uniqueness of ASD-related sex differences. xAI revealed that brain features associated with key nodes of the motor, language, and visuospatial attentional systems, consistently distinguished between females and males with ASD in both cohorts. Furthermore, brain features associated with the primary motor cortex node of the motor system emerged as a robust predictor of the severity of restricted/repetitive behaviors in females but not in males with ASD.

**Conclusions:**

Our findings, replicated across independent cohorts, reveal that the brains of females and males with ASD are functionally organized differently, contributing to their clinical symptoms in distinct ways. Our findings inform the development of more refined sex-specific diagnoses and targeted treatment strategies, and ultimately advance precision psychiatry.

**416.056 (Poster)** SLEEP Disturbance Is Associated with Anomalous Default and Attention Network Dynamic Functional Connectivity in Children with Autism

**D. E. Lidstone<sup>1</sup>**, **D. Crocetti<sup>1</sup>**, **A. Spira<sup>2</sup>**, **H. E. Volk<sup>3</sup>**, **S. H. Mostofsky<sup>4</sup>** and **M. B. Nebel<sup>1</sup>**, (1)Center for Neurodevelopmental and Imaging Research, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Center for Autism and Related Disorder, Kennedy Krieger Institute, Baltimore, MD

---

**Background:** Sleep disturbance is highly prevalent among children with ASD compared to typically developing (TD) children. The neural basis for sleep disturbances in ASD is unknown; however, disrupted functional connectivity (FC) both within default mode network (DMN) and between DMN and dorsal attention networks (DAN) have previously been associated with both sleep deprivation in TD adults and ASD diagnosis.

**Objectives:** To examine FC between the DMN and DAN and associations with sleep disruption in children with ASD. Given that ASD is associated with greater variability at behavioral and neurophysiologic levels, we chose to investigate DMN-DAN connectivity using innovative dynamic FC (dFC) methods that not only assess mean (static) FC, but also dynamic FC (i.e., FC variability), which is thought to be an indicator of cognitive processing.

**Methods:** Participants were 98 children with a diagnosis of ASD (80% male, 10.4±1.4 years) and 246 TD children (70% male, 10.3±1.3 years). Parents completed the Children's Sleep Habits Questionnaire (CSHQ) (ASD = 45±8, TD = 39±5;  $p < 0.001$ ) and children completed a resting-state fMRI scan (duration=5-6.5 min). We used group independent component analysis to decompose the aggregate fMRI data into 30 temporally coherent and spatially independent components (ICs). ICs corresponding to the dorsal attention network (DAN; IC-19) and DMN subsystems (ICs 17, 25, 26) were extracted. dFC was examined for all six edges (3 within-DMN and 3 DMN-DAN) using dynamic conditional correlations (DCC). Linear models were fit for each edge, separately for dFC-mean and dFC-variance, with terms for diagnosis (DX) [ASD=1/TD=0], presence of clinical-level of sleep disturbance (CSD = CSHQ score  $\geq 41$ ) or typical sleep (TYP) [CSD=1/TYP=0], DX-by-CSD interaction, and nuisance covariates (age, sex, MRI coil, meanFD). Lastly, to examine dFC prediction of CSHQ total scores, linear regression models were constructed separately for dFC-mean and dFC-variance with terms for DX, DX-by-dFC interaction, and nuisance covariates ( $\alpha=0.05$ ).

**Results:** A chi square analysis of CSHQ responses revealed a significantly higher level of CSD among children with ASD (59%) as compared with TD children (26%) ( $p < 0.001$ ). We observed a main effect of DX on dFC-mean for two within-DMN edges (IC17-IC25 and IC-25-IC26); the ASD group showed weaker dFC-mean for both edges compared with the TD group (both  $t = -2.1$ ,  $p = 0.03$ ); in contrast, there was no effect of DX on DMN-DAN dFC-mean. For dFC-variance, there was a marginally significant DX-by-CSD interaction for an anti-correlated DAN to anterior DMN (aDMN) edge (IC19-IC25;  $p = 0.05$ ); aDMN-DAN dFC-variance was greater in the ASD+CSD vs. TD+CSD group yet was lower in the ASD+TYP vs. TD+TYP (Fig. 1A). Further, the aDMN-DAN DX-by-dFC-variance interaction term was the only significant predictor of total CSHQ score, such that a 0.1 increase in dFC-variance was associated with a 2.83-point increase in total CSHQ score in the ASD group ( $t = 2.79$ ,  $p = 0.005$ ) (Fig. 1B).

**Conclusions:** Our findings suggest that alterations in dorsal attention-default mode network connectivity are associated with greater sleep disturbance in autism. Validation of these brain imaging biomarkers would benefit from additional studies using objective sleep measures (e.g., actigraphy, polysomnography).

#### **416.057 (Poster)** Self- and Other-Related Processing in the Brain: An fMRI Study

**A. D. Nijhof<sup>1</sup>, M. Brass<sup>2</sup> and J. R. Wiersema<sup>3</sup>,** (1)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (2)Berlin School of Mind and Brain, Department of Psychology, Humboldt-Universität zu Berlin, Berlin, Germany, (3)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium

#### **Background:**

Humans have been shown to respond uniquely to stimuli that are self-related, such as their own face or name. Such self-specific effects are thought to be crucial for self-awareness and social functioning, and research suggests that these effects may be diminished in individuals with autism. However, findings are currently mixed, and neural responses to self-related stimuli have rarely been investigated across different stimulus types. As a consequence, it is still debated whether different self-bias effects are supported by one unitary or separate mechanisms, and which aspects of self-processing may be altered in autism.

#### **Objectives:**

The aim of the current study was twofold. Firstly, we wanted to map the typical representational structure of self- and other-related information in the brain, independently of stimulus type (own face or own name), using multi-voxel pattern analysis. Secondly, we wanted to investigate, in a neurotypical sample, whether the found neural activation patterns for self-related stimuli were related to self-reported levels of autism characteristics.

#### **Methods:**

In a Siemens 3T MRI scanner, 36 neurotypical participants were presented with six runs of face images, and six runs displaying first names, in three categories (Self, Close Other, Stranger). As an attention check, they were asked to press a button each time a black cross presented centrally changed color to red. Finally, they filled out the Autism Spectrum Quotient and Social Responsiveness Scale for Adults as measures of self-reported autism characteristics.

#### **Results:**

Representational similarity analyses across faces and names revealed higher similarity in activation patterns for different self-specific stimuli in visual areas of the brain, as well as the basal ganglia and insula. When looking at activation patterns for faces specifically, additional areas in ACC, parietal cortex and right STS were found, with no additional regions for names. The self-specificity metric for none of these regions showed a significant correlation with levels of autistic traits.

#### **Conclusions:**

These results suggest that self-related processing may be supported by stimulus-specific as well as more abstract self-related mechanisms that are independent of stimulus type. Although in this neurotypical group no relation to autism characteristics was found, we are currently planning a follow-up study in a group of adults with and without autism, which will shed further light on the question of which aspects of self-processing might be altered in autism.

#### **416.058 (Poster)** Sex Differences in Neural Response to Faces in Autistic Adults

**Background:** Sex differences in ASD have long been of interest given a notable male bias in prevalence estimates. Sex-specific biological factors may contribute to ASD etiologies and have demonstrable effects on neurodevelopmental trajectories (Walsh et al., 2021). Given that much of what we know about sex differences in ASD is derived from behavioral observation, more investigation is needed to determine the extent to which sex differences in ASD may be related to neural function. The N170 event-related potential is a promising neural marker of social perception in ASD (Kang et al., 2017). Despite this promise, only one study to date has focused specifically on sex differences in the N170 to faces in autistic children (Coffman et al., 2016). In this study, sex differences were observed, with shorter latencies in males and higher amplitudes in females. Neural responses correlated with autism severity in females but not in males. It is not known whether these sex effects are specific to children.

**Objectives:** To evaluate sex differences in N170 response in adults with and without ASD.

**Methods:** The preliminary sample included 32 individuals with ASD (8 female) and 28 typically developing adults (16 female). Data collection is ongoing. EEG was recorded using a Hydrocel 128-channel sensor net, and dependent variables were extracted over right occipitotemporal scalp (T6). Participants viewed upright faces and houses for 1 second. Each stimulus was preceded by a crosshair cueing gaze to the right eye, left eye, center nose, or center mouth regions. Event related potentials were extracted between 120 and 220ms, filtered, artifact rejected, baseline corrected, re-referenced to the whole scalp average, and averaged across trials. N170 amplitude and latency were examined via 2x2x2 repeated measures ANOVA for condition, sex, and diagnosis. Co-registered eye-tracking will support evaluation of associations with gaze in forthcoming analyses.

**Results:** A condition-by-sex interaction emerged for N170 amplitude such that males had more negative amplitudes than females and more negative N170s to faces than houses,  $F(1, 56)=4.55, p<.05$ . In females but not males with ASD, N170 latency to faces was negatively associated with the social motivation subscale of the Social Responsiveness Scale (SRS),  $r=-.85, p<.01$ , as well as the Reading the Mind from the Eyes Task  $r=-.82, p<.05$ . In addition, in females but not males with ASD, marginal correlations emerged between N170 latency and the social communication index of the SRS  $r=-.66, p=.08$  and the Benton Facial Recognition task,  $r=-.65, p=.08$ . There were no main effects for N170 latency.

**Conclusions:** These data add to the growing body of research on sex differences in neural information processing in ASD. In contrast to prior findings in children, males had higher amplitude N170s than females, and no main effects of diagnosis emerged. In females with ASD, shorter N170 latencies were associated with higher self-report ratings of social ASD features and social anxiety but also with better performance on behavioral tasks of facial and emotion recognition. Future work should examine neurodevelopmental trajectories of social perception by sex throughout the lifespan.

#### **416.059 (Poster) Somatosensory Duration Mismatch Negativity in Young Adults with and without Autism Spectrum Disorder**

E. Isenstein<sup>1</sup>, A. Xu<sup>1</sup>, I. DeAndrea-Lazarus<sup>2</sup>, L. A. Oakes<sup>1</sup>, E. G. Freedman<sup>1</sup> and J. J. Foxe<sup>1</sup>, (1)University of Rochester Medical Center, Rochester, NY, (2)University of Rochester, Rochester, NY, (3)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY

---

**Background:** Both hyper- and hypo-sensitivity to tactile stimuli are commonly reported in people with autism spectrum disorder (ASD), yet little is known about the neurological underpinnings of this atypical tactile sensitivity. Compared to other sensory domains, few studies exist that examine the neurophysiology of tactile perception in ASD. The limited evidence that exists shows mixed results, but all known research has used repetitive, identical stimuli with a predictable intensity or duration. In this experiment we aim to clarify the role of predictability in how the brain responds to tactile stimulation in neurotypical and autistic young adults.

**Objectives:** To measure whether people with and without ASD have different patterns of cortical response to predictable and unpredictable passive somatosensory stimulation.

**Methods:** This study used a somatosensory duration mismatch negativity (MMN) paradigm to assess vibrotactile novelty detection in 17 neurotypical and 3 autistic young adults. ASD diagnoses were confirmed by administration of the Autism Diagnostic Observation Schedule by a trained clinician. The MMN is a specific event-related potential that occurs when a repeated sequence of identical, predictable 'standard' stimuli is interrupted by a novel, unpredictable 'deviant' stimulus that differs from the standard majority. By maintaining one stimulus as the majority of the input (80%), any perceived deviation from the anticipated stimulus results in a distinct, measurable electrophysiological response known as the MMN. In this study, vibrations of standard (100 ms) and deviant (115, 130, 145, and 160 ms) durations were presented while an electroencephalogram (EEG) measured cortical activity. Data collection is ongoing.

**Results:** Difference waves were calculated by subtracting the standard waveform from each respective deviant waveform. The average of the 10 milliseconds surrounding the peak amplitudes of the difference waves as well as the peak latencies of the difference waves were extracted from fronto-central electrodes between 130 and 210 ms after stimulus presentation. The peak difference wave amplitudes did not differ significantly between groups: 115 ms:  $t=.72, p=.53$ ; 130 ms:  $t=.88, p=.44$ ; 145 ms:  $t=.49, p=.67$ ; 160 ms:  $t=.62, p=.57$ . The latency of each peak also did not differ between groups: 115 ms:  $t=1.21, p=.30$ ; 130 ms:  $t=.098, p=.93$ ; 145 ms:  $t=.19, p=.85$ ; 160 ms:  $t=.20, p=.86$ .

**Conclusions:** Additional data collection is needed to properly compare these two groups with appropriate power, but these preliminary results suggest that early low-level processing of novel vibrotactile information does not differ between the two groups. While preliminary, these results suggest that the level and processing speed of cortical activity in response to both predictable and unpredictable somatosensory stimuli is similar between autistic and neurotypical young adults.

**416.060 (Poster)** The Relationship between Visual Evoked Potentials, Sleep, and Autistic Traits As Markers of Excitatory/Inhibitory Imbalance and Gabaergic Functioning in Autism Spectrum Disorder

**L. M. Pisani<sup>1</sup>, G. T. Han<sup>2</sup>, A. Naples<sup>1</sup>, C. E. Finn<sup>3</sup>, M. E. Johnson<sup>4</sup>, C. J. Stevens<sup>1</sup>, M. A. Azu<sup>1</sup>, C. J. Franke<sup>1</sup>, R. Iqbal<sup>1</sup>, C. C. Cukar-Capizzi<sup>1</sup>, J. M. Wolf<sup>1</sup> and J. McPartland<sup>5</sup>, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale Child Study Center, New Haven, CT, (3)McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (4)Child Study Center, Child Study Center, Yale University, New Haven, CT, (5)Child Study Center, Yale Child Study Center, New Haven, CT**

**Background:** Balanced excitatory and inhibitory (E/I) activity, driven by glutamatergic and GABAergic input, enables adaptive neural responses optimal for information processing (Foss-Feig et al., 2017). Early waveform peaks (i.e., N1 and P1) generated by visual evoked potentials (VEP) represent early visual processing and reflect glutamatergic and GABAergic activity. In some individuals with autism spectrum disorder (ASD), E/I imbalance in critical neurocircuits leads to less efficient information processing (Sohal & Rubenstein, 2019). Additionally, altered GABAergic function in ASD may contribute to poor sleep due to GABA's role in sleep initiation and maintenance (Deliens & Peigneux, 2019).

**Objectives:** Compare (1) VEP P1 amplitude and latency and (2) sleep in autistic and neurotypical adults to evaluate (3) whether alterations in GABA-mediated processes explain variance in ASD characteristics.

**Methods:** Participants included 35 adults with ASD (29 males; age  $M=26.95\pm5.98$ ; FSIQ  $M=110.46\pm10.98$ ) and 28 neurotypical (NT) adults (12 males; age  $M=27.83\pm4.74$ ; FSIQ  $M=117.57\pm15.37$ ). Participants with ASD met diagnostic criteria via gold-standard assessments, and cognitive ability was assessed using the WASI-II. Self-reported ASD traits and sleep quality were indexed using the Social Responsiveness Scale-2 [SRS-2 total score, Social Communication Index (SCI), and Restricted Interests and Repetitive Behavior (RRB)] and the Pittsburgh Sleep Quality Index (PSQI). Electroencephalography (EEG) was used to record VEP over the occipital cortex (O1, O2, Oz) during a pattern-reversal checkerboard paradigm. N1 and P1 peaks were selected manually via a web hosted peak picker to extract peak amplitude and latency for analyses. Between-group differences in sleep, P1 amplitude and latency, and SRS-2 scores were assessed using independent samples t-tests. Linear regression was used to examine the relationships among these variables.

**Results:** Groups did not differ in P1 amplitude or latency ( $ps>0.05$ ). However, a significant group x P1 amplitude interaction for predicting SRS-2 scores was detected ( $F(3,58)=14.75$ ,  $p<.001$ ) such that increased P1 amplitude was associated with higher levels of ASD traits in the ASD group ( $F(1,29)=4.42$ ,  $p=.044$ ); no relationship between these variables was observed in the NT group ( $F(1,26)=2.46$ ,  $p=.129$ ). Compared to the NT group, adults with ASD endorsed poorer sleep via the PSQI with respect to global sleep quality ( $t(58)=4.26$ ,  $p<.001$ ), sleep efficiency ( $t(59)=2.35$ ,  $p=.022$ ), and sleep disturbance ( $t(40)=3.15$ ,  $p=0.003$ ). Within ASD, increased PSQI global scores were associated with more ASD traits [SRS-2 total scores: ( $r(32)=-.44$ ,  $p=.009$ ); SCI: ( $r(32)=-.46$ ,  $p=.007$ ); RRB: ( $r(32)=-.35$ ,  $p=.041$ )]. No significant relationships were found between PSQI global scores and P1 amplitude in ASD.

**Conclusions:** As expected, adults with ASD reported poorer sleep quality compared to neurotypical adults, which was associated with more ASD traits. Of note, there was no difference in P1 amplitude or latency between diagnostic groups. However, P1 amplitude was positively associated with ASD traits within the ASD group, which indicates differences in early visual processing, an index of E/I balance, may predict ASD features. Though poor sleep in ASD was associated with more autistic traits, no relationship between sleep, P1 amplitude, and ASD traits was found. Future research collecting objective measures of sleep, such as polysomnography or actigraphy, is recommended to further probe these relations.

**416.061 (Poster)** Visual Evoked Potential N1 Amplitude and Latency Differ between Children Diagnosed with Autism, Attention-Deficit/Hyperactivity Disorder, and Autism with Co-Occurring Attention-Deficit/Hyperactivity Disorder

**K. L. Carpenter<sup>1</sup>, S. Major<sup>2</sup>, T. Calnan<sup>3</sup>, R. E. Aiello<sup>1</sup>, S. Compton<sup>1</sup>, N. O. Davis<sup>4</sup>, L. Franz<sup>2</sup>, J. N. **Background:** Early visual processing differences, as measured through the visual evoked potential (VEP), have been reported in autistic individuals. Animal research suggests that the VEP reflects cortical excitation/inhibition balance, which has been implicated in the pathophysiology of autism. Furthermore, in autistic children, the VEP correlates with individual differences in social abilities. As such, the VEP represents a potential brain-based biomarker that may reflect both clinical and neurobiological aspects of autism. To date, research on the VEP in autistic children has not explored the impact of co-occurring disorders, such as attention-deficit/hyperactivity disorder (ADHD), despite estimates that 40-60% of autistic children have co-occurring ADHD.

**Objectives:** Compare differences in the VEP between autistic children, children with ADHD, autistic children with co-occurring ADHD, and neurotypical children.

**Methods:** Participants were 131 children ages 3-7 years old from 4 groups: neurotypical (NT;  $N=27$ ), ADHD ( $N=42$ ), autistic ( $N=34$ ), and co-occurring autism and ADHD (Autistic+ADHD;  $N=28$ ). VEP stimuli consisted of two black and white checkerboards that reversed phase. Amplitude and latency of the N1 and P1 peaks were derived. Group differences were tested using general linear models. Covariates (full-scale IQ, age, and sex) impeding the overall model were iteratively removed until best model performance was achieved. Follow-up pair-wise t-tests were corrected for multiple comparisons using the Benjamini-Hochberg correction.

**Results:** Neither P1 amplitude nor latency differed among groups. For N1 amplitude, there was an overall model effect when group, sex, and a group-by-sex interaction term were included in the model (neither IQ nor age significantly contributed to the model). However, group, sex, and their interaction were not independently associated with N1 amplitude. To explore what drove the significant model effect, we conducted separate analyses in male (N=96) and female (N=35) participants. In males, but not females, there was a significant group difference in N1 amplitude ( $F(3)=3.71$ ,  $P=.01$ ). Pair-wise analyses revealed a significantly larger N1 amplitude in autistic compared to ADHD males ( $F(1)=10.55$ ,  $P<.01$ ). This was associated with a large effect ( $d=.86$ ). For N1 latency, there was also a significant group effect when controlling for full-scale IQ (neither age nor sex significantly contribute to the model) in the full sample ( $F(3)=3.00$ ,  $P<.05$ ). Pair-wise analyses revealed that children with ADHD had a significantly faster N1 latency compared to both autistic ( $F(3)=6.56$ ,  $P=.01$ ) and Autistic+ADHD ( $F(3)=6.91$ ,  $P=.01$ ) children.

**Conclusions:** Based on the VEP, among males, autistic children were found to have a larger N1 amplitude compared to children with ADHD. Children with ADHD regardless of sex, however, exhibited a faster N1 latency compared to autistic children with and without co-occurring ADHD. These results suggest that, while the co-occurrence of ADHD does not influence VEP among autistic children, children diagnosed with ADHD versus those with autism appear to have different patterns of VEP. Furthermore, timing and magnitude of the VEP may be sensitive to diagnostic classification but are not influenced by co-occurring ADHD among autistic children.

## VIRTUAL POSTER SESSION — BRAIN FUNCTION (fMRI, fCMRI, MRS, EEG, ERP, MEG)

### 516 - Brain Function (fMRI, fCMRI, MRS, EEG, ERP, MEG) --- (V)

**516.031** (Virtual Poster) Altered Processing of Communication Signals in the Subcortical Auditory Sensory Pathway in Autism  
**S. Schelinski<sup>1,2</sup>**, **A. Tabas<sup>1,2</sup>** and **K. von Kriegstein<sup>1,2</sup>**, (1)Technische Universität Dresden, Dresden, Germany, (2)Max Planck Institute for Human Cognitive and Brain Sciences, Leipzig, Germany

**Background:** Human communication requires the fast and accurate processing of sensory signals, such as the voice. Traditionally, it is assumed that the cerebral cortex and limbic structures are specialised in processing speech, vocal identity, and emotional components of the sensory signal. Much less is known about the role of subcortical sensory pathway structures for communication and its impairments. For example, it is to-date unclear at which processing stage voice processing difficulties arise in autism.

**Objectives:** Here, we assessed the functional integrity of auditory pathway nuclei for processing voices in autism.

**Methods:** We tested functioning of the auditory midbrain (inferior colliculus; IC) and thalamus (medial geniculate body; MGB) in three independent functional magnetic resonance imaging (fMRI) experiments in groups of adults with autism and pair-wise matched typically developed controls (matched on age, sex, handedness, and full-scale intelligence quotient (IQ)). We focused on two aspects of voice processing that are impaired in autism: voice identity perception, and recognising speech-in noise. First, participants performed tasks on speaker identity and speech recognition (voice identity recognition experiment,  $n = 16$  per group). Second, both groups passively listened to blocks of vocal and non-vocal sounds (vocal sound experiment,  $n = 16$  per group). In the third experiment participants performed speech recognition tasks on speech that was either presented with or without noise (speech-in-noise recognition experiment,  $n = 17$  per group). All participants had normal hearing (confirmed with pure tone audiometry) and did not take psychotropic medication. All participants in the autism group had previously received a formal clinical diagnosis and underwent additional clinical assessment including the ADOS and ADI-R. For the fMRI analysis we used a general linear model implemented in SPM12. We focused on four regions of interest (left and right IC and left and right MGB).

**Results:** We found reduced blood-oxygenation-level-dependent (BOLD) responses for the autism as compared to typically developed control groups in the IC – the central midbrain structure of the auditory pathway ( $p < .05$  family wise error (FWE) corrected for the four regions of interest). The right IC responded less in the autism as compared to the control group for voice identity, in contrast to speech recognition. The right IC also responded less in the autism as compared to the control group when passively listening to vocal in contrast to non-vocal sounds. Within the control group, the left and right IC responded more when recognising speech-in-noise as compared to when recognising speech without additional noise. In the autism group, this was only the case in the left, but not the right IC. The autism and the control group did not differ significantly in the average amount of head movements (all  $p$  values  $> 0.1$  in all three experiments).

**Conclusions:** Our results show that communication signal processing in autism is associated with reduced subcortical sensory functioning in the midbrain. The results highlight the importance of considering sensory processing alterations in explaining communication difficulties, which are at the core of autism.

**516.032** (Virtual Poster) Auditory Processing Is Substantially Altered in Low-Functioning Children with ASD: ERP Study  
**O. V. Sysoeva<sup>1</sup>**, **S. Molholm<sup>2</sup>** and **J. J. Foxe<sup>3</sup>**, (1)Institute of Higher Nervous Activity and Neurophysiology, Moscow, Russian Federation, (2)Albert Einstein College of Medicine, Bronx, NY, (3)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY

**Background:** Event-related potential(ERPs) to sounds are atypical in ASD, although results are inconsistent with most studies focused on the latencies of ERP components and very few studies comparing amplitude of ERPs to pure tones and phonemes. Also most previous studies focused on high-functioning ASD children(HFA), leaving a substantial proportion of ASD children, those with poor language skills out of research.

**Objectives:** Our study aims to fill this gap in knowledge.

**Methods:** Children with ASD (18 high- and 18 low-functioning, HFA and LFA) and 18 typically developing peers (TD) (mean age 12, range 6-18 years, mean IQ = 116, 95 and 53 for TD, HFA and LFA, respectively) listened to pure tones (327/367 Hz) and phonemes ("ba"/"da") presented in separate odd-ball sequences (intensity about 75dB and interstimulus interval(ISI) 760-930ms). Concurrently, 64-channels EEG(BiosemiActiveTwo) were registered. After recording EEG data were re-referenced to average reference, epoched -200 to +500 ms post-stimulus latencies, and then separately averaged for the tones and phonemes standard stimuli with artifacts (more than 5 STDs over mean) removed. For the analysis we took peak amplitude of P1, N1, P2 and N2 components measured at fronto-central sites (FC3 and FC4) as well as their polarity-reversed counterparts at temporal-parietal (TP7 and TP8) sites within the following time windows: 60-90ms, 100-130ms, 135-165ms, 245-275ms, respectively. Repeated-measures ANOVA with Stimulus Type(Tone vs Phonemes), Hemisphere(left vs right), Frontality(frontal- central vs temporo-parietal) as within-subject factors and Group(TD, HFA and LFA) as between-subject factor used for statistical inference.

**Results:** LFA group showed more pronounced ERP abnormalities compared to HFA: Significant Group effect for P1 ( $F(2,51)=3.228, p=0.047$ ) was triggered by significant difference only between LFA and TD group with values of HFA lying in between. N1 was, on the contrary, increased in the ASD group with more pronounced difference in the right hemisphere(Group by Hemisphere interaction,  $F(2, 51)=4.724, p=0.013$ ): LFA group differed from TD in both hemispheres, while TD vs HFA difference was significant in the right but not left hemisphere. P2 was attenuated in LFA both in the left and right fronto-central site as compared to TD, but LFA vs HFA difference was insignificant in the latter(post-hoc follow-up of Group by Frontality by Hemisphere interaction:  $F(2,51)=3.426, p=0.040$ ). N2 was smaller in response to Tones also specifically to the LFA group with TD vs HFA not reaching significance in any hemisphere, and LFA vs HFA in the right hemisphere(follow-up of Group by Stimulus Type by Hemisphere interaction,  $F(2,51)=3.299, p=0.045$ ).

**Conclusions:** Neurophysiological response to sounds is substantially affected in ASD with more severe phenotype associated with more pronounced ERPs abnormalities characterized by differential involvement of the right and left hemisphere. These ERPs abnormalities are mostly common in response to tones and phonemes or even specific to more simple stimuli - tones, suggesting general deficits in basic auditory processing.

**516.033 (Virtual Poster)** Brain to Brain Synchrony during Natural Social Interaction of Children with Autism Spectrum Disorder Using fNIRS  
**H. Ayaz<sup>1</sup>, Y. Topoglu<sup>1</sup>, A. Curtin<sup>1</sup>, J. Day-Watkins<sup>2</sup>, B. Garvin<sup>1</sup>, G. Foster<sup>1</sup>, E. S. Sheridan<sup>2</sup>, J. Connell<sup>1</sup>, D. Bennett<sup>3</sup> and K. Heffler<sup>5</sup>,** (1)School of Biomedical Engineering Science and Health Systems, Drexel University, Philadelphia, PA, (2)AJ Drexel Autism Institute, Drexel University, Philadelphia, PA, (3)St. Christopher's Hospital for Children, Philadelphia, PA, (4)School of Education, Drexel University, Philadelphia, PA, (5)Department of Psychiatry, Drexel University, Philadelphia, PA

**Background:**

Deficits in social communication and engagement represent a core symptom of autism spectrum disorder (ASD). As an optical brain monitoring technology, functional Near-Infrared Spectroscopy (fNIRS) provides a measure of cerebral hemodynamics in response to sensory, motor, or cognitive activation. Consistent with neuroergonomics, fNIRS can measure the brain in ecologically valid everyday settings during complex natural tasks. In this project, we investigate prefrontal brain activity, using fNIRS wearable neuroimaging, during toddler's natural social interaction of toddlers. We measure fNIRS brain response to social stimuli and brain to brain coupling of an adult confederate with toddlers with and without ASD.

**Objectives:**

Evaluate brain to brain coupling as a measure of neural synchrony, between toddler and adult confederate pairs while they communicate and play with each other.

**Methods:**

Experimental protocol involves naturalistic communication and gameplay between participant children (age 18-42 months) and our confederate adult. The child was unfamiliar to our confederate adult and hence represented a greater barrier than parent for social interaction. There are two conditions (dyad together and apart), each five-minutes long. In the together condition, the Adult played and interacted with the child participant, doing activities such as reading stories, singing, and playing with toys. In the apart condition, the child and the Adult were still in the same room, but not interacting while their brain activity is monitored. Instead, the child played with their parent while the confederate adult conversed with another person (See Figure 1). Children with ASD and their parents completed the TELE-ASD-PEDS and Childhood Autism Rating Scale (CARS-2) to confirm autism diagnoses. During the sessions, raw light intensities at 16 anterior prefrontal regions sampled continuously 10Hz via wearable fNIRS sensors from both the child and adult. For analysis, data were low-pass filtered at 0.1Hz to eliminate high frequency noise and physiological artifacts such as cardiac and respiration cycles, and converted to oxygenated hemoglobin (HbO) concentration changes by using the Modified Beer Lambert Law. Five minutes long together and apart task segments were extracted, and Spearman's rank correlation coefficients were calculated for all channel pairs for child and adult ( $16 \times 16 = 256$ ) of each dyad.

**Results:**

Preliminary results based on our first two pairs (2 ASD toddlers and 2 adult sessions data) are presented in Figure 2 where correlation of fNIRS HbO time-series channels of Child (x-axis) and Adult (y-axis) were presented as color coded. As expected, the together condition elicited higher correlations between child and adult during joint play, compared to the apart condition in which their activity was more independent.

**Conclusions:**

This fNIRS hyperscanning study explores neural correlates of natural social interaction of children with ASD and a confederate adult. Preliminary results suggest that joint and separate activity impact in neural synchrony can be observed with wearable neuroimaging sensors. We will continue with participant recruitment and data collection in order to compare children with ASD to typically developing children in this paradigm.

**516.034 (Virtual Poster)** Default Mode Network Connectivity Differences in Youth with Autism Spectrum Disorder Compared to Early-Onset Psychosis

**R. Jalal<sup>1</sup>**, A. Preston<sup>1</sup>, H. Gutierrez<sup>2</sup>, M. Rshouni<sup>3</sup>, C. E. Bearden<sup>4</sup>, K. Karlsgodt<sup>4</sup> and A. Nair<sup>1</sup>, (1)Psychology, Loma Linda University, Loma Linda, CA, (2)Loma Linda University, Loma Linda, CA, (3)University of California, Los Angeles, Los Angeles, CA, (4)Department of Psychiatry and Biobehavioral Sciences, Semel Institute for Neuroscience and Human Behavior and Department of Psychology, University of California-Los Angeles, Los Angeles, CA

---

**Background:**

The default mode network (DMN) is one of the most extensively studied brain networks (Whitfield-Gabrieli and Ford, 2021). Neuroimaging studies have found DMN is implicated across various neuropsychiatric disorders characterized by social impairments, notably in autism spectrum disorder (ASD) and early onset psychosis (EOP; Assaf et al., 2010; Kennedy and Adolphs, 2012; Nair et al., 2020). However, few studies have investigated functional dysconnectivity of the DMN and its association to diagnostic and social cognition measures in a group of ASD adolescents and age-matched individuals with EOP to identify any shared or distinct patterns unique to each group.

**Objectives:**

To examine whole-brain functional connectivity of the DMN and its relationship to behavioral correlates in a group of adolescents with ASD and adolescents with EOP, compared to typically developing (TD) adolescents.

**Methods:**

Resting-state functional magnetic resonance data were acquired on a 3T Siemens scanner for 62 adolescents, aged 12-21 years; 25 with ASD, 19 EOP adolescents, and 18 TD controls (Mean age = 16.35; % female = 39%). Data were preprocessed in FSL (Smith, 2004), and ICA-AROMA (Pruim et al., 2015) was used to remove motion confounds. Nuisance regressors (white matter, cerebrospinal fluid) were included to further reduce potential confounds. The DMN seed was derived from a prior study (Lawrence et al., 2019). For between-network connectivity, group analyses were limited to voxels (voxelwise threshold of  $Z > 2.3$  and corrected cluster threshold of  $p < 0.05$ ). Additionally, Pearson's correlations were run to examine the relationship between the DMN connectivity and various behavioral measures. Diagnostic measures include the Autism Diagnostic Observation Schedule, 2<sup>nd</sup> edition (ADOS-2; Lord et al., 2012), Scales for the Assessment of Negative and Positive Symptoms (SANS; SAPS; Andreasen, 1984). The social measures include WebCNP Emotion Recognition Test (Gur et al., 2010), and The Awareness of Social Inference Test (TASIT; McDonald et al., 2003).

**Results:**

The ASD group demonstrated underconnectivity within the precuneus and medial frontal cortex compared to TD; but overconnectivity of the DMN with opercular gyri, bilateral insular cortex, and bilateral superior frontal cortex. ASD also demonstrated overconnectivity of left superior parietal lobule, bilateral insular cortex, and bilateral superior frontal regions compared to EOP. For the ASD group, atypical whole-brain DMN connectivity was associated with higher calibrated severity scores on the ADOS-2. In contrast, whole-brain DMN connectivity was associated with poorer performance on an emotion recognition task in EOP group.

**Conclusions:**

Results suggest distinct whole brain DMN connectivity patterns in the ASD and EOP groups were associated with socioemotional functions. Specifically, ASD group showed underconnectivity in major DMN hubs such as the precuneus, but overconnectivity with extraneous regions such as bilateral insular cortex and superior frontal gyri compared to both TD and EOP groups. Atypical DMN connectivity pattern in the ASD group was associated with higher diagnostic symptom severity scores. Contrastingly, youth with EOP showed associations between DMN connectivity patterns and poorer performance on an emotion recognition task. Collectively, these findings suggest atypical DMN connectivity may be relevant to social impairments observed in each of these neuropsychiatric conditions.

**516.035 (Virtual Poster)** Detection of an Autism EEG Signature through a New Processing Method Based on a Topological Approach

**E. Grossi<sup>1</sup>**, R. White<sup>2</sup> and R. J. Swatzyna<sup>3</sup>, (1)Autism Research Unit, Villa Santa Maria Foundation, Tavernerio, Italy, (2)Belmont University, Nashville, TN, (3)Research, Houston Neuroscience Brain Center, Houston, TX

---

**Background:**

Many different mathematical approaches have been tested in the last few years to disentangle the EEG data complexity and determine if it is possible to distinguish children with ASD from typically developing children or children with other neuropsychiatric disorders. Each method has advantages and disadvantages, like for example, the large computational time required to achieve the final task.

## Objectives:

We present an alternative pre-processing approach of EEG data based on a novel algorithm applied to raw data to detect topological EEG features. Our assumption is that brain connection abnormalities can be detected through a specific mathematical topological approach, which is able to compare the minimal structure of functional networks beneath scalp electrodes.

## Methods:

This new pre-processing approach of EEG data to detect topological EEG features has been applied to a continuous segment of artifact-free EEG data lasting 10 minutes in ASCII format derived from 50 ASD children and 50 children with other Neuropsychiatric disorders matched for age and male/female ratios whose data were obtained from a clinical archive. Both groups had the same age range (4-10 years) and the same gender distribution (m=39, f=11). None of the subjects were affected by genetic conditions, cerebral malformations, or epilepsy. In the control group, the range of primary diagnoses were ADHD (n=41), mood disorders (n=4), anxiety disorders (n=16), sleep disorders (n=12), ODD (n=6), and TBI (n=5).

Each EEG was manipulated using “Cin-Cin” algorithm, based on an input vector characterized by a linear composition of city-block matrix distances among 19 electrodes. From the resulting triangular matrix of 171 numbers expressing all of the one-by-one distances among the 19 electrodes a minimum spanning tree (MST) is calculated. Electrode identification serial codes sorted according to the decreasing number of links in MST, and the number of links in MST are taken as input vectors for machine learning systems. With this method all the content of an EEG is transformed in 38 numbers which represent the input vectors for machine learning systems

classifiers. The advantage is the simplicity and the small computational time required.

## Results:

The robust set of 38 features related to MST were used as input for Machine Learning classifiers. KNN algorithm was used to develop a predictive model to distinguish subjects belonging to the two diagnostic classes (autism vs other disorders). Models' performances were tested with training/testing cross-validation procedures.

The best machine learning system (KNN algorithm) obtained a global accuracy of 93.2% (92.37 % sensitivity and 94.03 % specificity) in differentiating ASD subjects from NPD subjects (table 1).

## Conclusions:

In conclusion the results obtained in this study suggest that the new preprocessing methods introduced, in particular the MST algorithm, have great potential to allow a machine learning system to discriminate EEGs obtained from subjects with autism from EEGs obtained from subjects affected by other psychiatric disorders.

### **516.036** (Virtual Poster) EEG Based Non-Linear Measures in Pre-School Children with Autism and Other Neurodevelopmental Disorders during Awake and Sleep States

**A. Vasista<sup>1</sup>, S. M. Kaku<sup>2</sup>, G. Sarma<sup>3</sup>, S. Rajagopalan<sup>4</sup>, M. W. James<sup>1</sup> and A. Mysore<sup>2</sup>,** (1)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India, (2)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India, (3)Neurology, St John's Medical College Hospital, Bangalore, India, (4)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India., Bangalore, India

## Background:

While Electroencephalography (EEG) studies have investigated spectral power, coherence rhythms and hemisphere asymmetries, newer methods are being employed for investigating the complex brain networks in Autism Spectrum Disorder (ASD). Nonlinear measures can potentially help to interpret time-series data obtained from EEG signals and facilitate understanding of the complex symptom profile seen in ASD [1-3]. Studies comparing ASD and other neurodevelopmental disorders (here non-ASD) in both awake and sleep states of EEG recording are minimal.

## Objectives:

The aim of this study is to characterize EEG patterns in ASD and non-ASD cohorts by extracting non-linear features from time-frequency data using paradigms of Recurrence Plots (RP), Entropy and Fluctuation Analysis in awake and sleep states.

## Methods:

Preschool children ages 2 to 6 underwent prolonged EEG recording (up to 180 mins) with 64 Channel EGI-GES400 system. They were divided into two groups. ASD group had 28 children (24 males, 4 females). Non-ASD had 10 children (6 males, 4 females) with other neurodevelopmental disorders (ADHD, Speech Delay, Global Developmental Delay. Awake and sleep stages (N1, N2 & N3) were included as available. An artifact free

continuous segment of 60s in all 4 states was selected manually. Wavelets were extracted for 10s epoch with 50% overlap for spatially separated subset of 19 channels to constitute 6 bands viz.  $\gamma'$  [ $>64\text{Hz}$ ],  $\gamma$  [ $32-64\text{Hz}$ ],  $\beta$  [ $16-32\text{Hz}$ ],  $\alpha$  [ $8-16\text{Hz}$ ],  $\Theta$  [ $4-8\text{Hz}$ ],  $\Delta$  [ $0.1-4\text{Hz}$ ].[2]. 9 non-linear parameters of which 7 from Recurrence Quantification Analysis (RQA), Sample Entropy (SE) and Detrended Fluctuation Analysis (DFA) were computed for each band per channel. Mean Differences were computed between groups in all 4 states and the significance level were measured with p-values using  $\alpha=0.05$ .

## Results:

In our study group differences were seen in -

- Sample Entropy - N2 & N3 for Gamma & Delta respectively.
- DFA - N2 for Gamma & Beta in Occipital, Parietal & Frontal areas.
- Recurrence Rate - N1 & N2 over Alpha & Theta and additionally for Gamma High in N1.
- Determinism - N1-Gamma & N2-Gamma & Theta.
- Laminarity - N1 for Alpha and in N3 for Alpha, Beta & Delta.
- Trapping Time - N1 for Theta & Delta
- Entropy from RP - N1 or GammaH, Beta & Delta while in N2 for GammaH, Gamma, Theta & Delta.
- Max Line Length - N1 for GammaH & Gamma while in N2 for GammaH, Alpha & Delta.
- Mean Line Length - Theta & Delta in N1 & N2 respectively.

Table 1 summarizes areas of significant differences between the ASD (red) & non-ASD (blue) groups ( $p < 0.05$ ). It represents all 9 non-linear parameters over 6 bands in 4 states of Awake & Sleep (N1, N2, N3).

## Conclusions:

Majority of significant differences are seen in N1 & N2 across parameters & bands. Most single point deviations have occurred at Pz across all states. There are clear patterns for each nonlinear parameter across the states in both groups. This becomes effective for a binary classification in Machine learning paradigm. Deriving clinical implications of these patterns correlating with functional behavioral changes are underway.

**516.037 (Virtual Poster)** Face-Encoding Fusiform Gyrus (FFG) Neural Activity in Preschool Children with and without Autism Spectrum Disorder  
**O. Allison, J. C. Edgar, H. Green, K. Mol, M. Kim, E. S. Kushner, S. Liu, M. Slinger, T. Chiang, L. Bloy, T. Roberts and Y. Chen, Lurie Family Foundations MEG Imaging Center, Department of Radiology, Children's Hospital of Philadelphia, Philadelphia, PA**

**Background:** Encoding facial information is a fundamental pillar of the 'social brain'. Electrophysiology studies of adults and school-age children have identified FFG responses to face stimuli as potential diagnostic and prognostic markers for autism spectrum disorder (ASD). However, given developmental changes in brain activity from infancy through adolescence, it cannot be assumed that the FFG findings translate to children with ASD at the time of initial diagnosis (age ~3 years).

**Objectives:** The present study used magnetoencephalography (MEG) to examine face-encoding FFG activity in 3 to 4 year old children with ASD and typical development (TD). Study aims were to identify TD and ASD group differences in FFG activity to face and non-face stimuli at the time of initial diagnosis, with both time-domain and time-frequency domain FFG measures of interest.

**Methods:** Nineteen children with TD (11 males; mean age 4.16 +/- 0.60 years) and 7 children with ASD (5 males, mean age 3.87 +/- 0.67 years) viewed 80 face and 80 non-face stimuli (randomly presented). For each child, MEG data (CTF 275, Coquitlam, BC) were co-registered to an age-appropriate MRI template. Artifact-free epochs 200 ms pre- to 500 ms post-stimulus were averaged according to stimulus type. Dynamical Statistical Parametric Mapping (dSPM) estimated whole-brain neural activity. FFG source timecourses to both conditions were extracted from a cortical regional source model (Desikan-Killiany Atlas). For time-domain measures, FFG peak latency (= the latency with the largest amplitude difference between the face and non-face conditions) and amplitude (time window where FFG source strength differed between conditions) were obtained. For time-frequency measures, single-trial phase and magnitude were calculated from FFG source timecourses using Morlet Wavelets, and total power (TP) and phase-locking (PL) measures were computed. ANOVAs with hemisphere entered as a repeated measure examined group differences in FFG measures.

**Results:** Time-domain analyses showed later left and right FFG responses in ASD ( $M = 238\text{ms} \pm 78$ ) compared to TD ( $M = 168\text{ms} \pm 45$ ) post-stimulus ( $p < 0.01$ ). No group difference in FFG source strength was observed. Time-frequency analyses showed reduced left and right FFG 12-15 Hz PL in ASD ( $M = 0.15 \pm 0.06$ ) than TD ( $M = 0.28 \pm 0.12$ ) 150-250 ms post-stimulus ( $p < 0.05$ ). No TP group difference or other frequency ranges were observed.

**Conclusions:** ASD children took longer to encode facial information compared to TD children. The trial-to-trial similarity of the response to faces was also more variable in ASD than TD, in the low beta band. Present findings thus extend the adult and older child studies, here finding the latency of the FFG face response as a possible diagnostic and prognostic marker at the time of initial diagnosis (~3years). Study findings also showed beta-band PL to be of potential interest. Follow up studies are needed to replicate present findings and to examine if the FFG neural measures obtained at time of initial diagnosis predict later functioning.

**516.038 (Virtual Poster) Frontal Lobe Hyperconnectivity As a Biomarker for Executive Dysfunction in Fragile X Syndrome**

**J. Li<sup>1</sup>, L. M. Schmitt<sup>2,3</sup>, R. Liu<sup>4</sup>, C. A. Erickson<sup>4,5</sup>, G. Westerkamp<sup>4</sup> and E. V. Pedapati<sup>4,5,6</sup>**, (1)University of Cincinnati College of Medicine, Cincinnati, OH, (2)Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (3)Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH, (4)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)Psychiatry and Behavioral Neuroscience, University of Cincinnati College of Medicine, Cincinnati, OH, (6)Neurology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

---

**Background:**

Fragile X Syndrome (FXS) is the leading inherited monogenetic cause of Autism Spectrum Disorder and intellectual disability. The cysteine-guanine-guanine trinucleotide repeat expansion (>200 repeats) on the *FMRI* gene leads to an absence of Fragile X Protein (FXP, formerly FMRP), a crucial protein for neurodevelopment. Executive function (EF), necessary for adaptive goal-oriented behavior and associated with frontal lobe activity, is impaired in individuals with FXS. Previous resting state electroencephalogram (EEG) research has indicated reduced alpha activity and increased gamma activity in FXS compared to typically developing controls (TDC). Yet, little is known how these alterations in neural activity are related to EF deficits in FXS.

**Objectives:**

Using high-density EEG recordings, we aim to quantify the strength of phase-based connectivity of the resting state frontal cortex activity for alpha and gamma band in individuals with Fragile X Syndrome compared to age- and sex- matched controls as well as to evaluate the correlation between phase-based connectivity and EF performance.

**Methods:**

Sixty-one participants with FXS (5.9-45.7; 54% males) and 71 age- and sex-matched TDC (5.9-48.2) completed a five-minute resting state EEG recording and KiTAP, a computer-based measure testing multiple aspects of EF. We computed debiased-weighted phase lag index (dWPLI), a phase connectivity value, for each gyrus paring in the frontal and prefrontal regions for the alpha (10.5-12.5 Hz) and gamma (30-55 Hz) bands. Linear mixed-effect models were generated with fixed factors of group, sex, and gyri with correction for multiple comparisons. Last, we conducted Spearman's correlations between KiTAP variables and dWPLI values.

**Results:**

The linear mixed-effect model showed significant group x sex x gyrus interactions for both alpha and gamma bands. Individuals with FXS, especially FXS males, demonstrated reduced alpha band connectivity the left and right frontal regions and increased gamma band connectivity in the right frontal and left prefrontal regions compared to TDC. Increased error rates on EF tasks of inhibition, flexibility, and distractibility were associated with reduced alpha band connectivity within the right frontal regions and increased bilateral gamma band connectivity.

**Conclusions:**

During high-density resting state EEG study, we documented increased frontal gamma band connectivity and reduced frontal alpha band connectivity in FXS compared to TDC. As expected, these findings were particularly pronounced among males, implicating hyper-connectivity within frontal brain regions in FXS, especially among males, as previously found. We also report relationships between resting state frontal hyper-connectivity and executive dysfunction in FXS. These findings suggest increased connectivity within high frequency (gamma) bands may impair EF performance whereas increased connectivity within lower frequency (alpha) bands may provide compensatory support for EF in FXS. Our study supports and extends previous findings demonstrating excitatory-inhibitory imbalance in FXS, and for the first time links these findings to executive dysfunction. Together, these findings provide important insight into potential mechanisms of deficit in EF in FXS and future directions for treatment intervention.

---

**Background:**

Individuals with neurodevelopmental disorders (NDDs), including autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) demonstrate deficits in emotional face processing, which is associated with altered emotional face processing networks. Despite high rates of symptom overlap amongst these NDDs, functional connectivity underlying emotion processing across NDDs compared to typical development (TD) has scarcely been examined.

#### Objectives:

Using magnetoencephalography (MEG) we investigated whole-brain functional connectivity during the presentation of happy and angry faces in ASD, ADHD and TD children to determine possible processing differences. We also performed data-driven clustering to determine whether patterns of connectivity differed amongst the diagnostic groups.

#### Methods:

Happy or angry faces were presented while MEG was recorded in 258 children (5-19 years; ASD=100, ADHD=71, TD=87). Children attended to the colour of the border and ignored the emotional content of the faces (75% of trials). Randomly presented 'catch' trials were included to ensure task attention (25% of trials), identified by the colour of the border, where participants responded with a button press. Time-series for each emotion were derived from 90 cortical and subcortical sources of the AAL atlas using the LCMV beamformer. The phase lag index was used to assess phase synchronization of neural oscillations among sources. Main effects of group, emotion and their interactions were assessed using Network Based Statistics. Group-by-age, group-by-sex, emotion-by-age and emotion-by-sex interactions were tested. For data-driven subgrouping, the main effect of each emotion (happy, angry) compared to the baseline was extracted for each frequency band (theta=4-7Hz, alpha=8-14Hz, beta=15-29Hz, gamma=30-55Hz).

#### Results:

We found a main effect of group in the beta frequency band, with covariates age and sex ( $p_{corr}=0.007$ ). *Post hoc* tests showed that mean network connectivity strength was reduced in ADHD compared to ASD ( $p_{corr}<0.001$ ) and TD ( $p_{corr}<0.001$ ) groups, and in ASD compared to the TD group ( $p_{corr}=0.021$ ; all Bonferroni-corrected for multiple comparisons). The network contained frontal, subcortical and temporal connections, mostly anchored in the left hemisphere, with the most highly connected areas being the left middle frontal gyrus, pallidum and superior temporal gyrus (STG). The network also involved key face processing regions including the bilateral amygdalae, right fusiform gyrus and left insula, along with orbital frontal areas. No significant main effects of emotion, emotion-by-age or emotion-by-sex interactions were found.

We also observed a group-by-emotion interaction in the gamma frequency band ( $p_{corr}=0.026$ ). Greater connectivity to happy compared to angry faces was found in the ADHD, ( $p<0.0005$ ) and TD groups, ( $p=0.011$ ); while the opposite pattern was found in ASD, such that connectivity was greater to angry relative to happy faces, ( $p<0.0005$ ). The network involved connections among bilateral frontal, largely inferior and orbital frontal, along with limbic and temporal brain areas. No group-by-age or group-by-sex interactions were found. Data-driven subgrouping identified two distinct subgroups: NDD-dominant and TD-dominant. Emotion-specific and frequency-specific differences in connectivity were found between subgroups.

#### Conclusions:

Our findings establish atypical frequency- and emotion-specific patterns of functional connectivity between NDD and TD children. Importantly, data-driven clustering highlights no distinction between the ASD and ADHD children.

**516.040** (Virtual Poster) Hearing the World Differently: Examining Predictive Coding Accounts of Autism Using MEG and a Roving Auditory Oddball Paradigm

**H. Rapaport<sup>1</sup>**, R. A. Seymour<sup>2</sup>, W. He<sup>3</sup>, E. Pellicano<sup>1</sup> and P. F. Sowman<sup>3</sup>, (1)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia, (2)Wellcome Centre for Human Neuroimaging, University College London, London, United Kingdom, (3)School of Psychological Sciences, Macquarie University, Sydney, NSW, Australia

#### Background:

According to the 'predictive coding' theory of brain function, our perceptual experience is determined by (a) incoming sensory signals from the world, and (b) stored knowledge and beliefs about the world. The relative influence of sensory signals and prior knowledge on perception is thought to be flexibly adjusted in response to environmental volatility. This flexibility ensures that the perceptual experience is not dominated by unreliable sensory signals, nor by prior knowledge when there is important sensory information to respond to in the world. Differences in brain development – such as in the case of autistic people – could give rise to perceptual experiences that might be vastly different from the norm. The precise nature of this neurodivergence, however, is disputed.

#### Objectives:

Here, we sought to evaluate several competing predictive coding accounts of autism by testing them at the neural level.

#### Methods:

We used paediatric MagnetoEncephaloGraphy (MEG) to record the auditory evoked fields of 10 autistic ( $M_{age} = 6.2$  years, range = 4.2 – 8.6) and 63 neurotypical children ( $M_{age} = 6.1$  years, range = 3.0 – 9.8) as they listened to a roving auditory oddball paradigm. For each participant, we subtracted the evoked responses to the ‘standard’ from the ‘deviant’ pure tones to calculate the mismatch field ‘MMF’: an electrophysiological component that is widely interpreted as a neural signature of predictive coding. Under the ‘hypo-prior’ predictive coding account (Pellicano & Burr, 2012), autistic children should show smaller MMF amplitudes relative to their neurotypical counterparts. Conversely, under the ‘HIPPEA’ account (Van de Cruys et al., 2014), autistic children should show larger MMF amplitudes relative to their neurotypical counterparts.

## Results:

We found no significant differences between the autistic and neurotypical children’s MMF amplitudes. However, between-group differences may have been obscured by within-group, age-related variability in the MMF waveforms. To address this potential confound, we conducted a series of exploratory case-cohort analyses, comparing the MMF amplitudes of each of the 10 autistic children to that of their average-age-matched neurotypical counterparts. Six of the 10 autistic children showed significantly larger MMF amplitudes relative to their neurotypical counterparts. An additional two autistic children likewise showed larger MMF amplitudes relative to neurotypical children, although these differences did not reach significance. We interpret these exploratory findings as offering preliminary evidence in support of the HIPPEA predictive coding account of autism.

## Conclusions:

Given the exploratory nature of the case-cohort analyses, as well the small autistic sample on which it was based, the results need to be both replicated and modelled on a trial-by-trial basis in future work if they are to be used in strong support of the HIPPEA account. If the HIPPEA account is ultimately supported, it would provide a comprehensive and compelling neurocognitive account of why autistic people often perceived the world differently.

### 516.041 (Virtual Poster) Investigating EEG Band Differences in Preschool Children with Autism during Awake and Sleep States

A. Vasista<sup>a</sup>, S. M. Kakur<sup>a</sup>, G. Sarma<sup>a</sup>, S. Rajagopalan<sup>a</sup>, M. W. James<sup>a</sup> and A. Mysore<sup>a</sup>, (1)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India, (2)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India, (3)Neurology, St John's Medical College Hospital, Bangalore, India, (4)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India, Bangalore, India

## Background:

Electroencephalography (EEG) studies in Autism Spectrum Disorder (ASD) have investigated spectral power, coherence of EEG rhythms and asymmetry of the bands across various brain regions. In ASD cohorts, Frontal Alpha Asymmetry has been identified as a potential neural endophenotype[1]. There is inadequate evidence in literature for ascertaining hemispherical dominance or asymmetry using four or more spectral bands. Further, natural sleep state EEG recordings are generally not frequent[2].

## Objectives:

In this study we aim to compute spatial band asymmetries across cerebral hemispheres using EEG in preschool children diagnosed with ASD and compare them with non-ASD age matched clinical controls in both awake and sleep states.

## Methods:

Preschool children between the ages of 2 and 6 years underwent prolonged EEG recording (up to 180 mins) with 64 Channel EGI-GES400 system after sleep deprivation for at least 4 hours. ASD group had 28 children (including 4 females). The clinical controls who were diagnosed with ADHD, Specific Speech Delay, and Global Developmental Delay had 10 children (6 males, 4 females). None of the children were on any medication.

Awake state (ASD= 24, non-ASD=8) and sleep stage 1 (N1)(ASD=19,non-ASD=9), stage 2 (N2) (ASD=18,non-ASD=8) and stage 3 (N3)(ASD=10,non-ASD=7) recordings were included. An artifact free continuous segment of 60s in all 4 states was selected manually. Power Spectral Density was computed for each epoch of 10s duration with 50% overlap using Welch's periodogram. Powers for 4 bands viz. beta [13-30Hz], alpha[8-13Hz], Theta [4-8Hz], Delta [0.5-4Hz] were computed using composite Simpson's rule. All computations were carried out for 36 scalp locations spanning 10 regions in both hemispheres (Left and Right of frontal, central, parietal, temporal, occipital). Asymmetry Indices were calculated for each band averaged per region using difference of natural logarithms[3].

## Results:

In the awake state, non-ASD group had left beta dominance in frontal, temporal and occipital while left occipital was alpha dominant. Theta and delta had right dominance. In the ASD group, all four bands were occipital dominant on the left side. Group differences were found for beta in frontal & delta in central.

In N1, most bands were left dominant in non-ASD, while the ASD group had right dominance for delta and theta in parietal and occipital areas. In N2, most bands were left occipital dominant in non ASD, whereas in ASD, delta and theta were left dominant in central and right dominant in

occipital. In N3, all bands were right dominating at central, while alpha and beta were towards left in temporal in the non-ASD group. In ASD, except alpha in occipital, rest of regions had right dominance for all bands.

#### Conclusions:

In the awake state, left occipital predominance in ASD may demonstrate potential deficits in frontal, parietal and temporal functions including cognition, motivation, emotion, verbal, and executive functions of the left cerebral hemisphere compared to the non-ASD group. [4].

We demonstrate band power differences over multiple cerebral regions indicating differences in activity in terms of spectral density which could be related to trait differences and tendencies.

#### **516.042 (Virtual Poster) Neural Response to Intervention: Alpha Asymmetry and Theta Oscillations of Reward**

**E. Baker<sup>1</sup>, E. Veytsman<sup>2</sup>, T. Choy<sup>3</sup>, J. Blacher<sup>4</sup> and K. K. Stavropoulos<sup>5</sup>,** (1)UC Riverside, Riverside, CA, (2)Graduate School of Education, University of California Riverside, Riverside, CA, (3)University of California, Riverside, Riverside, CA, (4)School of Education, University of California, Riverside, Riverside, CA, (5)School of Education, University of California Riverside, Riverside, CA

---

#### Background:

Autistic individuals demonstrate varied neural responses when anticipating and responding to social and nonsocial rewards. The PEERS social skills intervention is a well-established program that has been shown to increase social behaviors and reward processing using event-related potentials (ERPs) (Baker et al., 2020; 2021). Examining neural oscillations may further inform what is known about reward anticipation and processing in response to intervention, particularly changes from pre- to post-intervention. Oscillatory brain activity may also serve as a meaningful and objective measure of intervention outcome.

#### Objectives:

Examine pre- and post-PEERS intervention effects by measuring alpha asymmetry (during reward anticipation) and theta (during reward response) in 13 autistic teens (ASD) and 11 age and IQ-matched neurotypical (TD) teens.

#### Methods:

Electroencephalography (EEG) was recorded during a social/non-social reward task with ASD adolescents ( $n = 13$ ,  $M_{age} = 14.2$  years) before and after the 16-week PEERS intervention. This group of ASD participants has previously demonstrated enhanced social behaviors after PEERS (see Baker et al., 2021). TD teens ( $n = 11$ ,  $M_{age} = 13.2$  years) had brain activity measured at two time points—16 weeks apart, but did not participate in the intervention. Anticipatory alpha asymmetry (8-12 Hz) was examined in central-temporal-parietal regions in both hemispheres in a time window corresponding with the stimulus-preceding negativity (SPN) component. Post-feedback theta band oscillations (4-6 Hz) were examined in the frontal-midline region in a time window corresponding with the reward positivity (RewP) component.

#### Results:

**Pre-stimulus alpha asymmetry:** A four-way interaction was observed between time, condition, region, and group,  $F(2,21) = 4.46$ ,  $p = .054$ . Post-hoc tests revealed an effect of time in the social condition for the ASD group within the parietal region, such that there was more left hemisphere alpha suppression at Time 1 compared to Time 2,  $F(1,22) = 6.80$ ,  $p = .02$ .

**Post-stimulus theta:** An interaction between group and feedback was observed ( $F(1,25) = 4.08$ ,  $p = .054$ ), such that in the ASD group, larger theta-band activity was observed in the incorrect condition compared to the correct condition ( $F(1,25) = 4.70$ ,  $p = .04$ ).

#### Conclusions:

Approach motivation increased after intervention in the ASD group, evidenced by greater left-hemisphere alpha suppression after intervention in the parietal region. Thus, for the ASD group, more approach motivation was observed in the social condition after intervention, suggesting an enhancement of social motivation after learning social skills in PEERS. Additionally, incorrect feedback elicited larger theta activity vs correct feedback in the ASD group, indicating an increased evaluation of negative feedback. As such, adolescents with ASD appear to find incorrect feedback more salient than correct feedback. In sum, these objective and brain-based findings demonstrate that social motivation was strengthened in teens with ASD after PEERS.

#### **516.043 (Virtual Poster) Relative Alpha Power in Autism Spectrum Disorder: Sex Differences and Association with ASD Features**

**C. E. Finn<sup>1</sup>, A. Naples<sup>2</sup>, J. M. Wolf<sup>3</sup> and J. McPartland<sup>1</sup>,** (1)McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Child Study Center, Yale Child Study Center, New Haven, CT

---

**Background:** Autism spectrum disorder (ASD) affects males at a rate of 4:1 compared to females (Baird et al., 2006), and females with ASD tend to exhibit fewer repetitive behaviors (Mandy et al., 2012) and lower IQ (Banach et al., 2009). These sex differences remain poorly understood, and there

is increasing effort to understand neural mechanisms involved. Alpha activity is an electroencephalographic (EEG) measure of particular interest given that shifts in alpha activity throughout childhood index neural development (Boersma et al., 2011). In typically developing (TD) children, females exhibit reduced alpha power, indicating increased neural activation (Clarke et al., 2001). Recent research found similar sex differences in children with ASD (Neuhaus et al., 2021), but there remains a notable lack of literature examining sex differences in alpha activity within this population.

**Objectives:** The current study examined sex differences in relative alpha activity in TD and ASD cohorts of children and evaluated the relationship between relative alpha activity and ASD symptomatology.

**Methods:** Resting EEG data (with eyes closed) and behavioral measures were collected from 72 children with ASD (n=19 female) and 47 TD controls (n=21 female) aged 8 to 18 years. At least 30 seconds of artifact free EEG data were available for each participant. Relative alpha power was extracted from occipital electrodes. Statistical analyses included a two-way ANOVA and post-hoc Tukey HSD to examine sex and diagnostic group differences, and Spearman correlations to examine bivariate relations among EEG and clinical measures.

**Results:** A significant effect of sex on relative alpha power was observed ( $F(1, 112)=11.43, p<.001$ ), such that females showed reduced alpha power. There was not a significant effect of diagnosis on relative alpha power. Post-hoc comparisons indicated that, in the ASD group, males exhibited significantly increased relative alpha power compared to females ( $p=.01$ ). A pattern of increased relative alpha power was also observed in TD males relative to TD females, but the difference was not statistically significant. Among participants with ASD, relative alpha power was positively associated with Social Communication subscale scores on the SRS-2 ( $r(70)=.247, p=.04$ ) and with Restricted Interests and Repetitive Behavior subscale scores on the SRS-2 ( $r(70)=.244, p=.04$ ). Relative alpha power was not associated with SRS-2 scores in the TD group, and there were no sex differences among SRS-2 scores in either cohort.

**Conclusions:** Our results replicate prior findings indicating greater relative alpha power in males with ASD. Notably, sex differences in alpha activity were independent of differences in ASD symptomatology. This finding suggests that females with ASD exhibit greater neural activation at rest and underscores the importance of considering sex differences in EEG power spectra in the context of ASD. It remains to be determined if sex differences in alpha activity reflect a differential mechanistic pathway to social function in ASD. Similar to previous studies (Leno et al., 2018; Neuhaus et al., 2021), findings also suggest that reduced neural activation is associated with more pronounced ASD symptomatology. Future research should further examine the relationship among neurophysiological measures and phenotypic outcomes associated with ASD.

#### **516.044** (Virtual Poster) Resting State EEG Connectivity: Functional Neural Differences in Toddlers and Preschoolers with ASD

**Y. Braverman, S. Faja and M. Surmacz, Boston Children's Hospital, Boston, MA**

Background: Atypical functional connectivity is one of the most widely replicated neural findings in autism spectrum disorder (ASD) (Courchesne & Pierce, 2005, Just et al., 2004, Shepard et al. 2019). Infants later diagnosed with ASD exhibit significantly lower coherence (Righi et al., 2014). Further, positive correlations between connectivity and both social-cognitive functioning and reduced ASD symptom severity support the role of connectivity in behavioral phenotypes (Jaime et al., 2016, Keehn et al., 2015, Mathewson et al., 2012). Yet, inconsistent patterns of functional connectivity suggest that neural substrates may be variably impacted across development. Uddin (2015) suggests that consideration of childhood development is critical to understanding these varying results related to connectivity. Resting EEG functional coherence provides a useful tool to characterize connectivity differences in early development as it (a) is easier to collect in younger children than fMRI and (b) patterns of EEG coherence during resting tasks in ASD vs non-ASD samples may provide the foundation for contextualizing coherence differences at older ages and during other event-related paradigms. To our knowledge, few EEG studies have examined awake resting coherence among toddlers and preschool children with ASD; however, examining coherence in this population may be critical to delineate the course of functional neural differences in children with ASD.

**Objectives:** To evaluate whether resting state EEG coherence (a) differs in young children with ASD compared to age matched non-ASD children and (b) correlates with core behavioral features of ASD, namely an average of social and communication skills scores from the Vineland Scales of Adaptive Functioning (VABS-3).

**Methods:** Parents completed the VABS-3 for two- and four-year-old children with ASD (ns = 12 and 24, 66% and 87.5% boys, respectively) and no developmental concerns (ns = 20 and 31, 55% and 58% boys). Resting EEG coherence was computed in this sample in the theta band (4-7.99 Hz) interhemispherically as well as in the left and right hemispheres. Independent t-tests examined whether EEG coherence significantly differed in the (a) left (b) right, or (c) across hemispheres between diagnostic groups. When differences were significant, we examined whether (1) IQ correlated with coherence and (2) coherence predicted the socialization and communication composite score (SCC).

**Results:** In both the two- and four-year-old group, EEG coherence in the right hemisphere was significantly reduced in ASD compared to non-ASD participants ( $ps = .030$  and  $.017$ ). IQ did not significantly correlate with coherence. Coherence significantly predicted SCC at both ages (standardized  $\beta s = .391$  and  $.317, ps = .027$  and  $.019$ ). Coherence did not differ significantly in the left hemisphere or interhemispherically.

**Conclusions:** Children with ASD exhibited reduced right hemispheric coherence at age 2 and age 4 compared to non-ASD children. Right hemispheric coherence positively correlated with the SCC, suggesting that improved socialization and communication skills are correlated with increased functional coherence. This extends previous findings showing reduced coherence in older children (Shepard et al. 2019) and lends preliminary support for using resting coherence in early development as a tool to characterize neural and behavioral differences in ASD.

#### **516.045** (Virtual Poster) Similarities and Differences within a Pediatric Sample of High Intellectual Potential Vs High Functioning Autism: The Potential Role of Event Related Potentials (ERPs)

#### Background:

High Intellectual Potential (HIP) and High Functioning Autism (HFA), are two different conditions, which share some clinical features such as specific cognitive profile (greater verbal skills, executive functions deficits), social skills difficulties as well as the presence of restricted and specific area of interests. Moreover, an atypical neurodevelopmental trajectory has been described in both, HFA and HIP. As a matter of fact, in clinical and research activities, the distinction between these conditions has proved to be challenging.

Neurophysiological techniques, such as Event Related Potentials (ERPs)- particularly referred to Mismatch Negativity (MMN) and P300 paradigms- have been used in these populations, in order to better evaluate psychophysiological features. Specifically, evidences of reduced MMN amplitude have been found in the HFA individuals. By contrast, few and contrasting results are available for the HIP population, with no previous studies aimed to investigate differences within ERPs indexes between HIP and HFA and the correlation to clinical features.

#### Objectives:

To characterize a pediatric sample of HIP individuals in comparison to those with HFA and to neurotypical developmental (NTD) ones, from clinical and neurophysiological perspectives, particularly referred to ERPs.

#### Methods:

A sample of 43 individuals (age range 6-16 years) was included, divided into three groups: HIP (n 16), HFA (n 17) and NTD (n:10). The sample was recruited from the Child Psychiatry Unit of the University of Rome Tor Vergata Hospital. The HIP and the HFA groups underwent a standardized clinical assessment of cognitive and adaptive skills, autistic symptoms, executive functions and behavioral aspects. The NTD group underwent a screening evaluation of IQ and autistic symptoms. Finally, the whole sample underwent ERPs recordings, aimed to evaluate the MMN and the P300 paradigms.

#### Results:

From a clinical perspective HIP individuals demonstrated greater cognitive ( $p<0.001$ ) and adaptive skills ( $p<0.001$ ) as well as neuropsychological performances if compared to HFA ones. Moreover, our data highlighted the presence of subthreshold autistic symptoms ( $p=0.004$ ) as well as adaptive skills impairment ( $p=0.010$ ) in HIP population when compared to the NTD ones.

Interestingly so, no significant alterations of neurophysiological patterns came out within the HIP and NTD group, with evidence of reduced Mismatch Negativity (MMN) amplitude only in the autistic population (HFA vs HIP:  $p=0.001$ ; HFA vs NTD:  $p<0.001$ ; HIP vs NTD:  $p=0.99$ ). Finally, no differences on P300 component came out (HIP vs HFA  $p=0.347$ ; HIP vs NTD  $p=0.420$ ; HFA vs NTD  $p=0.616$ ).

#### Conclusions:

Despite similarities within the intellectually gifted individuals and the ones with autism came out at a clinical level, from a neurophysiological perspective a distinct characterization between groups came out. Particularly, our results highlight the potential role of MMN index as candidate *neuromarker* for autistic condition, thus starting to provide a more informative characterization of the HIP phenotype in comparison to those with autism and to NTD ones.

#### **516.046 (Virtual Poster)** Use of Computer Vision Analysis for Coding Visual Attention during EEG Experiments

**D. Y. Isaev<sup>1,2</sup>, S. Major<sup>3</sup>, C. Sullivan<sup>4</sup>, J. N. Grapel<sup>5</sup>, T. Calnan<sup>1</sup>, Z. Chang<sup>4</sup>, J. M. Di Martino<sup>6</sup>, G. Sapiro<sup>6</sup> and G. Dawson<sup>7</sup>**, (1)Duke Center for Autism and Brain Development, Durham, NC, (2)Department of Biomedical Engineering, Duke University, Durham, NC, (3)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Duke University, Durham, NC, (5)Psychology, Duke Center for Autism and Brain Development, Durham, NC, (6)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (7)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC

---

#### Background:

Traditionally, EEG experiments have required human coding to determine periods in which participants attended to the visual stimulus, which is critical for visual experiments that require the participant to be actively viewing the stimulus. Typically, researchers manually code the participant's visual attention in real-time, or code videos taken of the participant during EEG acquisition post-hoc. This is a labor-intensive process and relies on human judgement. The use of computer vision analysis (CVA) for the automatic coding of participant visual attention during EEG experiments could reduce the time burden of human coding and minimize the variation in attention coding strategies.

## Objectives:

We hypothesized that automatic CVA codes of eye gaze coordinates in the presentation screen plane, as well as head pose descriptors pitch, yaw, and roll, could reliably predict visual attention to the screen. To compare CVA to human coding, visual attention to the screen was coded in two ways by a human: first, eye gaze on the screen, and second, head position towards the screen. Our objective was to compare the CVA codes with the human codes to validate the use of CVA measures of visual attention in a sample of young children with autism.

## Methods:

To assess the reliability of CVA coding of attention in young children, we compared human vs. CVA coding of attention during EEG acquisition for 22 autistic children, 3-8 years of age. We videotaped the child's face using a separate camera while EEG was recorded. Inattention (moments when the child's gaze/eyes were not directed towards the screen) and head turns were hand coded. Start and endpoint of each occurrence of inattention or head turning was noted. Because inattention was part of head turning, any occurrence that included both head turning and inattention was coded as a head turn. 778,612 frames of data were hand coded. CVA measures for gaze ("X" and "Y" coordinates in the presentation screen plane) and head pose (pitch, yaw, and roll) were automatically extracted from the video (see Fig. 1). A general linear mixed effects logistic regression model with CVA measures as predictors was fit to the data separately for "head turn" and "gaze off screen" as a binary target variable.

## Results:

Head turn and gaze off screen events were detected by the model with AUC = 0.95 and AUC = 0.90, respectively, with all CVA measures being significant ( $p < 0.001$ , see Table 1). For the prediction of gaze off screen events, gaze X (horizontal axis) was the strongest CVA predictor (Odds Ratio [OR] = 1.22). For the prediction of head turns, Yaw was the strongest CVA predictor (OR=1.12).

## Conclusions:

Our results confirm that CVA measures can reliably code participants' attention during EEG acquisition. Thus, compared to human annotators, CVA may provide an efficient and more systematic way of coding attention in EEG experiments. However, the decision thresholds can be subject-dependent, thus requiring calibration of CVA measures before the experiment and possibly using machine-learning techniques to predict subject-specific thresholds.

### 516.047 (Virtual Poster) Amplitude of Low Frequency Fluctuations during Resting State fMRI in Autism

**K. A. Smitha<sup>1</sup>, K. L. Coburn<sup>1</sup>, M. E. Beckerson<sup>2</sup> and R. K. Kana<sup>2</sup>,** (1)Department of Psychology, University of Alabama, TUSCALOOSA, AL, (2)Department of Psychology, University of Alabama, Tuscaloosa, AL

**Background:** Disrupted brain functional connectivity has been widely reported as a neurobiological signature of autism (Maximo, Cadena, Kana, 2014). Resting state functional MRI (rs-fMRI) studies provide an excellent platform for examining spontaneous low frequency fluctuations and their temporal correlations during rest (Fox & Raichle, 2007). The resting amplitude of low-frequency fluctuations (ALFF) and fractional amplitude of low frequency fluctuations (fALFF) are such measures which have been used only sporadically in autism. The ALFF and fALFF measures can provide more insights into the underlying mechanisms of brain functioning in autism.

**Objectives:** The goal of this rs-fMRI study is to quantify the differences in ALFF and fALFF measures in autistic children in comparison with typically developing (TD) children.

**Methods:** rs-fMRI data from 73 children (44 autistic, mean age =  $8.83 \pm 2.75$  years; and 29 TD, mean age =  $9.02 \pm 1.97$  years) were obtained from the NYU Langone Medical Center of the Autism Brain Imaging Data Exchange (ABIDE II). Imaging was done on a 3T Siemens Allegra MRI Scanner, and the participants were instructed to keep their eyes open during rest. All processing of ALFF and fALFF measures were done using the CONN Connectivity Toolbox (conn20b; [www.nitrc.org/projects/conn](http://www.nitrc.org/projects/conn)) and SPM12 software ([www.fl.ion.ucl.ac.uk/spm/](http://www.fl.ion.ucl.ac.uk/spm/)). Harvard-Oxford Cortical atlas was used for selecting the regions of interest (ROI) and Networks. A two-sampled t-test and a 2 Group (ASD, TD) x 4 Networks [Default Mode Network (DMN), Salience Network (SN), Frontoparietal Network (FPN) Language Network (LN)] repeated measures ANOVA was conducted to test the difference in ALFF and fALFF values between autistic and TD participants. We hypothesized that low frequency fluctuations in DMN would be significantly different between the two groups. In addition to whole brain analysis to determine group differences in ALFF and fALFF, regression analyses were conducted with age and Full-Scale IQ as covariates.

**Results:** The ANOVA revealed a main effect of group for both ALFF and fALFF values, for DMN and SN. The ALFF values were found to be significantly reduced in autistic, relative to TD children, in DMN [ $F(1,71)=4.45$ ,  $p=0.38$ ] and SN [ $F(1,71)=10.73$ ,  $p=0.002$ ]. The fALFF values were found to be significantly reduced in autistic, relative to TD children, in SN [ $F(1,71) = 4.19$ ,  $p=0.045$ ]. No significant difference was found in FPN or LN. Whole brain analysis controlling for age and FSIQ revealed decreased ALFF and fALFF values in autistic, relative to TD, children in posterior and anterior cingulate cortex and superior parietal areas.

**Conclusions:** These findings suggest that the alterations in brain connectivity widely reported in autistic individuals may underlie differences in low frequency fluctuations in key resting state networks, such as the DMN, and networks involved in task regulation and attention switching such as the SN. Such intrinsically different network level responses in autistic participants may have implications for task-level recruitment and synchronization of brain areas, which in turn may impact optimal cognitive functioning in this population.

**516.048 (Virtual Poster)** Association between Eyes Closed Resting State Alpha EEG Power and Social Responsiveness in Youth with and without ASD: The Gendaar Study

**M. Premkumar<sup>1</sup>, M. Santhosh<sup>2</sup>, K. Pelphrey<sup>3</sup>, S. J. Webb<sup>4</sup>, E. Neuhaus<sup>1</sup> and G. A. Consortium<sup>1</sup>,** (1)Seattle Children's Research Institute, Seattle, WA, (2)Center for Child Health, Behavior and Development, Seattle Children's Research Institute, Seattle, WA, (3)University of Virginia, Charlottesville, VA, (4)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA

---

**Background:** Autism Spectrum Disorder (ASD) is a neurodevelopmental disorder characterized by deficits in communication, and social impairments. Alpha power, EEG activity between 8 and 12 Hz, is found present during quietly resting with greater power (amplitude squared) when the individual's eyes are closed than when eyes are open. This is thought to reflect increased cortical activation (decreased power) when eyes are open in preparation for attention and cognition (Klimesch, 2012). Previous research has found lower alpha power in individuals with ASD compared to typically developing (TD) (Neuhaus et al., 2021, review Wang et al, 2013) and has been associated with attention and cognition and social understanding and imitation in individuals with ASD (Neuhaus et al., 2021; Perry et al., 2011).

**Objectives:** To evaluate association between eyes closed EEG resting state alpha power and social responsiveness in youth with and without ASD by gender and diagnosis.

**Methods:** Data were collected from 152 youth (ASD = 76) ages 8-17 years, from an NIH funded study investigating sex and gender differences in youth with ASD. Youth sat with eyes closed while high density EEG data was collected. Data were processed per Neuhaus et al. (2021). A fast fourier transformation (FFT) was applied to artifact free EEG data to extract alpha power for central and posterior electrodes. Regions of interest (ROIs) for alpha power were calculated over: left frontal (LF: 23, F3-24, 27, 28), mid frontal (MF: 5, FZ-11, 12, 16), right frontal (RF: 3, 117, 123, F4-124), left central (LC: 35, 36, 41, 42); left posterior (LP: 51, P3-52, 59, 60) mid central (MC:7, 31, 80, 106); mid posterior (MP: 62, 71, 72, 76); right central (RC: 93, 103, 104, 110); and right posterior (RP: 85, 91, 92, 97). Parents of children completed the Social Responsiveness Scale-2 (SRS-2) which is a 65-item rating scale measuring autism traits. A series of one-way ANOVAs and correlations were conducted to evaluate the differences in frontal, central and posterior alpha power x group (ASD/TD), gender (male/female) and associations with social responsiveness. We previously report on EEG alpha power during eyes open calm viewing (Neuhaus et al., 2021) and extend this work to the eyes closed resting condition.

**Results:** Preliminary analysis shows significant main effect of diagnosis for eyes closed alpha power in LF, MF, RF, LC, MC, MP, RC and RP regions ( $F(1,150)s > 6.14, ps < .05$ ). No significance was observed for the LP region ( $F(1,150) 2.17, p = .14$ ). Power was significantly lower in the ASD group compared to the TD group. Within the ASD group, correlations between the SRS total score and alpha power was non-significant for any regions, including the SCI subscale ( $p = > .05$ ).

**Conclusions:** Initial findings are consistent with prior research suggesting alpha power is reduced in youth with ASD when compared to TD, and extends this work to EEG acquired during eyes closed. No significant correlations were observed with SRS-2 parent report of autism traits. Additional analysis will include additional phenotypic correlates (Vineland and verbal/nonverbal IQ) and will examine relations by gender.

**516.049 (Virtual Poster)** Bringing EEG from the Lab into the Clinic for Autism Biomarker Implementation

**R. Haartsen<sup>1</sup>, T. Del Bianco<sup>1</sup>, L. Mason<sup>1</sup>, P. E. Springer<sup>2</sup>, M. Potter<sup>1</sup>, W. L. Mackay<sup>3</sup>, C. du Plessis<sup>3</sup>, P. Smit<sup>4</sup>, H. J. Odendaal<sup>3</sup>, E. Loth<sup>1</sup> and E. J. Jones<sup>1</sup>,** (1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Department of Paediatrics and Child Health, Stellenbosch University, Cape Town, South Africa, (3)Department of Obstetrics and Gynecology, Stellenbosch University, Cape Town, South Africa, (4)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom

---

**Background:** Biomarkers from electroencephalographic (EEG) measures may help identify young autistic people. EEG methods have great potential for use in field and clinical settings due to their scalability, relatively low costs, and portability. Combined EEG and eye-tracking (ET) may furthermore help improve data quality. EEG recordings while watching social and non-social videos are suitable for children across developmental stages.

**Objectives:** In this study we aimed to examine the feasibility of the implementation of an EEG-ET paradigm in a large longitudinal study at a clinical site in South Africa. We tested how demographic and clinical variables relate to data availability and neural oscillations across children.

**Methods:** 100 children from the Safe Passage Study (Perinatal Alcohol SIDS and Stillbirth (PASS) Network) follow-up participated, of whom 76 provided sufficient EEG and ET data - including 31 females, mean age = 8.19(2.23), mean WASI FSIQ = 74(12.25). The videos consisted of 2 women singing nursery rhymes (social condition), and spinning toys (non-social condition), with a duration of 1 minute each, and were presented twice. A 20-channel gel-based Enobio EEG system and screen-based Tobii Pro X2 eye-tracker were used. Data availability was quantified using the number of clean trials (NCT). For both conditions we calculated neural oscillatory measures - log theta (4-7Hz) and alpha (8-12Hz) power across frontal and central regions - and proportional looking time (PLT) - ratio between the number of gaze samples on the scene and the total valid samples. We set up 3 mixed models assuming NCT /alpha /theta power as dependent variables, demographic and clinical variables (sex, age, FSIQ, Childhood Autism Rating Scale, maternal years in education) as fixed effects, with varying intercepts per participant, and condition and region as random slopes.

**Results:**

Participants provided 74% clean trials on average (SD = 15%), and average PLT was 86% (SD = 14%). The models showed 1) higher NCT in the non-social condition (Coef. = 10.28%, SE = 3.47, p-value = 0.003), which decreased with higher CARS scores (Coef. = -0.76%, SE = 0.21, p-value =

0.0003) 2) a decreasing effect of age on alpha (Coef. = -0.05, SE = 0.02, p-value = 0.04) 3) higher theta in the social condition (Coef. = 0.07, SE = 0.02, p-value = 0.003).

**Conclusions:** This study demonstrated good EEG and ET data quality in a clinical setting. The high NCT allows for high inclusion rates. The observed interaction from condition and autistic traits on the NCT may arise from preferential engagement and/or marked individual variability in the social condition. We found a condition effect for theta power and a developmental change for alpha power, which are both consistent with previous findings. Together, these findings show good potential for use of EEG-ET methods in large scale field developmental studies examining EEG biomarkers for autism.

**516.050 (Virtual Poster)** Elevated E/I Ratio Is Associated with Intellectual Disability in Children with Autism

**V. O. Manyukhina<sup>1</sup>, A. O. Prokofyev<sup>1</sup>, I. A. Galuta<sup>1</sup>, D. E. Goiaeva<sup>1</sup>, T. S. Obukhova<sup>1</sup>, J. F. Schneiderman<sup>2</sup>, D. I. Altukhov<sup>1</sup>, T. A. Stroganova<sup>1</sup> and E. V. Orekhova<sup>1</sup>,** (1)MEG-Center, Moscow University of Psychology and Education (MSUPE), Moscow, Russian Federation, (2)Department of Clinical Neurophysiology, Institute of Neuroscience and Physiology, Sahlgrenska Academy, University of Gothenburg, Gothenburg, Sweden

---

**Background:** An altered balance of neuronal excitation and inhibition (E-I balance) might be implicated in the co-occurrence of autism and intellectual disability, but this hypothesis has never been tested. E-I balance changes can be estimated from the spectral slope of the aperiodic 1/f neural activity.

**Objectives:** Herein we used magnetoencephalography (MEG) to test whether the 1/f slope would differentiate ASD children with and without intellectual disability.

**Methods:** MEG was recorded at rest with eyes open/closed in 49 boys with ASD aged 6-15 years with a broad range of IQs, and in 49 age-matched typically developing (TD) boys. The cortical source activity was estimated using individual brain models and the LCMV beamformer approach. By fitting a linear function to the source activation spectra in the 35-45 Hz range, we extracted the 1/f slope.

**Results:** The grand averaged 1/f slope was steeper in the eyes closed than in the eyes open condition, but had high rank-order stability between these conditions. In line with the previous research, the slope flattened with age. Children with ASD and below-average (<85) IQ had flatter slopes than either TD or ASD children with normal IQ. These group differences could not be explained by differences in signal-to-noise ratio or power of periodic (alpha and beta) activity.

**Conclusions:** The atypically flattened spectral slope of aperiodic activity in children with ASD and below-average IQ suggests a shift of the global E-I balance toward neuronal hyper-excitation. The spectral slope can provide an accessible non-invasive biomarker of the E-I ratio for translational research and making objective judgments about treatment effectiveness.

**516.051 (Virtual Poster)** Fewer Transient Alpha Frequency Events Predict Phase Synchronization Impairments during the Sensory Auditory Chirp in Fragile X Syndrome

**G. Westerkamp<sup>1</sup>, L. E. Ethridge<sup>2</sup>, C. A. Erickson<sup>1</sup>, R. Liu<sup>1</sup>, E. Blank<sup>3</sup>, M. Miyakoshi<sup>4</sup>, L. M. Schmitt<sup>5,6</sup>, E. Smith<sup>6</sup>, L. A. De Stefano<sup>6</sup>, K. Cullion<sup>3</sup>, K. Dominick<sup>6</sup>, R. Shaffer<sup>7</sup>, J. A. Sweeney<sup>8</sup> and E. V. Pedapati<sup>1</sup>,** (1)Psychiatry, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)Pediatrics, University of Oklahoma Health Science Center, Oklahoma City, OK, (3)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (4)Schwartz Center, University of California San Diego, San Diego, CA, (5)Pediatrics, University of Cincinnati College of Medicine, Cincinnati, OH, (6)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (7)Division of Developmental and Behavioral Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (8)University of Cincinnati College of Medicine, Cincinnati, OH

---

**Background:** Sensory hypersensitivity is common in Fragile X Syndrome (FXS) and can be quantified with EEG (1). For example, individuals with FXS do not mount precise neural responses to the sensory auditory chirp and have excessive background gamma activity. Resting-state EEG studies have shown decreased alpha power and alpha power is commonly associated with . To date, alpha activity at the trial level is poorly understood but is predicted to have an impact on sensory processing (2). Previous work has observed that high-power beta spectral events can predict sensory function across species (3).

**Objectives:** 1) studying transient alpha frequency events instead of spectral average trial data may reveal mechanisms related to abnormal sensory processing in FXS and 2) study relationship of novel analysis with conventional measure of sensory auditory chirp intertrial coherence.

**Methods:** Auditory event related potentials (ERPs) were obtained from 17 adolescents and adults with FXS and 17 age- and sex-matched healthy controls using 128-channel EEG. Subjects heard a sensory auditory chirp generated using an amplitude-modulated 1000-Hz tone linearly increasing in frequency from 0–100 Hz over 2 s. We calculated intertrial coherence (phase synchrony) and identified high-power alpha spectral events using the Jones laboratory spectral events toolbox (3).

**Results:** Transient alpha events were successfully detected across both groups (**Fig. 1A**). In FXS the alpha event rate was between .6 to .9 events for a 2.5 second trial (**Fig. 1B Left**). On average, there were significantly fewer alpha events per a 2.5 s trial in FXS compared to controls ( $p < .001$ ; **Fig. 1B Right**). Interestingly, in FXS a higher alpha rate (in the direction of controls) was significantly associated with greater phase locking to the sensory auditory chirp ( $R = .45$ ,  $p < .001$ ; **Fig. 1C**).

**Conclusions:** Transient spectral events are a novel approach to understanding trial level neural responses in EEG data that may overcome limitations of trial averaged data. We show a markedly reduced alpha event rate in FXS which is associated with a decreased ability to phase synchronize with sensory perception. Spectral events in ERP neural activity may be predictive of subject-specific features of trial-averaged tasks and may pose a novel method of understanding neurophysiology in neurodevelopmental disorders.

## **516.052** (Virtual Poster) Imbalanced Empathy in Children with Autism Spectrum Disorder: Evidence from Hemodynamic Responses Measured By Functional Near-Infrared Spectroscopy

**G. Liu<sup>1</sup>, T. Li<sup>1</sup>, W. Ni<sup>2</sup> and L. Yi<sup>1</sup>**, (1)School of Psychological and Cognitive Sciences and Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China, (2)School of Psychological and Cognitive Sciences, Peking University, Beijing, China

### Background:

Deficits in empathy have been widely reported in individuals with Autism Spectrum Disorder (ASD; Bons et al., 2013; Hadjikhani et al., 2014; Rogers et al., 2007). The empathy imbalance hypothesis (EIH) proposed that individuals with ASD may display intact or even heightened emotional contagion, accompanying by a perspective-taking deficit (Smith, 2009). However, this hypothesis has not been fully examined yet.

### Objectives:

The current study investigates the imbalanced empathy and empathy-related prosocial behaviors in children with ASD and typically developing (TD) controls, using the functional near-infrared spectroscopy (fNIRS) technique. We aimed to provide new evidence for the inappropriately empathic reactions to others' pain in children with ASD in terms of their hemodynamic responses, as well as their behavioral indices.

### Methods:

We used the moral reasoning task modified from Cheng and colleagues (2014). This task included two experimental conditions depicting an individual's limb in painful situations or non-painful control situations. Each condition consisted of 10 trials, and each trial lasted for about 12 sec (3 sec for stimuli display, about 3 sec for behavioral rating, and 6 sec for inter-trial rest).

Twenty-three 5- to 7-year-old children with ASD and twenty-three age-matched TD controls were shown static images depicting an individual's limb in pain or control situations. Their hemodynamic responses were recorded by optical imaging instruments (Nirsport, NIRx Medical Technologies) with 46 measure channels covering the somato-sensory cortices (SI/SII), temporo-parietal junction (TPJ), and temporal regions (Figure 1a). They were asked to rate the pain intensity of the person. After the scanning, children were asked to share some stickers out of 10 to an anonymous child who was suffering in pain.

### Results:

We found that (a) compared with the TD controls, children with ASD showed increased brain activation in the SI/SII (channels 27, 33, 38, and 41), TPJ (channels 40 and 46), and the temporal areas (channels 16, 22, and 35) when perceiving others' pain (Figure 1b) but no differences in non-painful control situations; b) children with ASD repeatedly overestimated the pain intensity of other people (Figure 2a); and (c) children with ASD were less willing to share their stickers than the TD peers (Figure 2b).

### Conclusions:

Our study proved imbalanced empathy and reduced empathy-related prosocial behaviors in children with ASD. These findings indicated that the impaired empathic reactions in children with ASD may be explained by their hyperarousal to the pain stimuli, which interferes cognitive processing towards others and reduces empathic behaviors.

## **516.053** (Virtual Poster) Neural Effects of Sham-Controlled Alpha Auditory Entrainment in Fragile X Syndrome: Pilot Study

**E. Blank<sup>1</sup>, M. Miyakoshi<sup>2</sup>, L. E. Ethridge<sup>3</sup>, G. Westerkamp<sup>4</sup>, L. M. Schmitt<sup>5</sup>, C. A. Erickson<sup>6</sup>, R. Liu<sup>7</sup>, E. Smith<sup>8</sup>, L. A. De Stefano<sup>9</sup>, K. Cullion<sup>1</sup>, K. Dominick<sup>1</sup>, R. Shaffer<sup>1</sup>, J. A. Sweeney<sup>8</sup> and E. V. Pedapati<sup>4</sup>**, (1)Cincinnati Childrens Hospital Medical Center, Cincinnati, OH, (2)Schwartz Center, University of California San Diego, San Diego, CA, (3)Pediatrics, University of Oklahoma Health Science Center, Oklahoma City, OK,

**Background:** Fragile X Syndrome (FXS), a monogenetic neurodevelopmental disorder, has a variable phenotypic presentation, including autistic symptomatology, cognitive disability, and sensory hypersensitivity. FXS subjects do not mount precise neural responses to the sensory auditory chirp and, instead, have “noisy” asynchronous gamma activity (Ethridge, 2017). These changes may be involved in the reduced ability to detect signal from noise and represent potential tractable targets for entrainment.

**Objectives:** We hypothesized that external alpha auditory entrainment (AAE) of corticothalamic drive would individually modulate and normalize peak power frequency with the ultimate goal to increase the ability to mount precise neural responses to stimuli and diminish asynchronous gamma “noise” in FXS. We aim to measure neural responses to sham controlled AAE stimulus including quantification of 1) individual response variability, 2) regional causality analysis of AAE information outflow, 3) peak frequency response in FXS during AAE.

**Methods:** We performed AAE on 8 age- and sex-matched subjects (N=4 FXS, N=4 control; ages 6-48) using a block-design AAE stimulus that creates a differential rhythm between the left and right ear starting at high theta range (7-Hz) through high alpha (13-Hz) in 2 Hz steps on a 500 Hz sine carrier tone. The sham stimulus was the carrier tone alone. Subject-level neural responses to continuous EEG (128-channels) were measured and analyzed measured through AAE blocks.

**Results:** We demonstrate spectral response variability to AAE (controlled by sham) across eight subjects (**Fig. 1A**). Using causality analysis (direct directed transfer function), we observed alpha phase entrainment from temporal lobes to frontal, central, and occipital regions (**Fig. 1B**). In a 15 year old FXS subject we identified both an endogenous peak frequency in the theta range and a novel alpha peak frequency around 10 Hz (and mu rhythm) emerged in the presence of AAE (**Fig. 1C**). AAE appeared to increase alpha power and decrease theta power over sham AAE in this subject (**Fig. 1D**).

**Conclusions:** We observed highly individualized physiological changes across all 8 subjects following sham controlled AAE. In one participant with FXS, we observed reversal of EEG power abnormalities. The findings support speculation that alpha entrainment that may provide compensatory action within the FXS brain. To what degree AAE can improve signal-to-noise abnormalities in well-characterized paradigms such as the sensory auditory chirp or has therapeutic potential remains an open question.

#### **516.054 (Virtual Poster)** Predictive Coding in Autism Spectrum Disorder: Electrophysiological Alterations in Early Auditory Predictive Processing As Potential Markers for Autistic Symptomatology

**T. van Laarhoven<sup>1</sup>, J. J. Stekelenburg<sup>1</sup>, M. Eussen<sup>2</sup> and J. Vroomen<sup>1</sup>, (1)Cognitive Neuropsychology, Tilburg University, Tilburg, Netherlands, (2)Yulius Mental Health Organization, Dordrecht, Netherlands**

---

**Background:** Autism spectrum disorder (ASD) is a pervasive neurodevelopmental disorder that has been linked to a range of perceptual processing alterations, including hypo- and hyperresponsiveness to auditory stimulation. A recently proposed theory that attempts to account for these symptoms suggest that autistic individuals have a decreased ability to anticipate upcoming sensory stimulation.

**Objectives:** If the ability to anticipate upcoming sensory stimulation is indeed decreased in ASD, perception in ASD could be less affected by prior expectations and more driven by sensory input. Here, we tested this hypothesis with a series of event-related potential (ERP) studies in which we examined the neural correlates of motor-auditory prediction (N1 attenuation), visual-auditory prediction error (omission N1) and deviancy detection of auditory, visual and audiovisual speech (MMN).

**Methods:** In a series of ERP studies, we first compared the electrophysiological brain response to self- versus externally-initiated tones between a group of individuals with ASD and a group of age matched individuals with typical development. Next, we assessed between-group differences in prediction error signaling by comparing ERPs evoked by unexpected auditory omissions in a sequence of audiovisual recordings of a handclap in which the visual motion reliably predicted the onset and content of the sound. Finally, we examined between group differences in deviancy detection of auditory, visual and audiovisual speech by applying a MMN paradigm.

**Results:** The results of our first ERP study showed that, unlike in age-matched participants with typical development, self-initiation of tones through a button press did not attenuate the auditory N1 in autistic individuals, indicating that the ability to anticipate the auditory sensory consequences of self-initiated motor actions might be decreased in ASD. The results of our second study showed that unexpected omissions of a sound of which the timing and content could be predicted by preceding visual anticipatory motion elicited an increased early auditory omission response (oN1) in the ASD group, indicating that violations of the prediction model produced larger prediction errors in autistic individuals when compared to their peers with typical development. Finally, the results of our third study showed that deviancy detection of auditory speech is reduced in autistic individuals, while deviancy detection of visual speech and incongruent audiovisual speech seems to be intact.

**Conclusions:** Taken together, our findings suggest that individuals with ASD may indeed experience difficulties in anticipating upcoming auditory stimulation. Importantly, these difficulties might be due to domain-specific alterations, rather than general impairments in predictive coding. This notion provides potential avenues for future research on electrophysiological markers for autistic symptomatology

**516.055** (Virtual Poster) Relation of Imagination Deficit with Severity ASD Symptoms Associated with N-Acetyl-Aspartyl Glutamate Metabolism Imbalance.

**C. D. Jiménez-Espinoza<sup>1</sup>**, F. J. Marcano Serrano<sup>2</sup> and J. L. González-Mora<sup>3</sup>, (1)Physiology, University of La Laguna, Santa Cruz de Tenerife, Spain, (2)Neurochemistry and Neuroimage Lab., University of La Laguna, Santa Cruz de Tenerife, Spain, (3)University Hospital of Canary Islands HUC, La Laguna, Spain

**Background:** Autism is defined neurodevelopmental disorder characterized by significant impairments in social interaction, and imagination as symptoms highlights. Recently have described been the differences of brain function in voluntary and involuntary imagination. Although, individuals with moderate to severe autism spectrum disorder (ASD) usually manifest a range of deficits related to the voluntary imagination network, its neurological etiology follow unclear. The AQ is a psychometric test has five developmental domains to assess autistic characteristics in adults (social, communication, imagination, attention to detail, and attention switching/tolerance of change), and in this study we will focus on the domain of 'Imagination', that is directly related to the development of social skills in healthy subjects. Previously, we had described been the altered N-Acetyl-aspartyl-glutamate (NAAG) levels found in cingulated cortices by 1H-MRS in individuals with ASD that suggested the neuronal damage. In this sense and following our research line linked to the neuropeptide NAAG as a key mechanism underlying symptoms of ASD, arise the hypothesis of NAA-NAAG metabolism imbalance and their relationship with impairments of the imagination linked to cingulated cortices in ASD.

**Objectives:** To study the participation of neuropeptide NAAG metabolism in the cingulated cortices and their correlation with the AQ domain 'Imagination' associated with ASD severity using 1H-MRS.

**Methods:** We quantified NAAG, and NAA signal in anterior (ACC) and posterior (PCC) cingulated cortices separately from the 1H-MRS assessed in 22 patients with ASD and 44 healthy comparison subjects, matched for age, gender on a 3.0 Tesla MR scanner. We used the 'Imagination' subscale of the Autism Spectrum Quotient (Baron-Cohen et al., 2001), since nine of the ten items on this subscale involve aspects of social imagination. Statistic one-way ANOVA and Bonferroni correction was applied. Pearson correlation hallmarks the goal.

**Results:** Pearson correlation represented graphically, was observed that there is a positive correlation between the AQ domain 'Imagination' and the NAA/NAAG ratio in the ACC ( $r = 0.21$ ,  $p = 0.63$ ) and PCC ( $r = 0.30$ ,  $p = 0.31$ ) in ASD group (see Fig.1). In contrast to TD group, the correlation was negative. However, when was stratified ASD plus TD groups by AQ1, AQ2, AQ3, and AQ4 threshold, was shown a positive correlation in AQ2 ( $r = 0.32$ ,  $p = 0.12$ ), AQ3 ( $r = 0.001$ ,  $p = 0.79$ ), and AQ4 ( $r = 0.47$ ,  $p = 0.50$ ) (see Fig. 2). Highlighting, that in PCC, the AQ2, AQ3, and AQ4 groups maintain a pattern correlation to 'imagination' different than the AQ1 group that was considered (below the mean of the autistic characteristics) as a group of healthy subjects that indicate undisturbed metabolism. These results make us suggest the relation of deficit of Imagination with severity ASD symptoms in PCC, and its correlation with NAA/NAAG imbalance according to, (Vyshedskiy, A., 2020).

**Conclusions:** The opportunity to measure NAAG in cingulated cortices creates a new and promising approach for intensified research on this neuropeptide and on the effects of new venue novel drug candidates in ASD.

**516.056** (Virtual Poster) Relationships Among Social Motivation, Sex, and Neural Response during Vocal Emotion Recognition in Youth with and without ASD

**M. R. Dudi<sup>1</sup>**, T. C. Day<sup>1</sup>, D. Krishnathasan<sup>1</sup> and M. D. Lerner<sup>1</sup>, Psychology, Stony Brook University, Stony Brook, NY

**Background:** Autism spectrum disorder (ASD) is characterized by social communication impairments (APA, 2013) which may stem from differences in social reward processing as posited by the Social Motivation Hypothesis (Chevallier et al., 2012). Social motivation is reduced in children with ASD (Neuhäus, Bernier, & Webb, 2020), specifically in males (e.g., Sedgewick et al., 2016) and partially mediates the association between better facial emotion recognition and faster face processing, measured by Event-Related Potentials (ERPs; Garman et al., 2016). Social motivation and face processing are well studied, yet there is relatively less research on vocal emotion processing. The N100 is an ERP elicited 100 ms after onset of an auditory stimulus that indexes early encoding of sound (Näätänen & Picton, 1987; Paulmann & Kotz, 2008). The N100 is delayed (Korpilahti et al., 2007) and a longer latency is related to poorer vocal emotion recognition in ASD (Lerner et al., 2013). However, the relationship between the N100 and social motivation, and whether a plausible covariate (i.e., sex) better accounts for this relationship, is unclear.

**Objectives:** Examine associations among N100 amplitude and latency (during a standardized vocal emotion recognition task), social motivation, and sex in youth with and without ASD.

**Methods:** Eighty-seven youth with and without ASD completed a vocal emotion recognition task while electroencephalography (EEG) was recorded (Table 1). Social motivation was measured by the parent-report Social Responsiveness Scale, Second Edition (SRS-2) Social Motivation T-Score (Constantino & Gruber, 2012). Relationships among variables were examined using Pearson and point-biserial correlations, and corresponding post-hoc partial correlation analyses controlling for sex.

**Results:** Social motivation impairments were more prevalent in females, compared to males, with ASD and males, compared to females, without ASD (Table 2). In participants with ASD, social motivation and N100 amplitude were correlated (Table 2), and remained so when controlling for sex ( $r(37) = -0.317$ ,  $p < 0.05$ ).

**Conclusions:** A more negative N100 amplitude was associated with lower social motivation in youth with ASD. Youth with ASD who have lower social motivation may exhibit "hyper-orientation" to emotional prosodic cues like youth with ADHD (Chronaki et al., 2015). Females with ASD and

males without ASD group displayed more social motivation impairments, contrary to prior work showing males with ASD exhibit reduced social motivation (e.g., Sedgewick et al., 2016). Since we found social motivation is higher in males with ASD while others have found it is higher in females with ASD (Sedgewick et al., 2016) and still others have not found differences between males and females with ASD (Neuhaus, Bernier, & Webb, 2020), future research should explore when and for whom social motivation differences emerge as a function of sex in ASD. Nevertheless, the association between the N100 amplitude and social motivation remained significant after controlling for sex, suggesting that this relationship is durable even in the face of potential sex-related effects on social motivation.

---

#### Background:

Aberrant mismatch negativity and P50 sensory gating have been demonstrated in individuals with autism spectrum disorder (ASD). The mismatch negativity and P50 sensory gating involve pre-attentive mechanism. Whether the mismatch negativity and P50 sensory gating in ASD can be attributable to the alterations in the resting-state functional connectivity in the brain has not been examined.

#### Objectives:

This study aimed to investigate the mismatch negativity, P50 sensory gating and their interrelationship with functional connectivity in ASD.

#### Methods:

This study recruited 75 ASD participants and 50 TDC. All the participants underwent clinical assessment, mismatch negativity on the oddball paradigm, and resting-state functional MRI. Part of the sample (n=20) also took P50 paradigm. We compared the mismatch negativity, P50 sensory gating, and resting state brain connectivity between ASD and TDC, then examined the relationship between mismatch negativity, P50 sensory gating, and functional connectivity.

#### Results:

The ASD and TDC groups were not significantly different on mismatch negativity, while the ASD group showed N100 sensory gating deficits and a higher functional connectivity between auditory network and thalamus compared to the TDC group. As for the relationship between mismatch negativity and functional connectivity, we found that P3a latency towards duration deviant was negatively correlated with functional connectivity between auditory network and right orbitofrontal cortex. Higher connectivity was related to an earlier response in the orbitofrontal cortex. As for sensory gating paradigm, we found a N100 suppression deficit in ASD was associated with functional connectivity between auditory network and frontal cortex.

#### Conclusions:

Our findings implied that earlier P3a response in ASD was associated with higher intrinsic connectivity between auditory network and orbitofrontal cortex. Whether sensory sensitivity in ASD is related to higher intrinsic connectivity between sensory processing networks warrants further investigation.

**516.058** (Virtual Poster) Spanning the Auditory System: Subcortical and Cortical Auditory Processing of Speech Sounds in Autistic and Typically Developing Children

**E. Matsuba<sup>1</sup>, E. L. Cary<sup>1</sup>, A. Madrid<sup>2</sup>, D. Pacheco<sup>2</sup>, B. Prieve<sup>2</sup> and N. Russo<sup>1</sup>,** (1)Department of Psychology, Syracuse University, Syracuse, NY, (2)Department of Communication Sciences and Disorders, Syracuse University, Syracuse, NY

---

#### Background:

Autistic individuals often report atypical sensory processing, particularly in the auditory domain. However, the neural mechanisms which produce such symptoms are poorly understood. Speech Auditory Brainstem Responses (speech-ABRs) and the Mismatch Negativity (MMN) are neurophysiological measures that capture different levels of auditory processing, such that speech-ABRs reflect subcortical processing whereas the MMN assesses cortical brain activity. These measures are rarely examined together despite their adjacent neuroanatomy and findings that both are atypical in autism.

#### Objectives:

The purpose of the present study was to bridge subcortical and cortical auditory processing of speech sounds by collecting speech-ABRs and the MMN in a sample of autistic children and their age and IQ matched typically developing (TD) peers. In so doing, we test whether the integrity of

subcortical processing measured via the V-O interpeak latency of the speech-ABR could predict the latency of the speech-MMN and whether these differ by group.

#### Methods:

Participants included 11 autistic children (mean age = 12.8) and 11 TD children matched on chronological and non-verbal mental age using the Perceptual Reasoning Index (PRI) of the WASI-II. Participants completed audiological testing, which elicited the speech-ABR using 40ms /da/ syllables with an alternating polarity of 11.1/sec. An oddball paradigm with the syllables /ba/ and /da/ was used to capture the MMN. speech-ABR integrity was measured via the V-O interpeak latency while the latency onset of the MMN was measured via the point at which 30% of the rectified area under the curve was accrued.

#### Results:

The interpeak V-O latency of the speech-ABR significantly predicted the latency of the MMN across participants ( $F(1, 18) = 11.6, p = .00315$ ), such that a longer V-O interpeak latency predicted a later MMN latency across TD and autistic participants. However, visual inspection of the data suggested that this relationship may be weaker in autism, as the latency of the MMN was less variable in this group. No group differences in interpeak V-O latency ( $t(1, 20) = 0.15, p = 0.96$ ) nor MMN latency ( $t(1,20) = 0.00, p = 0.52$ ) were noted.

#### Conclusions:

Preliminary results from this ongoing study suggest that subcortical speech processing can predict cortical speech processing. However, this relationship between the subcortical and cortical auditory system may be different in autistic and TD children, which warrants future investigation. Lastly, the lack of group differences on the subcortical and cortical neurophysiological measures highlights the importance of matching participants on the basis of developmental level in research with atypically developing populations.

#### **516.059 (Virtual Poster)** Task-Based Functional Connectivity Predicts Language Ability of Autistic and Typically-Developing Adolescents Using Connectome-Based Predictive Modeling

**R. Jordan<sup>1</sup>, D. G. Sukhodolsky<sup>2</sup>, J. S. Wolff<sup>3</sup>, T. Evans<sup>4</sup>, K. Pelphrey<sup>5</sup> and J. Eilbott<sup>2</sup>**, (1)Yale Child Study Center, New Haven, CT, (2)Yale Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Neurology, University of Virginia, Charlottesville, VA, (4)University of Virginia, Charlottesville, VA, (5)Autism and Neurodevelopment Disorders Institute, George Washington University and Children's National Medical Center, Washington, DC

**Background:** Communication deficits are a core feature of ASD. While there is significant variability in language ability across autistic individuals, most show some impairment. Language is an important area for assessment and intervention across the lifespan: from infancy when many parents observing speech delay first seek ASD assessment, to childhood when language difficulties are linked to risk for anxiety, to adulthood when they are tied to job attainment and friendship. One way to investigate neural correlates of language deficits is using functional connectivity. Existing work reported decreased activation in the superior temporal gyrus (STG), a region involved in auditory processing. Connectome-based Predictive Modeling (CPM) is a method which predicts individual behavior using such functional connectivity data (connectomes) derived from fMRI. Most studies use fMRI data collected during “rest,” a supposed task-free state; however, recent work calls into question its ecological validity and predictive power.

**Objectives:** Determine CPM’s efficacy in predicting language ability in ASD and TD individuals using connectomes derived from rest and a language task. Explore the role of sex and/or diagnosis on predictive power of these tasks.

**Methods:** Subjects were 144 adolescents (75 girls, 8-17), autistic (ASD,  $n=57$ ) and typically developing (TD,  $n=87$ ). Language ability was assessed with Clinical Evaluation of Language Fundamentals (CELF-4) Core Language Score (range 40-134,  $M=105.6, SD=17.6$ ). MRI scans were collected across several sites. Functional sequences included resting state and a language paradigm where participants listened to streams of nonsense speech. Subjects with mean FD  $>0.35\text{mm}$  were excluded. Connectomes were generated from nuisance-corrected functional data (fmrprep, AFNI) after applying the Shen-268 atlas. We compared the predictive power of resting state and language task on CELF in the entire sample and then explored effects of sex and/or diagnosis on overall predictive power. Finally, we projected features into brain space (Bioimage Suite) and assessed whether brain networks used to make successful predictions were the same across groups and tasks.

**Results:** In the combined sample, the language task was able to predict the CELF Core Language Score ( $R^2=0.07, MSE=287.6$ ), whereas resting state could not. Brain regions involved in the auditory network (e.g., rSTG) had a high degree of predictive power. Within TDs, females appeared to drive the predictive power of the language task ( $R^2=0.10, MSE=87.3$ ). Conversely, within ASDs-only, males appeared to drive the task’s predictive power ( $R^2=0.36, MSE=339.7$ ), recruiting visual and memory processing regions. Additionally, resting state was minimally predictive of CELF in both TD groups (females:  $R^2=0.02, MSE=95.3$ ; males:  $R^2=0.047, MSE=120.3$ ) and in ASDmales.

**Conclusions:** Task-based fMRI connectomes can not only be used in place of traditional resting state to predict behavior and clinical characteristics, but may improve accuracy. Examination of the models underlying these predictions suggest heterogeneity in brain recruitment across sex and diagnosis. While TDs employed a more classic language network, ASDmales used an alternative network. Further examination of ASDfemales’ connectomes may elucidate individual differences that preclude prediction, assisting in design of interventions targeting language deficits in ASD, and increasing favorable mental health outcomes into adulthood. Task-based CPM provides novel insight and a more targeted method to investigate the neural underpinnings of symptoms in ASD.

**516.060** (Virtual Poster) The Dual Pathways of Oxytocin Neural Effects in Youth with ASD: A MEG Study

**A. Korisky<sup>1</sup>, I. Gordon<sup>2</sup> and A. Goldstein<sup>3</sup>,** (1)Gonda multidisciplinary brain research center, Bar-Ilan University, Ramat Gan, Israel, (2)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (3)Department of Psychology, Bar-Ilan University, Ramat Gan, Israel

---

**Background:**

Autism Spectrum Disorders is a neurodevelopmental condition characterized by difficulties in the social domain. In addition to the clinical symptomatology, studies have shown that individuals with ASD tend to present atypical patterns in face perception. Several studies have shown that oxytocin (OT), a naturally occurring hormone that relates to social communication in mammals, can modulate social behaviors in ASD. However, the mechanism underlying the effects of OT in ASD is relatively unknown. One of the possible reasons for this gap in the literature could stem from the lack of research on the effect of OT during the early stages of the perceptual processes using tools with high time resolution.

**Objectives:**

The current work focused on the effects of single-dose OT on the early stages of face processing in individuals diagnosed with ASD during social and non-social perception. Using magnetoencephalography (MEG), we investigate, in several social-related neural regions, the effect of OT on M100, M170, and M250, neural components that relate to face perception. We also examined the effects of OT on alpha and gamma connectivity between these regions during social and non-social perception.

**Methods:**

Twenty-five individuals diagnosed with ASD took part in this double-blind placebo-controlled design and performed a social task which required identification of social and non-social stimuli during a scan in the MEG.

**Results:**

Our results show that OT influence both social and non-social stimuli from the early stages of the perceptual process. OT enhances social-related perception within and between social-related regions, but it also increases the general attention toward external stimuli, regardless of their social context. Namely, our results suggest that OT increased social perception in medial frontal regions alongside modulation of the top-down and bottom-up processes between this region and posterior tempo-occipital regions

**Conclusions:**

The current study highlights the complexity of the effects of OT during early perceptual stages in ASD. By providing a new model that is composed of both social-related influence and modulation of the overall attention, we provide a new platform for exploring and establishing novel treatments for early attentional phases in ASD.

**516.061** (Virtual Poster) Preliminary Sex Differences in Longitudinal Functional Connectivity in Mid-to-Older Adults with Autism

**M. Walsh<sup>1</sup>, B. A. Pagni<sup>1</sup>, L. Monahan<sup>1</sup>, S. Delaney<sup>1</sup> and B. B. Braden<sup>2</sup>,** (1)Arizona State University, Tempe, AZ, (2)College of Health Solutions, Arizona State University, Tempe, AZ

---

**Background:** Research on cognitive and brain aging in autistic adults is emerging, but no studies have examined sex differences. Mid-to-older autistic women show poorer employment retention (Taylor & Mailick, 2014), quality of life (Mason et al., 2018), and greater Parkinson's risk (Hand et al., 2020; Geurts et al. 2021), suggesting distinct vulnerabilities in brain aging.

**Objectives:** The objectives of this study were to use a data-driven, connectome-wide approach to examine sex differences in functional connectivity (FC) changes in mid-to-older autistic adults in a small, preliminary longitudinal sample.

**Methods:** Participants included autistic men/women and neurotypical (NT) counterparts ages 40-71 years at enrollment (average age: 52.2 [8.0]; follow-up interval: 2-3 years; autistic females:  $n=8$ ; autistic males:  $n=23$ ; NT females:  $n=7$ ; NT males:  $n=19$ ). There were no significant differences across groups for age at enrollment. Participants completed a six-minute, resting-state fMRI scan. A conservative preprocessing/denoising pipeline was implemented in SPM12 and the CONN Toolbox. Group-MVPA tested three regression models: 1) diagnosis group differences in FC changes, 2) "sex-typical" FC changes, and 3) "sex-atypical" FC changes. Post-hoc seed-to-voxel analysis characterized significant group-MVPA effects. A height threshold of  $p<.001$  and cluster threshold  $p<.05$  FWE-corrected was used across analyses. Associations with baseline cognitive control (Wisconsin Card Sorting Task errors) and fine motor abilities (finger tapping) were examined. Model significance identified substantial associations (one model per MVPA cluster containing suprathreshold post-hoc cluster mean FC values as predictors), and post-hoc inspection of predictor significance provided qualitative characterization.

**Results:** Diagnosis group MVPA revealed differences in age-related changes in cerebellar vermis 8, characterized by increasing somatosensory FC in autism and decreasing FC in NT (driven by females). No significant behavioral associations were identified. For sex effects, all patterns were characterized by declining FC in females and stable or increasing FC in males. These patterns were observed in four clusters including 1) the mid-brain, driven by intrinsic midbrain and intraparietal sulcus FC, 2) bilateral frontal poles, driven by visual cortex/precuneus FC, 3) and the right paracingulate, driven by default mode network FC. Left FP changes, especially "male-typical" increasing FC with the precuneus, predicted worse

baseline cognitive control. For the midbrain, greater “female-typical” FC declines within the midbrain and with the thalamus predicted poorer baseline motor performance. The left frontal pole showed sex-by-diagnosis patterns of longitudinal FC change, driven by greater FC declines with the default mode network and frontal poles in autistic males/NT females and inverse patterns in autistic females/NT males (again, driven by females). No significant behavioral associations were identified.

Conclusions: “Sex-typical” FC changes in autistic males suggest greater age-related vulnerability to cognitive decline than for autistic females. In contrast, autistic females may show more risk to brain aging linked to Parkinson’s disease. Both “sex-atypical” and diagnosis effects are driven by female groups, and given the small female sample, there is limited power to detect behavioral correlates. Furthermore, given substantial sex-related effects, the role of hormones and menopause in aging in autistic females requires further examination. Validation of these results is warranted with larger sample sizes.

## Brain Structure (MRI, neuropathology)

### ORAL SESSION - 3B — BRAIN STRUCTURE (MRI, NEUROPATHOLOGY)

#### 309 - The Neuroanatomical Underpinnings of Different Clinical ASD Phenotypes

#### Background:

Autism spectrum disorder (ASD) is a neurodevelopmental condition that is accompanied by an atypical development of the brain (Ecker et al., 2015). Neuroanatomical differences in ASD are, however, highly variable across individuals (Amaral et al., 2008) and most likely represent different clinical phenotypes (Mizuno et al., 2019). To parse heterogeneity, it is therefore essential to establish how, and to what degree, the neuroanatomy of ASD is modulated by inter-individual differences in clinical symptom profiles, and commonly occurring comorbid conditions such as Attention Deficit Hyperactivity Disorder (ADHD) (Baker & Blacher, 2015).

#### Objectives:

This study aimed to investigate neuroanatomical differences between autistic people with and without co-morbid ADHD relative to typically developing (TD) controls to determine whether autistic individuals with ADHD represent a distinct neuroanatomical subgroup on the autism spectrum.

#### Methods:

Our sample consisted of N=535 individuals aged 7-31 years from the Longitudinal European Autism Project (LEAP, Charman et al., 2017) cohort. Based on ASD DSM-IV or DSM-5 diagnostic criteria and an estimate of a diagnosis of ADHD based on questionnaire data on the DSM ADHD rating scale, we divided the total sample into four subgroups: ASD only (N=172), ASD with comorbid ADHD (N=142), ADHD only (N=25), TD: N=196. Cortical thickness (CT) and surface area (SA) were extracted from T1-weighted volumetric images using FreeSurfer\_v6.0.0 (<http://surfer.nmr.mgh.harvard.edu/>). Vertex-wise differences in neuroanatomy were quantified using a general linear model (GLM) of the form:  $Y \sim \text{ASD} + \text{ADHD} + \text{ASD} \times \text{ADHD} + \text{Sex} + \text{Age} + \text{IQ} + \text{Total\_Brain} + \text{Site}$ .

#### Results:

Following random field theory (RFT)-based cluster-correction ( $p < 0.05$ , two-tailed), autistic participants on average had increased CT in the anterior-cingulate cortex, left temporal lobe (superior and middle temporal gyrus), right superior frontal gyrus, and right occipital lobe (Figure 1A). Decreases in CT in ASD were observed in the right parietal cortex, and in the superior frontal gyrus. The main effect of ADHD was associated with decreased CT in the right anterior cingulate, and in the occipital lobe. We observed significant ASD-by-ADHD interactions for measures of CT in fronto-parietal areas, the right temporal gyrus, and in occipital regions. In these regions, autistic people with ADHD had increased - or decreased - CT compared to individuals with ASD or ADHD only depending on the brain region.

For measures of SA (Figure 1B), autistic participants on average had decreased SA in the right anterior-cingulate cortex relative to non-autistic people. The main effect of ADHD was associated with increased SA in left parahippocampal gyrus only. Significant ASD-by-ADHD interactions for measures of SA were observed in the right frontal gyrus exclusively.

#### Conclusions:

Our results of atypical CT in individuals with ASD or ADHD are in accordance with previous findings reporting differences in surface neuroanatomy in these conditions (Ecker et al., 2021; Almeida et al., 2010). Moreover, our finding of significant ASD-by-ADHD interactions implies that the neuroanatomy of ASD is significantly modulated by ADHD, and that individuals with ASD and comorbid ADHD may constitute a distinct neuroanatomical subgroup on the autism spectrum that differs from individuals with idiopathic ASD or ADHD only.

#### **309.002 (Oral)** Variation in Neuroanatomical Development Is Associated with Variation in Adaptive Outcome in Autism

**C. M. Pretzsch<sup>1</sup>, T. Schäfer<sup>2</sup>, A. Bletsch<sup>3</sup>, C. Mann<sup>2</sup>, D. L. Floris<sup>4</sup>, M. V. Lombardo<sup>5</sup>, T. Bourgeron<sup>6</sup>, T. Ecker<sup>10</sup>**, (1)IoPPN King's College London, London, United Kingdom, (2)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University Frankfurt am Main, Frankfurt, Germany, (3)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe-University Frankfurt am Main, Frankfurt, Germany, (4)University of Zurich & ETH Zurich, Nijmegen, Switzerland, (5)Center for Neuroscience and Cognitive Systems, Istituto Italiano di Tecnologia, Rovereto, Italy, (6)Human Genetics and Cognitive Functions, Institut Pasteur, Paris, France, (7)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (8)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (9)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (10)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University, Frankfurt am Main, Frankfurt, Germany

Background: Autism spectrum disorder (ASD) is associated with significant difficulties in adaptive behaviour and variation in clinical (e.g., adaptive) outcome across the life span. The neurobiological underpinnings of this clinical variability remain poorly understood; but understanding them is essential to develop effective, personalised interventions in ASD. We have previously shown that neuroanatomical (and associated genetic) variation is associated with adaptive outcome ~12-24 months later.

Objectives: However, it remains unclear if adaptive outcome in ASD is also associated with variation in the developmental *trajectory* of specific aspects of cortical anatomy and their associated genetic factors.

Methods: Therefore, we carried out a longitudinal follow-up study of 304 individuals (149 ASD, 155 neurotypicals, 6-30 years) collecting behavioural (Vineland Adaptive Behaviour Scale-II; VABS-II), neuroanatomical (structural magnetic resonance imaging), and genetic (DNA) data at T1 and T2 (timepoints separated by ~12-24 months). We grouped autistic individuals into clinically meaningful 'Improvers/No-changers/Decreasers' in adaptive behaviour (defined using previously published VABS-II Minimal Clinically Important Difference [MCID] measures). We then compared neuroanatomy (cortical volume, cortical thickness, surface area) at i) T1, ii) T2, and iii) the change in neuroanatomy ( $\Delta T = T2 - T1 / T1$ ) between the neurotypicals and each outcome group. Further, we explored the genetic underpinnings of the observed neuroanatomical differences. All results were corrected for multiple comparisons using standard procedures (Random Field Theory, False Discovery Rate etc.).

Results: Outcome groups differed from neurotypicals in neuroanatomy at T1, T2, and  $\Delta T$  in regions previously associated with ASD (e.g., prefrontal cortex, temporal lobe) (see Figures 1 and 2 for the most pronounced between-group contrasts). 'Improvers' displayed the most neurotypical neuroanatomical *development* (Figure 1 b), while 'No-changers' and 'Decreasers' (Figure 2 b) developed atypically – with each group displaying widespread neuroanatomical differences at T2 (Figure 1c and 2c). Moreover, cross-sectional and longitudinal neuroanatomical variation was associated with genetic variation in pathways previously implicated in ASD, including excitatory cells, inhibitory (GABAergic) pathways, and intermediate progenitor cells.

Conclusions: Here, we provide proof-of-concept that clinical (adaptive) outcome groups/profiles in ASD display distinct neuroanatomical developmental *trajectories*, which are associated with genetic factors relevant both to these neuroanatomical phenotypes and to ASD.

#### **309.003 (Oral)** Subcortical Brain Alterations across Copy Number Variants Converge with Those in Autism and Neurodevelopmental Psychiatric Disorders

**Background:** Rare copy number variants (CNVs) are important contributors to neurodevelopmental psychiatric disorders (NPDs) including autism spectrum disorder (ASD). While brain mechanisms mediating genetic risk for NPDs remain largely unknown, a growing number of morphometry studies of CNVs using T1-weighted structural MRI have begun to address this challenge. Subcortical brain regions, which play a critical role in cognitive and social functions in humans, are broadly affected by CNVs with mild to large effect sizes (Ching et al. 2020). Knowledge gap: Prior studies of subcortical alterations in CNV-carriers have been conducted one mutation at a time, leaving the field with a complex catalog of alterations linked to different genomic loci. It is unknown if CNV-associated brain alterations are related to or distinct from those observed in idiopathic ASD and other NPDs (attention-deficit-hyperactivity-disorder, bipolar-disorder, major-depressive-disorder, obsessive-compulsive-disorder, schizophrenia).

**Objectives:** We aimed to i) characterize subcortical brain alterations in 11 CNVs, ii) compare effect sizes with previously reported effects for 6 NPDs, and iii) identify latent subcortical brain morphometry dimensions across CNVs and NPDs.

**Methods:** We analyzed 1,457 T1-weighted MRI scans (675 CNV-carriers and 782 controls) including individuals who carry one of the 11 CNVs at the following loci: 1q21.1, 1q21.1-TAR, 13q12.12, 15q11.2, 16p11.2, 16p13.11, and 22q11.2. Data were pooled across six cohorts (Modenato et al. 2021): SimonsVIP, Montreal, UCLA, Cardiff, SFARI, and UK-Biobank. FreeSurfer v5.3.0 segmented volumes for seven subcortical regions were used as morphometry measures of interest. Linear regression models (R v3.6.3) were used to compute case-control differences (Cohen's d) for the 11 CNVs, after adjusting for age, sex, site, and Intracranial-volume using Gaussian processes regression. Cohen's d for subcortical volumes of 6 NPDs were obtained from previously published ENIGMA studies (Ching et al. 2020). Principal component analysis (PCA) was run to identify latent dimensions across CNVs and NPDs.

**Results:** Nine of the 11 CNVs had significant effects on the volume of at least one subcortical structure that survived FDR correction. The largest effects were observed for 22q11.2 deletions. Every structure was affected by at least 2 CNVs, and the hippocampus and amygdala were affected by 5 CNVs. Effect sizes of CNVs were 2-fold larger than those of NPDs. The ASD alteration profile was most highly correlated with that for the 16p11.2 deletion; separate clusters emerged for childhood and adult NPDs. PCA identified the same latent dimension - defined by opposing loadings on basal ganglia and limbic structures - across CNVs and across NPDs explaining 45% of the Cohen's d profiles' variance across all CNVs and NPDs.

**Conclusions:** The simultaneous analysis of CNVs and NPDs showed that the effect sizes of CNVs were larger than NPDs. A parsimonious set of brain dimensions captured global common effects on subcortical volumes of a seemingly heterogeneous group of genetic variants. However, over half of the variance in the mean CNV effects on subcortical structures remained distinct. This approach may help subgroup the complex landscape of rare genetic variants conferring risk to NPDs and dissect the heterogeneity of NPDs.

### **309.004 (Oral) Clinical Correlates of GABAergic Interneuron Pathology in the Autistic Prefrontal Cortex**

**B. Dufour<sup>1,2</sup> and V. Martinez-Cerdeno<sup>2,3</sup>,** (1)Psychiatry and Behavioral Sciences, UC Davis School of Medicine, Sacramento, CA, (2)MIND Institute, UC Davis Medical Center, Sacramento, CA, (3)Pathology & Laboratory Medicine, UC Davis School of Medicine; Institute for Pediatric Regenerative Medicine and Shriners Hospitals for Children of Northern California, Sacramento, CA

**Background:** Autism Spectrum Disorder (ASD) is a prevalent and debilitating neurodevelopmental disorder, characterized by social communication deficits and restricted repetitive behaviors. Patients often show comorbidities, including impairments in intellectual ability, epilepsy, and ADHD. While a variety of pathological changes have been identified in the human ASD brain, including work from our group that identified alterations in GABAergic interneurons in the ASD prefrontal cortex, it remains largely unclear how specific neuropathological changes are related to ASD symptomatology.

**Objectives:** Here, in an exploratory retrospective study, we assessed the relationship between GABAergic interneuron pathology and ASD symptom severity and comorbidity.

**Methods:** Clinical records were collected from Autism (n=20) and control (n=19) brain donors, from whom we previously identified a reduction in parvalbumin+ Chandelier Cells (ChCs), a specific type of GABAergic interneuron, in the ASD prefrontal cortex (BA9, BA46, and BA47). The relationship between ASD core symptom severity, as indicated by ADI-R scores, and ChC pathology was assessed using Pearson Correlation. The relationship between ASD comorbidities and GABAergic interneuron cell counts (including parvalbumin+ [PV], calbindin+ [CB], and calretinin+ [CR] interneurons) were assessed using repeated measures ANOVA.

**Results:** We found a significant correlation between the severity of ChC loss in the Orbitofrontal Cortex (BA47) with the severity of stereotypic motor behaviors in ASD subjects. This finding was replicated in two sets of subjects measured with two separate indicators of ChC loss – reductions in PV+ interneurons in one cohort (r= -0.722, p=.043), and reduced GAT1+ cartridges in a second cohort (r= -0.710, p=.049), both corresponding to increased severity of stereotypic motor behavior. Patterns of interneuron loss in the prefrontal cortex differed between ASD subjects with Intellectual Disability (ID, IQ<70) and ASD subjects without ID. While all ASD subjects showed a significant reduction in PV+ interneurons (p<.05), ASD with ID exclusively showed a reduction in total interneuron number (PV+, CB+, CR+), relative to non-ID ASD (-38.7%, p<.05), and also relative to controls (-36.6%, p<.01).

**Conclusions:** Through this retrospective study, we identified that distinct patterns of GABAergic interneuron pathology in the ASD prefrontal cortex are associated with specific types of ASD symptomatology. ChC pathological severity in the orbitofrontal cortex (BA47) corresponded with the severity of stereotypic motor symptoms in ASD patients. ASD subjects with comorbid ID showed more widespread and severe loss of GABAergic interneurons throughout the prefrontal cortex than ASD subjects without ID, suggesting that ID in ASD may reflect a more severe form of a shared underlying ASD pathology. These findings highlight the importance of accounting for clinical subtypes when investigating neuropathological

changes in the ASD brain, emphasize the importance of GABAergic dysfunction to the neurobiology of ASD, and thus provide strong rationale for further investigation.

## ORAL SESSION - 9B — BRAIN STRUCTURE (MRI, NEUROPATHOLOGY)

### 321 - White Matter Differences and Their Impact on Clinical Symptoms Across the Human Lifespan in ASD

**321.001** (Oral) White Matter Microstructure Differences in Autism: A Pilot Study from the Enigma ASD Working Group

**K. E. Lawrence<sup>1</sup>**, D. van Rooij<sup>2</sup>, E. Laltoo<sup>3</sup>, J. McCracken<sup>1</sup>, J. K. Buitelaar<sup>2</sup>, P. M. Thompson<sup>4</sup> and -. ENIGMA ASD working group<sup>5</sup>, (1)University of Southern California, Los Angeles, CA, (2)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (3)UCLA Semel Institute, Los Angeles, CA, (4)Stevens Neuroimaging & Informatics Institute, University of Southern California, Los Angeles, CA, (5)The ENIGMA – Autism Spectrum Disorder (ASD) working group, Nijmegen, Netherlands

**Background:** Converging lines of evidence – ranging from genetics and postmortem studies to neuroimaging work – indicate that autism is characterized by altered neural connectivity. Prior analyses using diffusion tensor imaging (DTI) generally reported weaker white matter connections in autism, but findings are inconsistent regarding the implicated tracts, greatly hindering our understanding of brain connectivity in autism. This variability in results may stem from demographic/clinical heterogeneity and differences in inclusion/exclusion criteria across samples, as well as variability in analytic techniques and limited statistical power. To address these methodological considerations and improve statistical power, the ENIGMA ASD Working Group aims to conduct the largest coordinated multi-site investigation to date of white matter microstructure in autism. Here we establish the feasibility of such a study by using a harmonized DTI protocol to examine microstructural alterations in a subset of contributing sites.

**Objectives:** Characterize white matter microstructure differences in autism using standardized ENIGMA pipelines.

**Methods:** Diffusion-weighted brain magnetic resonance imaging (dMRI) data was analyzed from 214 participants (122 with autism, 92 neurotypical controls; 82.2% male; 5-46 years old) from 5 datasets available through the Autism Brain Imaging Data Exchange (ABIDE). All dMRI processing was completed according to standardized ENIGMA DTI protocols (<http://enigma.ini.usc.edu/protocols/dti-protocols/>). Preprocessing consisted of eddy current correction, echo-planar imaging-induced distortion correction, and tensor fitting. The following DTI metrics were derived for each subject: fractional anisotropy (FA), mean diffusivity (MD), axial diffusivity (AD), and radial diffusivity (RD). DTI indices were then projected to a standard white matter skeleton using FSL's tract-based spatial statistics, and mean values for each DTI measure were extracted from 25 bilateral white matter regions of interest (ROIs) across the brain. Primary group-level analyses examined white matter microstructure differences between the autism and neurotypical control groups, including the following nuisance covariates as fixed effects: sex, age, and the interaction between age and diagnostic group; site/scanner was modeled as a random effect. Supplemental analyses also included full-scale IQ as a fixed effect. A false discovery rate of 5% was applied across ROIs to correct for multiple comparisons.

**Results:** Significant and widespread white matter differences were observed between the autism and neurotypical control groups. Participants with autism exhibited lower FA ( $\beta=0.11-0.34$ ), as well as higher MD ( $\beta=0.12-0.25$ ) and RD ( $\beta=0.12-0.35$ ), on average. These differences included altered white matter microstructure in the corpus callosum, cingulum, *corona radiata*, external capsule, internal capsule, fornix, posterior thalamic radiation, *sagittal stratum*, superior longitudinal fasciculus, and uncinate fasciculus. There were no significant group differences in AD. Follow-up analyses statistically adjusting for full-scale IQ yielded similar results.

**Conclusions:** We found widespread white matter microstructure alterations in autism, which is consistent with and expands upon previous work in smaller samples suggesting weaker structural connectivity in autism. These analyses demonstrate the feasibility of examining microstructural differences using a coordinated multi-site approach. Our future work will expand on these findings by including a substantial number of additional sites and investigating the impact of possible sources of heterogeneity, such as the severity of autism symptoms and the presence of comorbid symptoms.

**321.002** (Oral) White Matter Microstructural and Morphometric Alterations in Autism: Implications for Intellectual and Verbal Capabilities

**H. Y. Lin<sup>1</sup>**, R. Y. Tseng<sup>2</sup>, H. C. Ni<sup>3</sup>, S. S. F. Gau<sup>4</sup> and C. H. Yeh<sup>2</sup>, (1)Department of Psychiatry, University of Toronto, Toronto, ON, Canada, (2)Chang Gung University and Chang Gung Memorial Hospital, Taoyuan, Taiwan, (3)Psychiatry, Chang Gung Memorial Hospital at Linkou, Taoyuan, TAIWAN, (4)Department of Psychiatry, National Taiwan University Hospital & College of Medicine, Taipei, Taiwan

**Background:** Neuroimage literature of autism spectrum disorder (ASD) has a moderate-to-high risk of bias, partially because those combined with intellectual impairment (II) and/or minimally verbal (MV) status are generally ignored.

**Objectives:** Using the state-of-the-art dMRI acquisition (four b-values with ~200 gradient directions), data processing framework (fixel-based analysis), as well as the extensive psychopathological measures, the current study aimed to provide more comprehensive insights into the structural brain changes underpinning ASD. The current study included individuals with II and MV, who are generally left out in the current lore. We hypothesized that the FBA could highlight potential differences in ASD that are driven by intellectual challenges. Autistic traits, cognitive impairment, and poor adaptive function were in fact expected to map onto fixel pathology in the tract interconnecting social and cognitive brain networks.

**Methods:** Sixty-five participants with ASD (ASD-Whole; 16.6±5.9 years; comprising 34 intellectually able youth, ASD-IA, and 31 intellectually impaired youth, ASD-II, including 24 ASD-II-Only plus 7 ASD-MV) and 38 demographic-matched typically developing controls (TDC; 17.3±5.6 years) were scanned in accelerated diffusion-weighted MRI. Fixel-based analysis was undertaken to investigate the categorical differences in fiber density (FD), fiber cross-section (FC), and a combined index (FDC), and brain-symptom/cognition associations.

**Results:** ASD-Whole had reduced FD in the anterior and posterior corpus callosum and left cerebellum Crus I, and smaller FDC in right cerebellum Crus II, compared to TDC. ASD-II, relative to TDC, showed almost identical alterations to those from ASD-Whole vs. TDC. ASD-II-Only had greater FD/FDC in the isthmus-splenium of callosum than ASD-MV. Autistic severity negatively correlated with FC in right Crus I. Non-verbal full-scale IQ positively correlated with FC/FDC in cerebellum VI. FD/FDC of the right dorsolateral prefrontal cortex showed a diagnosis-by-executive function interaction.

**Conclusions:** We confirmed that changes in anatomical connections linking hemispheres, as well as cerebellum Crus I/II might contribute to autism phenotypes. These ASD-associated alterations appear to be mainly driven by autistic individuals with minimally verbal status and/or intellectual impairment. Across the functional spectrum, autistic severity, nonverbal intelligence and executive function associated with white matter fiber-bundle properties in regions where white matter pathology based on diffusion MRI are seldom reported. These results highlight that by embracing the inclusion of understudied sub-populations on the spectrum, together with the development of novel neuroimaging methods, we may better reconcile heterogeneity across studies and advance the understanding of the neuropathology of ASD.

### **321.003 (Oral) Maternal Perinatal Depressive Symptoms, Neonatal White Matter, and Emerging Autistic Traits in Toddlers**

**A. Lautarescu<sup>1,2</sup>, A. F. Bonthron<sup>1</sup>, M. Pietsch<sup>1,2</sup>, D. Batalle<sup>1,2</sup>, L. Cordero-Grande<sup>1,3,4</sup>, J. D. Tournier<sup>1</sup>, D. Christiaens<sup>1,5</sup>, J. V. Hajnal<sup>1</sup>, A. Chew<sup>1</sup>, S. Falconer<sup>1</sup>, C. Nosarti<sup>1,6</sup>, S. Victor<sup>1,7</sup>, M. C. Craig<sup>2,8</sup>, A. D. Edwards<sup>1,7,9,10</sup> and S. J. Counsell<sup>1</sup>,** (1)Centre for the Developing Brain, Division of Imaging Sciences and Biomedical Engineering, King's College London, London, United Kingdom, (2)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Biomedical Research Networking Center in Bioengineering, Biomaterials and Nanomedicine, Madrid, Spain, (4)Biomedical Image Technologies, ETSI Telecomunicación, Universidad Politécnica de Madrid, Madrid, Spain, (5)Department of Electrical Engineering, ESAT/PSI, KU Leuven, Leuven, Belgium, (6)Department of Child and Adolescent Psychiatry, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Neonatal Unit, Evelina London Children's Hospital, London, United Kingdom, (8)National Female Hormone Clinic, South London and Maudsley National Health Service Foundation Trust, London, United Kingdom, (9)MRC Centre for Neurodevelopmental Disorders, King's College London, London, United Kingdom, (10)EPSRC/Wellcome Centre for Medical Engineering, King's College London, London, United Kingdom

**Background:** Poor maternal mental health during pregnancy may contribute to an increased likelihood of neurodevelopmental conditions such as autism. This relationship may be explained, at least in part, by changes in the developing brain during intrauterine life. However, much of the existing neuroimaging literature is based on studies with older participants, where it is difficult to separate the effects of prenatal and postnatal environment.

**Objectives:** The aim of this study was to examine associations between maternal perinatal depressive symptoms, infant white matter, and emerging autistic traits in toddlers.

**Methods:** 413 mother-infant dyads enrolled in the developing Human Connectome Project. Mothers completed the Edinburgh Postnatal Depression Scale (median = 5, range = 0-28, n=52 scores ≥ 11) prenatally or at the time of the neonatal study visit. Infants (n=223 male) (median gestational age at birth=40 weeks, range 32.14-42.29) underwent MRI scans (median postmenstrual age at scan=41.29 weeks, range 36.57-44.71). Fixel-based fibre metrics (mean fibre density, fibre cross-section, and fibre density modulated by cross-section) were calculated from diffusion imaging data in the left and right uncinate fasciculus, and cingulum bundle. For n=311, a neurodevelopmental assessment was conducted at a median corrected age of 18 months (range 17-24). This included the Quantitative Checklist for Autism in Toddlers (Q-CHAT) as a measure of emerging autistic traits, and the Child Behaviour Checklist (CBCL) as a measure of emotional and behavioural difficulties. Statistical analysis used multiple linear regression and mediation analysis with bootstrapping.

**Results:** Maternal perinatal depressive symptoms were positively associated with infant fibre density in the left (B =.0005, p=.003, q=.027) and right (B=.0006, p=.003, q=.027) uncinate fasciculus. Infants with higher fibre density in the left uncinate fasciculus had elevated autistic traits as reflected by higher scores on the Q-CHAT in toddlerhood (B =105.70, p=.0007, q=.004). In a mediation analysis, higher maternal depressive symptoms predicted toddler Q-CHAT scores (B=.342, t(307)=3.003, p=.003), but this relationship was not mediated by fibre density in the left uncinate fasciculus (Sobel test p=.143, bootstrapped indirect effect=.035, SE=.02, 95%CI [-.01,.08]).

**Conclusions:** Maternal perinatal depressive symptoms are associated with increased fibre density in the infant uncinate fasciculus and an elevated likelihood of emerging autistic traits in toddlers. Our findings have important implications for clinical practice, as a better understanding of how maternal depressive symptoms can impact offspring brain and behaviour can help inform future interventions and ensure more positive outcomes for mother and child.

### **321.004 (Oral) Brainstem White Matter Is Uniquely Related to Sensory Features and Motor Performance in Autistic Children.**

**O. J. Surgent<sup>1</sup>, B. G. Travers<sup>2</sup>, J. Guerrero-Gonzalez<sup>3</sup>, N. Adluru<sup>4</sup>, A. L. Alexander<sup>3</sup>, D. C. Dean<sup>4</sup>, K. K. Ausderau<sup>5</sup> and G. R. Kirk<sup>5</sup>,** (1)The University of Wisconsin-Madison, Madison, WI, (2)University of Wisconsin - Madison, Madison, WI, (3)Medical Physics & Psychiatry, University of Wisconsin - Madison, Madison, WI, (4)Pediatrics & Medical Physics, University of Wisconsin - Madison, Madison, WI, (5)Waisman Brain Imaging Lab, University of Wisconsin - Madison, Madison, WI

**Background:** The brainstem is associated with sensory and motor processing in both humans and animals and may play a unique role in the etiology of autism (Dadalko and Travers, 2018), making it a key region of interest for investigating the neural contributions to sensory and motor differences

autism. Previous investigations have broadly linked brainstem white matter to sensory features (Wolff et al., 2017) and motor behaviors (Travers et al. 2015) in autism, but historically, the brainstem has been a challenging area to image *in vivo*, preventing thorough investigation of individual brainstem white matter tracts. Fortunately, recent advancements in diffusion weighted imaging (DWI) have allowed us to assess the brainstem more accurately, providing the opportunity to investigate the relationships among brainstem white matter tracts, sensory features, and motor challenges in autistic youth.

**Objectives:** Examine how individual differences in sensory features and motor behavior relate to brainstem white matter in autistic and non-autistic children. Please note that we use identity-first language per the expressed preference of autistic individuals.

**Methods:** DWI and measures of both observed motor behavior (BOT-2SF; Bruininks and Bruininks, 2005) and caregiver-report sensory features (SEQ 3.0; Baranek, 2009) were acquired from 125 children (53 autistic; 6.9-10.9 years old). Multi-shell DWI was acquired using a 3T GE Scanner with a protocol optimized for enhanced visualization of the brainstem. Free water elimination diffusion tensor imaging was used to remove contaminating signal contributions from free water, and fractional anisotropy (FWE-FA) and mean diffusivity (FWE-MD) maps were generated. Eleven bilateral white matter tracts delineated using a probabilistic brainstem connectome atlas (Tang et al., 2018) were registered to the study-specific population fiber orientation distribution (FOD) template. Within diagnostic group (autistic and non-autistic) overall SEQ and BOT-2SF scores were correlated with weighted median FWE-FA/MD properties in each tract, controlling for age, sex, and DWI head motion (FDR-corrected  $p<.05$ ).

**Results:** In non-autistic children, there were no significant correlations with brainstem white matter FWE-FA or FWE-MD. In autistic children, more prominent sensory features were associated with lower FWE-MD in the medial lemniscus ( $r=-.38$ ,  $p=.006$ ) and the cerebello-thalamic portion of the superior cerebellar peduncle ( $r=-.40$ ,  $p=.004$ ) (Fig 1A). Better motor performance was associated with higher FWE-MD in the corticospinal ( $r=.42$ ,  $p=.002$ ) and frontopontine ( $r=.41$ ,  $p=.003$ ) tracts (Fig 1B). Within the middle cerebellar peduncle, more prominent sensory features were associated with lower FWE-MD ( $r=-.57$ ,  $p<.001$ ) and higher FWE-FA ( $r=.44$ ,  $p=.001$ ) and better motor performance was associated with higher FWE-MD ( $r=.33$ ,  $p=.01$ ) (Fig 1C).

**Conclusions:** In autistic, but not non-autistic children, brainstem white matter tracts were associated with individual differences in sensory and motor behavior. Specifically, sensory features were associated with white matter tracts that carry information from brainstem and cerebellar nuclei to the cortex, while motor performance was associated with white matter tracts that carry information from the cortex to the brainstem nuclei. Sensory and motor behaviors were associated with the middle cerebellar peduncle, a tract involved in transmitting information computed in brainstem nuclei to the cerebellum. Taken together, these results suggest a brainstem mechanism for sensory-motor computation in autism.

## POSTER SESSION — BRAIN STRUCTURE (MRI, NEUROPATHOLOGY)

### 422 - Brain Structure (MRI, neuropathology)

#### 422.001 (Poster) Investigating Transdiagnostic White Matter Complexity Using Shannon Entropy Analysis

N. Satapathy<sup>1</sup>, O. Ousley<sup>1</sup> and D. Zaras<sup>2</sup>, (1)Department of Psychiatry and Behavioral Sciences, Emory Autism Center, Emory University School of Medicine, Atlanta, GA, (2)Emory University, Atlanta, GA

#### Background:

CNS disorders associate with disruptions in white matter (WM) integrity and likely exist on a continuum of biologically defined phenotypes (IOM, 2013). Shannon entropy analysis (SE), which uses information theory to describe data complexity, yields a robust metric of WM complexity derived from diffusion tensor imaging (DTI; Delic et al., 2016). This neuroimaging study seeks to evaluate SE as an objective, noninvasive metric for measuring whole-brain WM complexity (Woo et al., 2017). Autism spectrum disorder (ASD) and Alzheimer's dementia (AD) may exist on a continuum of biological phenotypes that associate with cognitive and behavioral symptoms. ASD and AD share pathological markers, including increased levels of amyloid-beta precursor protein (Rhodus et al., 2020; Khan et al., 2016). A metric of WM complexity, evaluated by non-invasive DTI, may provide a proxy for these pathological disruptions.

#### Objectives:

We analyzed data from two neuroimaging databases, Autism Brain Imaging Data Exchange II (ABIDE II, BNI/SAARC subset) and the Alzheimer's Disease Neuroimaging Initiative Phase 3 (ADNI3), to conduct SE analysis of adult DTI scans, examine SE group differences, SE test-retest reliability, and the association between SE and behavior.

#### Methods:

Study participants included 29 adult males with ASD (mean age=37.5 years; SD=16; range = 18-62), 29 adult male controls with no diagnosis (CON) (mean age=39.6 years; SD = 15; range =18-64) from ABIDE II, 14 males with AD (mean age=68.01 years; SD=6.6; range=55-75), 47 males with MCI (mean age=68.16 years; SD=4.624; range=56-75), and 69 CON males (mean age=68.16 years; SD=4.002 years; range=57-75) were included. DTI scans were preprocessed and corrected for non-zero resonances and eddy currents, followed by the calculation of a whole-brain SE score (Andersson et al., 2016; Delic et al., 2016; Smith, 2004). FSL, version 6 was used (Jenkinson et al., 2012; Smith et al., 2004; Woolrich et al., 2009). Subsequent data analysis steps included screening for outliers, identifying covariates, and examining group comparisons. Correlations

between SE and clinical behavioral measurements [(e.g., Social Responsiveness Scale, Second edition; Clinical Dementia Rating Scale (CDR)] were conducted.

## Results:

Using SE as the dependent variable, a main effect for diagnosis was found,  $F(3, 163) = 20.28, p < .001$ . Post-hoc analysis revealed that individuals with ASD had significantly lower SE values than all other groups. When scanner type and age were included in the model, a significant interaction of diagnosis X age emerged,  $F(3, 157) = 5.23, p = .002$ , with older individuals with ASD having significantly lower SE values compared to other groups. Using FA as the dependent variable, no main effects of diagnosis were found  $F(3, 163) = 1.46, ns$ . Moderate correlations were found between SE and SRS-2 Awareness and Cognition; moderate correlations were found between SE and the Clinical Dementia Rating Scale items. Test-retest analysis revealed a strong correlation for SE,  $r(14) = .990, p = <0.001$

## Conclusions:

The results indicate SE as a reliable biomarker of WM integrity that associates with measures of social behavior and distinguishes ASD individuals from other diagnostic groups.

### 422.002 (Poster) Association of Subcortical Volumes with Sleep Problems in Autistic and Typically Developing Children

**D. S. Andrews<sup>1</sup>, B. Hatch<sup>2,3</sup>, J. K. Lee<sup>3</sup>, S. J. Rogers<sup>4</sup>, M. Solomon<sup>3</sup>, D. G. Amaral<sup>3</sup>, M. Miller<sup>4</sup> and C. W. Nordahl<sup>3</sup>,** (1)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (2)Psychology, Institute for Social Neuroscience, Melbourne, VIC, Australia, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, University of California at Davis, Sacramento, CA

**Background:** It is estimated that 80% of autistic children and adults have sleep problems -- a rate that far exceeds their typically developing (TD) peers. Common problems include delayed sleep onset, frequent nighttime awakenings, and restlessness. Both environmental and biological factors likely contribute to sleep problems in autism. For example, dysregulation of neurobiological process such as circadian rhythm (i.e., sleep that follows an ~24-hour cycle) and sleep-wake homeostasis (i.e., increased pressure to sleep driven by duration of wakefulness and duration of prior sleep) are likely contributors to sleep problems. While these processes involve several distinct neurobiological components, they function in a coordinated manner and are underpinned by subcortical neural regions that include the hypothalamus, thalamus, amygdala, hippocampus, globus pallidus, basal forebrain, and brainstem.

**Objectives:** Investigate associations between subcortical brain volumes and sleep problems in autism and typical development, and identify differences in these associations attributable to autism.

**Methods:** This study included 203 autistic children (131 males, 72 females) and 92 TD controls (49 males, 43 females) enrolled in the UC Davis MIND Institute Autism Phenome Project. Sleep transition problems were measured using a scale comprised of the sum of seven items from the Children's Sleep Habits Questionnaire (CSHQ). These items have been shown to capture a single reliable construct representing sleep problems in autistic and TD 2- to 4-year-olds. Total cerebral volumes and volumes from a priori regions of interest including the left and right hypothalamus, thalamus, amygdala, caudate nucleus, putamen, globus pallidus, hippocampus, nucleus accumbens, and pons were extracted using a multi atlas approach. Associations between regional brain volumes and measures of sleep quality were assessed using linear effects modeling in R version 3.6 and included sex as a categorical fixed effect factor, age in months, and total cerebral volume as continuous covariates, and an interaction term between diagnosis and both left and right regional volume.

**Results:** Compared to TD, autistic children had significantly higher CSHQ composite scores ( $t=5.42, p<0.001$ ). Of the nine brain regions investigated (18 bilateral ROIs), the right hypothalamus showed a significant negative association with CSHQ measures of sleep problems ( $p=0.002$ , FDR adjusted  $p=0.033$ ). Smaller right hypothalamus volume was associated with increased sleep problems. A similar relationship between right hypothalamus volume and sleep problems was observed within both the autistic and TD groups; no significant diagnosis-by-right hypothalamus effect was observed. No other brain regions investigated showed a significant association with CSHQ sleep problem scores, or significant ROI-by-diagnosis interactions.

**Conclusions:** There is a negative association between right hypothalamus volume and sleep problems in both autistic and TD children. This transdiagnostic relationship indicates a possible generalizable biomarker of sleep problems in young children, which represent a significant detriment to quality of life for both children and their caregivers

### 422.003 (Poster) Atypical Intrinsic Grey-Matter Connectivity in Autism Spectrum Disorder - an Analysis of the EU-AIMS Longitudinal European Autism Project (LEAP)

**J. Leyhausen<sup>1,2</sup>, T. Schäfer<sup>2,3</sup>, C. Mann<sup>2,3</sup>, L. Berg<sup>1,2</sup>, C. M. Pretzsch<sup>4</sup>, E. Loth<sup>5</sup>, J. K. Buitelaar<sup>6</sup>, C. Beckmann<sup>6</sup>, T. Charman<sup>7</sup>, T. Bourgeron<sup>8</sup>, D. Murphy<sup>9</sup> and C. Ecker<sup>2,3,4</sup>,** (1)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University Frankfurt / Department of Child and Adolescent Psychiatry, Frankfurt, Germany, (2)Brain Imaging Center, Goethe University Frankfurt am Main, Frankfurt, Germany, (3)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University Frankfurt am Main, Frankfurt, Germany, (4)Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (6)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud

#### Background:

Autism spectrum disorder (ASD) is a heterogeneous neurodevelopmental condition accompanied by atypical brain connectivity (Amaral et al., 2008). To date, structural connectivity in ASD has mainly been investigated within the white-matter using techniques such as Diffusion Tensor Imaging (e.g. Vissers et al., 2012). However, many genetic variants associated with ASD highlight genes related to synaptogenesis and axonal guidance, hence also implicating atypical 'intrinsic' (i.e. grey-matter) connectivity in the pathophysiology of ASD (Darbandi et al., 2020; McFadden & Minshew, 2013). Intrinsic connections typically travel in parallel to the cortex (Levitt et al., 1993), and might be assessed via global and local intrinsic wiring costs (Ecker et al., 2013). So far, only one MRI study has examined intrinsic brain connectivity in adults with ASD *in vivo*, reporting reduced intrinsic wiring costs on the global and local level (Ecker et al., 2013).

#### Objectives:

We aimed to replicate and extend previous findings of atypical grey-matter connectivity in a large and clinically heterogeneous sample of autistic participants to assess their importance as a characteristic cortical hallmark of the autism phenotype.

#### Methods:

We included N=360 autistic participants and N=279 controls, aged 7-31 years from the EU-AIMS Longitudinal European Autism Project (LEAP, Charman et al., 2017). FreeSurfer\_v6.0 was used to derive surface mesh representations to compute intrinsic grey-matter wiring costs across the cortex. Here, global wiring costs indicated the minimum length of connections required to connect a vertex to the remaining cortex. These costs were estimated using the so-called mean separation distance (MSD) representing the average geodesic distance (the shortest path connecting two points along the surface) from one vertex to all others. Local intrinsic wiring costs were derived using geodesic circles covering 5% of the total surface area. This allowed us to quantify (i) the 'intra-areal' connection lengths, i.e. the minimum length of connections required to connect a vertex with neighbouring vertices (so-called radius function); and (2) the 'inter-areal' wiring costs, which represent the costs required to wire a vertex to vertices outside the area (so-called perimeter function) (Ecker et al., 2013; Griffin, 1994). Vertex-wise neuroanatomical differences between the ASD and control group were assessed using a general linear model (GLM) with a main effect of group, covarying for age, IQ, gender, and acquisition site.

#### Results:

Following RFT-based cluster-correction ( $p < 0.05$ , two-tailed), autistic participants on average showed a decrease in MSDs (i.e. global wiring costs) in the bilateral medial and lateral prefrontal cortex. Here, participants with ASD also had significantly reduced intra-areal, and enhanced inter-areal, wiring costs based on the radius and perimeter function respectively (see Figure 1). In addition, between-group differences in local intrinsic wiring costs were observed in inferior temporal regions, and at the left temporoparietal junction (TPJ).

#### Conclusions:

This is the first study to report robust differences in intrinsic brain connectivity in ASD across developmental stages. Our results replicate previous findings (Ecker et al., 2013) in a large and clinically diverse sample representing the ASD phenotype, and highlight the importance of assessing grey-matter connectivity in characterizing the neuropathology of ASD *in vivo*.

**422.004 (Poster)** Decreased Number and Increased Activation State of Astrocytes in Grey and White Matter of the Prefrontal Cortex in Autism  
**V. Martinez-Cerdeno<sup>1</sup>**, B. Dufour<sup>2</sup> and G. Vakilzadeh<sup>3</sup>, (1)Pathology & Laboratory Medicine, UC Davis School of Medicine; Institute for Pediatric Regenerative Medicine and Shriners Hospitals for Children of Northern California, Sacramento, CA, (2)Psychiatry and Behavioral Sciences, UC Davis School of Medicine, Sacramento, CA, (3)Department of Pathology and Laboratory Medicine, Institute for Pediatric Regenerative Medicine/ Shriners Hospital for Children, Sacramento, CA

---

**Background:** The cerebral cortex presents with alterations in the number of specific cell types in Autism Spectrum Disorder (ASD). Astrocytes have many functions in the brain including a role in higher cognitive functions and in inflammatory brain processes.

**Objectives:** To determine if there is an alteration in number and/or activation state of astrocytes in ASD.

**Methods:** We quantified astrocyte number in the grey and white matter of the prefrontal cortex - BA9, BA46, and BA47 – in 15 ASD and 15 age and sex-matched control cases. We labeled astrocytes with antibodies against the protein GFAP and S100 $\beta$ , markers of astrocytes.

**Results:** We found a significant decrease in the number of astrocytes in the grey and white matter of all prefrontal areas of interest with both markers. We also found an increased state of activation of GFAP+ astrocytes in all areas.

Conclusions: A reduced number of astrocytes in the cerebral cortex in ASD could lead to impaired synaptic function and disrupted connectivity. An increased astrocyte activation may indicate a chronic mild inflammatory state of the cerebral cortex in ASD. Overall, we found that astrocytes are disrupted in ASD.

**422.005 (Poster)** Factors Influencing Sleep MRI Scan Success Rates in Preschoolers with Autism Spectrum Disorder Compared to Their Typically Developing Peers

**M. Mues<sup>1</sup>, E. Demurie<sup>2</sup>, S. Schaubroeck<sup>3</sup>, M. Erdogan<sup>4</sup>, P. Pullens<sup>5</sup>, A. Goodwin<sup>6</sup>, M. Bowdler<sup>7</sup>, F. dell'Acqua<sup>8</sup>, T. Charman<sup>9</sup>, J. K. Buitelaar<sup>10</sup>, R. Delorme<sup>11</sup>, T. Falck-Ytter<sup>12</sup>, E. Loth<sup>13</sup> and H. Roeyers<sup>14</sup>**, (1)Department of Experimental-Clinical and Health Psychology, Ghent University, Department of Experimental, Clinical and Health Psychology, Ghent, Belgium, (2)Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium, (3)Department of Radiology, Ghent University Hospital, Ghent, Belgium, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (6)Excellence centre for Autism and Neurodevelopmental disorders, Paris, France, (7)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (8)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom

---

Background: Rapidly evolving MRI techniques and specialized research teams have helped in overcoming some of the challenges inherent to pediatric MRI data acquisition, leading to increased interest of developmental scientists. Investigating brain anatomy and function during early childhood is imperative to understand the biological basis of typical and atypical development. Scanning children during their natural nocturnal sleep has improved data quality (Nordahl et al., 2016), but may be particularly challenging for preschoolers with autism spectrum disorder (ASD), for example because it requires them to fall asleep in a new environment.

Objectives: We examined the impact of different factors on the MRI success rate in preschoolers with and without ASD to gain insight into best practices for sleep scanning and potentially enhance future success rates.

Methods: As part of the Preschool Brain Imaging and Behaviour Project, 50 preschoolers (36 male, 14 female; 15 with ASD and 35 without, mean age 44 months (range 27 to 55 months)) were invited for a sleep MRI with structural scans, MRS, DTI and fMRI. Parent-reported questionnaire data (Highly Sensitive Child Scale and Sensory Experience Questionnaire), behavioral measures (Mullen Scales of Early Learning), observational data (time it took the child to fall asleep, if the child was difficult to move once they were asleep (i.e. they woke up when being moved), if ear protection could be easily placed, parent fear, child fear levels and parental preparation) and demographic data (age and sex) were collected during or before scan preparations. Hierarchical regression analyses and model comparison using AIC were used to observe the most parsimonious model predicting scan success rate.

Results: After two attempts, the entire protocol could be acquired for 42% of the children; at least structural scans could be acquired for 66%. Success rates did not differ between children with and without ASD. Hierarchical regression analyses with scan success rate as dependent variable showed that for children with ASD, only difficulty to move once they were asleep was a significant predictor for scan success ( $p = .05$ ,  $R^2 = .26$ ). For children without ASD, only child fear level was a significant predictor ( $p = .01$ ,  $R^2 = .17$ ). Child fear levels and difficulty to move did not differ significantly between the two groups. There was no effect of age or sex. No additional significant effects were observed for either group.

Conclusions: Scanning success rate did not differ between children with and without ASD. For children with ASD, difficulty to move was the primary predictor for scan success, for children without ASD this was child fear level. It is important to take into account that a different approach may be needed when scanning children with ASD compared to children without ASD. This information may be useful when conducting screening interviews with children with ASD for MRI scanning. Other variables not investigated here may play a role in the scanning success rate (e.g., level of ASD characteristics). This will be further investigated in a larger sample as data collection is ongoing, and presented during the INSAR meeting.

**422.006 (Poster)** Gray Matter Thickness and Gyrification in Language-Related Brain Areas Are Associated with Language Impairment in Primary-School-Aged Children with Autism Spectrum Disorder

**V. Arutiunian<sup>1</sup>, M. Gomozyova<sup>1</sup>, A. Minnigulova<sup>1</sup>, E. Davydova<sup>2</sup>, D. Pereverzeva<sup>3</sup>, A. Sorokin<sup>4</sup>, S. Tyushkevich<sup>2</sup>, U. Mamokhina<sup>2</sup>, K. Danilina<sup>2</sup> and O. Dragoy<sup>1</sup>**, (1)Center for Language and Brain, HSE University, Moscow, Russian Federation, (2)Federal Resource Center for ASD, Moscow State University of Psychology and Education, Moscow, Russian Federation, (3)Haskins Laboratories, New Haven, CT, (4)Institute of Linguistics, Russian Academy of Sciences, Moscow, Russian Federation

---

Background: Language impairment is usually co-occurred in children with Autism Spectrum Disorder, ASD (Kjelgaard & Tager-Flusberg, 2001) but its neural basis is poorly understood. Recent studies have revealed a multiple of volume- and surface-based abnormalities related to language impairment in autism (Lu et al., 2016; Zhao et al., 2018).

Objectives: The goal of the present study was 1) to provide a whole-brain comparison between groups of children with and without ASD on gray and white matter (GM and WM) volumes, GM thickness, gyrification (GI), sulcus depth (SD), fractal dimension (FD); 2) and to investigate the relationships between these parameters in language-related regions of interest (ROIs) and language abilities of children with ASD.

Methods: 36 children participated in the study: 18 children with ASD (13 boys, age range 8.01 – 14.01 years,  $M_{age} = 10.02$ ,  $SD = 1.8$ ) and 18 age- and gender-matched TD children (13 boys, age range 7.06 – 12.03 years,  $M_{age} = 10.00$ ,  $SD = 1.4$ ). All children with ASD were diagnosed according to ICD-10, and 16 out of 18 children were also assessed with ADOS-2. The non-verbal IQ of children with ASD was measured with the Kaufman Assessment Battery for Children, NVI index, and the Wechsler Intelligence Scale for Children – Third Edition, performance IQ score; the non-verbal intelligence of TD children was screened with the Raven's Colored Progressive Matrices. Language abilities were measured with the Russian Child

Language Assessment Battery. There was a high variability in both non-verbal IQ (from very low, IQ = 40, to normal, IQ = 118) and language abilities (from non-verbal / minimally verbal to normal) in the group of children with ASD.

The high-resolution whole-brain structural MRIs were acquired for each child on a 1.5 T Siemens Avanto scanner, using the following parameters: repetition time = 1900 ms, echo time = 3.37 ms, flip angle = 15°, matrix size = 256×256×176, voxel size = 1.0×1.0×1.0 mm<sup>3</sup>. The preprocessing and analysis were performed with CAT12 and SPM toolboxes.

**Results:** The whole-brain analysis revealed differences in multiple brain areas between groups of children in all parameters except SD. GM thickness was the most affected parameter and *was reduced* in 27 ROIs of both hemispheres in children with ASD. The analysis also showed the relationships between GM thickness and GI of all language-related ROIs (temporal cortex, speech motor cortex, inferior parietal lobule) and language abilities of children with ASD: a pathological *decrease* of GM thickness in all ROIs was associated with more severe language impairment; as well, pathological *increase* of GI in all ROIs was related to more severe language impairment. Importantly, there were no any relationships between GM thickness and GI of these ROIs and other individual characteristics of children (non-verbal IQ, severity of autism, and age).

**Conclusions:** We showed, first, that atypical patterns of brain development, reflected in both volume- and surface-based morphology, exist in primary-school-aged children with ASD; second, that the abnormalities in the surface morphology (GM thickness and gyrification) in language-related ROIs are associated with language impairment in these children.

**422.007 (Poster)** IQ Development across Childhood in Autism Differentiated By Structural Differences in Default Mode and Fronto-Parietal Network

**J. K. Lee<sup>1</sup>, A. C. Cho<sup>2</sup>, D. S. Andrews<sup>3</sup>, S. J. Rogers<sup>4</sup>, D. G. Amaral<sup>1</sup>, M. Solomon<sup>1</sup>, C. W. Nordahl<sup>1</sup> and S. Ozonoff<sup>5</sup>,** (1)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (2)Human Development & Psychology, University of California, Los Angeles, Los Angeles, CA, (3)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, University of California at Davis, Sacramento, CA, (5)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA

**Background:** Intellectual disability (IQ ≤ 70) affects a third of individuals with autism spectrum disorder (autism), yet a major unresolved question remains concerning the neurobiology that differentiates autistic individuals with and without intellectual disability. IQ is highly variable during childhood. We previously identified subgroups of autistic children with differentiated trajectories of IQ development from early to middle childhood: (a) Persistent-Higher: Individuals whose IQs remained in the normal range throughout development, (b) Persistent-Lower: Individuals whose IQs remained in the range of intellectual disability throughout development, and (c) Changers: Individuals whose IQs began in the range of intellectual disability but increased to the moderate or normal range by middle childhood.

**Objectives:** In the present research, we sought to identify neurobiology that would differentiate these trajectory-defined groups within our autism cohort in two brain networks with established links to intellectual functioning and its impairment (1) the frontoparietal network (FPN), and (2) the default mode network (DMN).

**Methods:** We conducted multivariate distance matrix regression (MDMR) and effect size analyses to examine the volumes of 22 (11 regions x 2 hemispheres) brain regions within the FPN and of 24 (12 regions x 2 hemispheres) brain regions within the DMN in 48 Persistent-Higher (18 female), 108 Persistent-Lower (32 female), and 109 Changers (39 female) individuals using structural MRI that had been acquired at baseline. FPN and DMN network regions of interest were defined on the basis of the large-scale networks defined in Smith et al., (2009).

**Results:** The Changers exhibited different DMN from both Persistent-Lower and Persistent-Higher trajectory groups at baseline, but Persistent-Higher did not differ from the Persistent-Lower group, suggesting that DMN structure may be an early predictor for change in IQ trajectory across childhood. In contrast, Persistent-Higher exhibited differences in the FPN from both Persistent-Lower and Changers as baseline, suggesting a difference related more to the concurrent IQ and perhaps the absence of intellectual disability.

**Conclusions:** Within autism, the DMN at baseline may differentiate individuals with persistently low IQ from those with more transitory low IQ that improve to moderate IQ through in early childhood, potentially indicating compensatory mechanisms which may be targeted by future interventions. The brain structure differences between these three IQ-based subgroups may be indicative of distinct neural underpinnings of ASD phenotypic subtypes.

**422.008 (Poster)** Investigating Homogeneous Subgroups across ASD, ADHD, and Typical Development Using Measures of Cortical Thickness, Surface Area, Cortical/Subcortical Volume, and Structural Covariance

Kushki<sup>2</sup>,** (1)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (2)Autism Research Centre, Bloorview Research Institute, Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (3)Wellcome Centre for Integrative Neuroimaging (WIN), University of Oxford, Oxford, ON, United Kingdom, (4)Diagnostic Imaging, Hospital for Sick Children, Toronto, ON, Canada, (5)Mouse Imaging Centre, The Hospital for Sick Children, Toronto, ON, Canada, (6)Department of Psychology, Queen's University, Kingston, ON, Canada, (7)Department of Psychiatry, Queen's University, Kingston, ON, Canada, (8)Department of Psychiatry, The Hospital for Sick Children, Toronto, ON, Canada, (9)McMaster Autism Research Team, McMaster University, Hamilton, ON, Canada, (10)Department of Psychiatry, University of Western Ontario, London, ON, Canada

**Background:** Autism Spectrum Disorder (ASD) and Attention-Deficit/Hyperactivity Disorder (ADHD) are complex neurodevelopmental conditions, with large within-diagnosis heterogeneity and significant between-diagnosis overlap. Several studies have highlighted the misalignment between biological homogeneity and the existing diagnostic labels. However, the existing approaches ignore *a priori* knowledge about the brain and its structure, knowledge which can further contextualize the contributions of differences across the brain.

**Objectives:** The objective of this work was to introduce a clustering method that integrates statistically-driven structural brain data into the clustering algorithm as an additional source of information.

**Methods:** This study used a dataset from the Province of Ontario Neurodevelopmental Disorder Network (POND) consisting of typically developing (TD; n=137) children as well as participants with ASD (n=288), and ADHD (n=171). Participants were characterized phenotypically using the Social Communication Questionnaire (SCQ) for autism-like traits, the Strengths and Weaknesses of ADHD-symptoms and Normal Behavior (SWAN) for ADHD-like traits, Adaptive Behavior Assessment System-II (ABAS) for adaptive functioning, and Wechsler or Stanford-Binet scale for IQ. Neuroimaging data were acquired on a 3-Tesla Siemens Trio TIM at the Hospital for Sick Children (n=184) with an upgrade to Siemens Prisma scanner. Cortical thickness, surface area, and cortical volume were extracted using CIVET pipeline (version 2.1.0), while subcortical volumes were computed using the multiple automatically generated templates (MAGeT) pipeline. Neuroimaging data were corrected for age, sex, and total brain volume. The analytic pipeline consisted of the following steps. First, participant-specific structural connectivity matrices were computed using the Gaussian-transformed Cook's distance of each participant to the regression line for each region pair; next, participant similarities were computed using the Lambda distance for the four brain measures, and fused using Similarity Network Fusion (SNF). The final similarity matrix was integrated with the measures of cortical thickness, surface area, and volume using a graph neural network and clustered using K-means clustering.

**Results:** The optimal number of clusters was found to be two based on Davies Bouldin score. Figure 1 depicts the proportion of each diagnosis group within the clusters. The first cluster was predominantly composed of individuals with ASD and/or ADHD (NDD cluster) whereas the second cluster contained a larger proportion of TD participants (mixed cluster). The two clusters were significantly different in age and sex proportion ( $p < 0.0001$ ). The mixed cluster had relative strengths in adaptive functioning (NDD:  $75.5 \pm 28$ , mixed:  $84 \pm 37$ ,  $p < 0.001$ ), attention (NDD:  $5 \pm 6$ , mixed:  $2 \pm 4$ ,  $p < 0.0001$ ), and full-scale IQ (NDD:  $100 \pm 23$ , mixed:  $105 \pm 22$ ,  $p = 0.007$ ). Different patterns of connectivity were observed for the two clusters (Figure 2). These differences were particularly prominent in the cingulate cortex and temporal gyri (overconnectivity in the NDD group). The NDD cluster was also associated with pervasive overconnectivity in subcortical regions, except the right thalamus.

**Conclusions:** This study integrated structural connectivity data with other measures of brain structure to derive homogeneous subgroups across ASD, ADHD, and typical development. The incorporation of structural covariance in the clustering allowed us to reveal differences in patterns of connectivity in measures of cortical thickness, surface area, and volume.

#### 422.009 (Poster) Linking Structural and Functional Imaging Modalities to Characterize Atypical Face Processing in Autism

D. L. Floris<sup>1</sup>, A. Llera<sup>2</sup>, T. Mei<sup>3</sup>, N. Forde<sup>2</sup>, C. Moessnang<sup>3</sup>, E. J. Jones<sup>4</sup>, L. Mason<sup>4</sup>, R. Haartsen<sup>4</sup>, C. Ecker<sup>5</sup>, J. K. Buitelaar<sup>2</sup> and C. Beckmann<sup>3</sup>, (1)University of Zurich & ETH Zurich, Nijmegen, Switzerland, (2)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (3)Department of Psychiatry and Psychotherapy, Central Institute of Mental Health, University of Heidelberg, Mannheim, Germany, (4)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (5)Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, Goethe University, Frankfurt am Main, Frankfurt, Germany

#### Background:

Atypical emotional and face processing is among the core social difficulties of individuals with autism. However, pinpointing neural underpinnings of atypical face processing in autism has yielded inconsistent results across different imaging modalities. Most analyses have been confined to separate modalities and linking them has so far been a methodological and statistical challenge. By cutting across single-modality analyses, and integrating different imaging modalities that have been associated with atypical face processing previously, we aim to increase sensitivity in detecting underlying and shared mechanisms of face processing in autism. To this end, we leveraged the large-scale EU-AIMS Longitudinal European Autism Project (LEAP) dataset which has a rich battery of different structural and functional imaging modalities available. Using Linked Independent Component Analysis (LICA) we combined different structural and functional modalities that relate to face processing and integrated these findings with clinical information.

#### Objectives:

To provide a more comprehensive characterization of atypical face processing at the neural level in autism by integrating several complementary neuroimaging modalities.

#### Methods:

We included 101 individuals with autism and 101 typically developing individuals, aged between 6 and 30 years from LEAP. This sample size reflects the intersection of available data across four imaging modalities that were integrated: a) neuroanatomy (voxel-based morphometry to derive grey matter volume within the fusiform gyrus), b) intrinsic brain activity (resting-state fMRI based functional-connectivity gradients within fusiform gyrus), c) task-fMRI during emotional face-matching task (contrast maps reflecting brain areas with higher sensitivity for emotional faces compared to shapes and confined to fusiform gyrus) and d) EEG-based event-related potential (ERP at P7/P8) timeseries in response to a facial stimuli paradigm. LICA was used to simultaneously factorize all subjects' data into 40 independent components (ICs) of spatial variations. A Generalized

Linear Model was used to examine case-control differences and univariate brain-behaviour-associations while regressing out the effects of age, sex, IQ, handedness and scanning site. Next, Canonical Correlation Analysis (CCA) was performed to quantify the aggregated effects between multi-modal ICs and subscales related to social functioning of ADI, ADOS, Social Responsiveness Scale, and the Vineland. The statistical significance of each pair of canonical variates was determined by permutation testing (10,000 times).

#### Results:

LICA resulted in seven multi-modal components. None of these were associated with categorical group membership or clinical features (when applying univariate tests). Applying multivariate CCA revealed a significant association between the seven multimodal ICs and the set of social-cognitive features ( $r=0.56$ , permutation  $p=0.01$ ). IC27 was most implicated in this pattern and comprised right and left grey matter volume within the fusiform gyrus and right connectivity changes within the fusiform gyrus as captured by resting-state fMRI.

#### Conclusions:

We successfully merged imaging data across four different modalities to characterize a multimodal neurophenotype of autism in a key region related to face processing. None of the components showed associations with the categorical labels, but there was a multivariate association with features related to social-communicative functions in autism. Thus, multimodal aspects related to face processing can explain variance in social functioning and daily living skills in autism.

#### **422.010 (Poster)** Predicting Accelerated Visual Memory Decline in Middle-Age and Older Adults with ASD with Multi-Modal MRI: The Case for Hippocampal System Free-Water

**B. B. Braden<sup>1</sup>**, M. Walsh<sup>2</sup>, E. Ofori<sup>2</sup>, B. A. Pagni<sup>2</sup>, G. Sullivan<sup>2</sup> and K. Chen<sup>3</sup>, (1)College of Health Solutions, Arizona State University, Tempe, AZ, (2)Arizona State University, Tempe, AZ, (3)Banner Alzheimer's Institute, Phoenix, AZ

Background: Research aimed at understanding cognitive and brain aging in adults with autism spectrum disorder (ASD) is growing, but critical longitudinal studies in middle-age and older adults and candidate brain-based biomarkers have yet to emerge. Adults with ASD struggle with visual memory compared with neurotypical (NT) adults, making this an area of concern for cognitive aging.

Objectives: We first described longitudinal aging trajectories in short- and long-term visual memory abilities in middle-age and older adults with ASD, compared with matched NT adults. Next, we evaluated baseline multi-modal imaging metrics of the hippocampus and fornix, including the relatively novel metric free-water, as predictors for longitudinal memory change.

Methods: Middle-age and older adults between the ages of 40 and 70 years (ASD,  $n=25$ ; NT adults,  $n=25$ ) were followed longitudinally at approximately two-year intervals (range 2-5 years) with 2 to 3 visits (mean 2.3). Participants completed the Wechsler Memory Scale III Visual Reproduction task. Longitudinal linear mixed effect models were run to detect group differences in memory change with baseline age and sex as covariates. Hippocampal volume was measured via T1-weighted MRI images with FreeSurfer. Fornix FA and hippocampal and fornix free-water were measured from diffusion tensor imaging (DTI) scans. Correlations between individual hippocampal system metrics and longitudinal slopes of visual memory change were examined, with correction for multiple comparisons (false discovery rate, FDR). Additionally, multi-modal hippocampal system components were generated via principal component analysis and correlated with longitudinal slopes of visual memory change without the need to correct for multiple comparisons ( $\alpha=0.05$ ).

Results: There was a significant group by age interaction for long-term visual memory, such that middle-age and older adults with ASD declined faster than matched NT adults ( $p=0.005$ ; Fig. 1a). Such interaction did not exist for short-term visual memory, suggesting groups changed similarly. Baseline free-water in the left hippocampus, bilateral fornix cres, and fornix body, and FA in the fornix body predicted long-term visual memory change in middle-age and older adults with ASD, but only left fornix cres free-water survived correction for multiple comparisons [ $r(23)=-0.549$ ,  $p=0.004$ ]. The first principal component loaded all hippocampal and fornix free-water metrics, and significantly predicted long-term visual memory change in middle-age and older adults with ASD [ $r(22)=-0.517$ ,  $p=0.01$ ; Fig. 1b]. The second component was multi-modal and loaded bilateral hippocampal volumes, bilateral hippocampal free-water, and fornix body FA (ascending order), but did not predict long-term visual memory change.

Conclusions: In one of the first longitudinal cognitive and brain aging studies in middle-age and older adults with ASD, findings suggest accelerated long-term visual memory decline, compared to matched NT adults. Baseline hippocampal system measures of the relatively novel DTI metric, free-water, outperformed traditional hippocampal volume and FA measures individually and in multi-modal combinations, as a biomarker for accelerated cognitive decline in middle-age and older adults. Free-water measures extracellular fluid as a marker of neurodegeneration and has previously been applied to Alzheimer's in Parkinson's disease. These preliminary findings lay the groundwork for future prognostic applications of free-water for cognitive aging outcomes in middle-age and older adults with ASD.

#### **422.011 (Poster)** Prenatal PM2.5 and Subcortical Volumes in Children with Neurodevelopmental Disorders

**E. Rechtman<sup>1</sup>**, L. Alexander<sup>2</sup>, D. M. Papazaharias<sup>1</sup>, A. Just<sup>1</sup>, R. O. Wright<sup>1</sup>, M. P. Milham<sup>2</sup>, C. Gennings<sup>1</sup> and M. K. Horton<sup>1</sup>, (1)Department of Environmental Medicine and Public Health, Icahn School of Medicine at Mount Sinai, New York, NY, (2)Child Mind Institute, New York, NY

Background: With the growing climate crisis, particulate matter (PM) air pollution is expected to increasingly impact human health with effects magnified in vulnerable populations including pregnant women and young children. Air pollution (particulate matter  $< 2.5$   $\mu\text{m}$ ; PM<sub>2.5</sub>) exposure increases risk for autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD), yet the neural mechanisms underlying these

associations are largely unknown. To understand links between prenatal PM<sub>2.5</sub> exposure and structural brain changes, we pilot a mixtures approach in cohort enriched for ASD and ADHD.

**Objectives:** To examine the impact of prenatal exposure to ambient PM<sub>2.5</sub>, on sub-cortical brain volumes in children with ASD and ADHD.

**Methods:** We used Freesurfer to quantify 14 subcortical volumes from high-resolution structural T1-weighted images acquired from 238 children (5-15 years; 88 females; 4% ASD; 49% ADHD; 11% comorbid ASD/ADHD; 24% other diagnosis, 12% no diagnosis) enrolled in the Healthy Brain Network (HBN); a well-established behavioral and magnetic resonance imaging (MRI) phenotyping biobank. We estimated average prenatal PM<sub>2.5</sub> levels using a satellite-based gradient boosting hybrid model at a 1x1 km spatial resolution. We used weighted quantile sum (WQS) regression to generate a subcortical volume index (representing 14 subcortical brain regions volumes) and investigated associations between the subcortical index and PM<sub>2.5</sub>.

**Results:** PM<sub>2.5</sub> was positively associated with the subcortical index ( $\beta = 0.19$  [95% CI 0.18, 0.20]), indicating higher prenatal exposure to PM<sub>2.5</sub> is associated with increased subcortical volumes. This association is driven mainly by volumetric changes in the thalamus and pallidum, regions that play key roles in ASD and ADHD.

**Conclusions:** Prenatal exposure to PM<sub>2.5</sub> is associated with changes in subcortical volumes in a pediatric population enriched with ASD and ADHD; these results may inform prevention and intervention efforts for reducing PM<sub>2.5</sub> exposures.

**422.012 (Poster)** Whole-Brain White Matter Compromise across the Lifespan in Autism Is Not Predictive of Behavioral Symptomatology  
**S. R. Otto, Y. Yang, L. M. Ray, J. A. Travers, J. Hutsler and S. M. Haigh, Psychology, University of Nevada, Reno, Reno, NV**

**Background:** Autism Spectrum Disorder (ASD) pathology involves multiple distributed neural networks. Abnormal white matter (WM) connectivity in particular has been implicated as a potential mechanism for perturbed neural functioning across these distributed networks. Much of the existing literature surrounding WM connectivity in ASD has primarily focused on children, while little is known about the structural and behavioral profile across the lifespan into adulthood. Diffusion MRI (dMRI) has developed into a promising technique to investigate complex brain network connectivity *in vivo* and its application in clinical populations is rapidly gaining popularity because of its sensitivity to changes in WM structure.

**Objectives:** The present study used diffusion MRI repository data from a large sample of children and adults to investigate the degree to which WM connectivity is abnormal in ASD compared to aged-matched neurotypical controls (NT). Furthermore, we examined whether a relationship exists between diffusion indices and both diagnostic indicators and behavioral symptom severity.

**Methods:** dMRI data was acquired from the ABIDE II repository, Carnegie Mellon University, and the University of Pittsburgh. In total, we analyzed 336 subjects (187 ASD, 149 IQ-matched NT controls). All data were collected on a 3-Tesla scanner. Tract Based Spatial Statistics (TBSS) was performed using FMRIB's FSL software. Due to the nested nature of the data, robust linear mixed-effects modeling was used to examine if group differences in diffusion measures were present between individuals with ASD and NT controls while controlling for several covariates (Age, IQ, motion, brain volume). To investigate the relationship between diffusion and symptomatology, we used Confirmatory Factor Analysis (CFA) and regression models to determine if the diffusion measures were predictive of diagnosis and behavioral symptom severity. Diagnostic indicators were measured using the Autism Diagnostic Observation Schedule (ADOS) and behavioral symptom severity was indicated by the Social Responsiveness Scale (SRS).

**Results:** Taken altogether, individuals with ASD exhibited poorer whole-brain diffusion, even after controlling for age, motion and IQ. Compared to NT controls, individuals with ASD showed decreased fractional anisotropy (FA), increased mean diffusivity (MD) and increased radial diffusivity (RD). These results were evident across the entire brain. CFA and regression analyses found that the biological measures of FA, MD, AD and RD were not predictive of behavioral outcome on the ADOS or SRS.

**Conclusions:** These results suggest that WM compromise begins early in ASD and persists throughout adulthood. Due to the nonlinear and dynamic nature of brain development in ASD, it is difficult to isolate aberrant changes in WM connectivity that might reflect core ASD symptomatology. Focusing more efforts on adults with ASD may give researchers a better understanding of which of these changes in diffusion are sustained beyond development and maturation. Our findings highlight the need for longitudinal studies to better understand how age-related changes in WM diffusion properties may relate to the behavioral profile often seen in ASD across the lifespan. Furthermore, measures of cognitive performance may be more suitable indicators in determining relationships between biological markers and behavioral outcome.

## VIRTUAL POSTER SESSION — BRAIN STRUCTURE (MRI, NEUROPATHOLOGY)

### 522 - Brain Structure (MRI, neuropathology) --- (V)

**522.001 (Virtual Poster)** Amygdala Subnuclei Involvement in Restrictive and Repetitive Behaviors in Children with Autism Spectrum Disorder  
**D. Seguin<sup>1</sup>, A. Hennessy<sup>1</sup>, S. Correa<sup>2</sup>, J. Martinez-Trujillo<sup>1</sup>, R. Nicolson<sup>2</sup> and E. Duerden<sup>1</sup>, (1)Western University, London, ON, Canada, (2)1137 Western Rd, Faculty of Education Building, Rm 1031, Western University, London, ON, Canada, (3)Department of Psychiatry, University of Western Ontario, London, ON, Canada**

**Background:** Restrictive and repetitive behaviors (RRBs) are included in the diagnostic criteria for Autism Spectrum Disorder (ASD). These heterogeneous behaviors can include motor stereotypies such as finger flapping, repetitive play and restrictive interests. Some forms of RRBs, like stereotypic movements, are thought to be linked to anxiety, and may serve as a self-soothing mechanism. The amygdala is a key structure involved in regulating emotion and controlling inhibitory behaviors.

**Objectives:** The main objective of our study was to investigate whether RRBs behaviors in children with ASD are associated with amygdala subnuclei development, and whether this relationship is modified by anxiety.

**Methods:** A total of 123 children underwent an MRI scan, 44 (34M) children with a diagnosis of ASD, and 79 (38M) typically-developing (TD) children. Children were 5-10 years of age (mean=7.98, SD=1.45). Parents completed the Child Behavior Checklist (CBCL), the Autism Spectrum Screening Questionnaire (ASSQ) and the Screen for Child Anxiety Related Disorders (SCARED). Restrictive and Repetitive Behaviors (RRBs) were measured using the subscale of the CBCL. We extracted the amygdala subnuclei volumes using FreeSurfer.

To examine whether RRBs were associated with amygdala subnuclei volumes and parent-reports of anxiety, a general linear model (GLM) with RRB total score as the dependent variable and amygdala subnuclei volumes, diagnosis (Dx), CBCL-Anxiety/Depression subscale scores, and Screen for Child Anxiety Related Disorders (SCARED-P) scores were predictor variables, adjusting for gender, age, scan site, and total cerebral volume (TCV).

**Results:** Children's RRB scores were significantly higher in children with ASD ( $p < .001$ ), as did gender ( $p = .003$ ), age ( $p < .001$ ), left Anterior/amygdaloid area (AAA) volume ( $p = .006$ ), left central subnuclei volume ( $p = .008$ ), left medial subnuclei volume ( $p < .001$ ), right accessory basal (AB) subnucleus volume ( $p = .008$ ) and right medial nucleus volume ( $p = .002$ ). Neither anxiety measures were associated with RRBs. An interaction analysis found significant main effects of diagnosis on left AAA volumes ( $p = .010$ ) and right AB volumes ( $p = .008$ ). Males with ASD had larger AB volumes, and females with ASD had smaller volumes.

**Conclusions:** Larger AAA and right AB subnuclei, regions deemed important for sensory information related to fear processing, were significantly larger in children with higher levels of repetitive behaviours. These enlarged amygdaloid subregions may be linked to repetitive behaviours in children with ASD. Longitudinal studies are needed to better understand these associations.

#### **522.002 (Virtual Poster) Cerebellar Anatomy and Sensorimotor Impairment in Autism Spectrum Disorder**

**W. S. McKinney<sup>1,2</sup>, S. E. Kelly, M. Styner, M. H. Campbell<sup>1,2</sup> and M. W. Mosconi<sup>1,2</sup>, (1)Clinical Child Psychology Program, Schiefelbusch Institute for Life Span Studies, University of Kansas, Lawrence, KS, (2)Kansas Center for Autism Research and Training (K-CART), University of Kansas, Lawrence, KS, (3)Psychiatry and Computer Science, University of North Carolina, Chapel Hill, NC**

**Background:** Sensorimotor issues and cerebellar structural abnormalities are common in autism spectrum disorder (ASD), but information on how they covary is limited. Studies examining the relationship between sensorimotor behaviors and discrete cerebellar systems are needed to clarify the brain basis of sensorimotor deficits.

**Objectives:** To test the overarching hypothesis that sensorimotor deficits across multiple effector systems are associated with discrete, localized cerebellar volumetric differences.

**Methods:** Fifty-eight participants with ASD (21 females) and 34 typically developing (TD) controls (18 females) matched on age (8-30 years), sex, and handedness completed a structural MRI scan and either precision grip testing, oculomotor testing, or both. Volumes of 18 cerebellar ROIs were extracted. Force variability was examined for each hand separately. Absolute error and variability of visually guided saccades were examined across multiple target locations (12° and 24°; left and right). Mixed effects models were used to compare sensorimotor behavioral performance and cerebellar volume between individuals with ASD and TD controls. Similar models were used to examine the relationship between force variability, saccade error, saccade variability, cerebellar lobular volume, and clinical symptoms of ASD.

**Results:** Relative to TD controls, individuals with ASD showed greater force variability across hands ( $p < .001$ ). Individuals with ASD showed reduced volume of cerebellar vermis VI-VII relative to TD controls ( $p = .005$ ). Relative to males with ASD, females with ASD showed reduced volume of cerebellar Crus II/lobule VIIB, while TD males and females showed similar volumes ( $p = .007$ ). Associations between saccade error and cerebellar volume for vermis I-V ( $p = .013$ ), bilateral Crus II/lobule VIIB (left:  $p = .002$ ; right:  $p = .010$ ), bilateral lobule VIII (left:  $p = .003$ ; right:  $p = .046$ ), and right lobule X ( $p = .013$ ) varied across groups: greater volume was associated with lower saccade error for TD controls only. Increased volume of vermis VI-VII was associated with reduced rightward saccade variability for TD controls only ( $p = .044$ ). More severe clinical issues were associated with greater right lobule VIII ( $p = .018$ ) and cerebellar white matter ( $p = .016$ ) volumes as well as reduced right lobule VI ( $p = .024$ ) and right lobule X ( $p = .003$ ) volumes. Reduced volume of right Crus II/lobule VIIB was associated with greater ASD symptom severity in males only ( $p = .043$ ), while reduced volume of right Crus I was associated with more severe restricted and repetitive behaviors in females only ( $p = .046$ ).

**Conclusions:** We identify multiple differences in cerebellar structure in ASD, including reduced volume of vermal lobules VI-VII across sexes and reduced volume of cerebellar Crus II/lobule VIIB specific to females, suggesting sex-specific structural alterations vary across cerebellar subregions. Together with our finding of associations between cerebellar dysmorphology and clinical severity, our finding of disassociations between cerebellar structure and oculomotor performance in individuals with ASD suggests cerebellar reorganization and structural variation contribute to multiple developmental issues in patients.

#### **522.003 (Virtual Poster) Gray Matter Covariations in Autism. out of Sample Replication of Using the Enigma-Autism Dataset**

#### Background:

Autism Spectrum Disorder (henceforth autism) is a complex condition associated with alterations in gray matter (GM) volume covariations, as reported in our previous study of a large multicenter dataset -- LEAP (Mei et al., 2020). One of the current aims for research into autism is to parse the neural heterogeneity of autism and better understand brain-behavior relationships.

#### Objectives:

To make progress on identification of potential neural markers and to validate the robustness of our previous findings, we intended to replicate our results using the Enhancing Neuroimaging Genetics Through Meta-Analysis (ENIGMA) autism working group.

#### Methods:

We studied 781 individuals with autism and 927 typically developing (TD) individuals, aged between 6 and 30 years, IQ>50 and across 37 sites. To quantify the GM volume, we used voxel-based morphometry (VBM) as before. Each participant's T1-weighted structural image was processed to acquire VBM maps using our previous customized group DARTEL template in CAT12. In the previous study, we found two independent components (ICs) with a significant group effect. Therefore, we used these two ICs spatial maps as masks and performed dual regression to separately estimate the participant's weights of corresponding ICs in the ENIGMA dataset. A Generalized Linear Model (GLM) was then used to examine case-control differences between participants loadings of each component while correcting for age, sex, IQ, and sites. Additionally, we also used GLM to investigate the relation between the brain GM covariation patterns and available Autism Diagnostic Observational Schedule (ADOS) scores in autism group (N = 494).

#### Results:

The two components of interest, isolated in the in the ENIGMA dataset, showed significant case-control differences in participant loadings (first IC:  $p=0.0013$ ; second IC:  $p=0.0021$ ), and we constructed the brain patterns of these two components in the ENIGMA data (Figure 1). These brain patterns were consistent with those found in the initial study. The first IC was primarily associated with decreased volumes of bilateral insula, inferior frontal gyrus, orbitofrontal cortex in the autism group relative to TD individuals. The second IC was related to decreased volumes of the bilateral amygdala, hippocampus, parahippocampal gyrus and cerebellum in the autism group relative to TD individuals. In keeping with our previous study, we did not find significant univariate associations between the brain measures and symptom severity in autism.

#### Conclusions:

In the present study, we have replicated our initial findings in a second large independent sample. This shows the robustness of GM covariation as a potential neural marker for autism and provides support for its future investigation as a biomarker.

#### References:

**522.004 (Virtual Poster)** Impact of Intermittent Theta-Burst Stimulation over the Bilateral Posterior Superior Temporal Sulcus on White Matter Structural Connectome in Children and Adolescence with Autism Spectrum Disorder

**H. C. Ni<sup>1</sup> and H. Y. Lin<sup>2</sup>,** (1)Psychiatry, Chang Gung Memorial Hospital at Linkou, Taoyuan, TAIWAN, (2)Department of Psychiatry, University of Toronto, Toronto, ON, Canada

---

#### Background:

Although theta burst stimulation (TBS) had therapeutic potential on autism spectrum disorder (ASD), no investigation explored the impact of TBS on white matter connectome in ASD.

#### Objectives:

In our randomized, double-blinded, sham-controlled and parallel trial, we aimed to explore the impact of TBS over the bilateral posterior superior temporal sulcus (pSTS) on white matter connectome in children and adolescence with ASD.

#### Methods:

65 children and adolescents with ASD were recruited and assigned randomly to the Active-Active (n=33; five female; mean age=13.5 years) or Sham-Active group (n=32; four female; mean age=12.7). First, participants received either iTBS or sham stimulations twice per week for the first 4 weeks. Later, all of the participants received iTBS stimulation twice per week for the following 4 weeks. Multishell high angular resolution diffusion imaging was acquired at baseline, week 4 and week 8. Whole-brain structural connectomes were reconstructed based on constrained spherical deconvolution and global tractography using MRtrix3. Schaefer-Yeo 100 cortical atlas combined with subcortical parcellations was used to generate a weighted structural network. Network-based statistics were employed to identify subnetworks of brain connections that exhibit significant group by time interactions.

#### Results:

In the between group analysis, no significant group by time interaction on subnetworks analysis from baseline to week4 and week8 was found. In the within group analysis, we found significant increase of white matter connectome between left post-central and dACC (Salience network) in the Active-Active group from baseline to week 8 (FDR-corrected  $p < 0.05$ ). However, we did not find significant change of white matter connectome in the Sham-Active group from baseline to week 8.

#### Conclusions:

Our preliminary results suggest 8-week iTBS over bilateral pSTS might induce neuroplastic changes in structural connectivity on the Salience network in ASD. We will further investigate how these white matter changes correlate with symptomatic changes following iTBS treatment.

#### **522.005 (Virtual Poster) Non-Verbal Cognitive Trajectories from Infancy through School-Age Reflect Brain Growth during the Same Period in Familial High-Risk Siblings**

Hazlett<sup>4</sup>, J. Piven<sup>4</sup> and J. B. Girault<sup>4</sup>,** (1)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (2)University of North Carolina, Chapel Hill, NC, (3)Gillings School of Global Public Health, University of North Carolina, Chapel Hill, NC, (4)\*co-senior author, University of North Carolina, Chapel Hill, NC, (5)Washington University School of Medicine, St. Louis, MO, (6)Speech and Hearing Sciences, University of Washington, Seattle, WA, (7)Radiology, University of Washington, Seattle, WA, (8)New York University, New York, NY, (9)Mallinckrodt Institute of Radiology, Washington University School of Medicine, St. Louis, MO, (10)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (11)University of Washington, Seattle, WA, (12)Psychiatry and Computer Science, University of North Carolina, Chapel Hill, NC, (13)University of Alberta, Edmonton, AB, Canada

**Background:** Cognitive ability is an important predictor of functional outcomes in individuals with autism spectrum disorder (ASD). In typical development, larger brain volume and surface area has been associated with greater cognitive ability. However, research in ASD suggests that disproportionately larger brain size may be related to poorer cognitive outcomes in the toddlerhood through school-age period (Amaral et al., 2017; Lee et al., 2020). Ideally, biomarkers of school-age cognitive outcomes would be identifiable in infancy, when the brain is most plastic and responsive to intervention. The relationship between brain growth in infancy, and school-age cognitive outcomes in ASD is unknown.

**Objectives:** This study aimed to understand how brain growth during the infant to school-age period is related to non-verbal cognitive trajectories in high familial risk siblings of children with ASD (high-risk siblings).

**Methods:** High-risk siblings (n=123) from the Infant Brain Imaging Study (IBIS) Network were seen at 12 and 24 months and followed up during the school-age period (5-11 years old) for structural MRI and clinical assessment. Non-verbal ability (NVIQ) was assessed at 12 and 24 months using the Mullen non-verbal developmental quotient (NVDQ), and at school-age using the Differential Ability Scales special nonverbal composite (SNC). Clinical diagnoses of ASD were assessed at 24-months (ASD+ = 29; 83% male, ASD- = 94; 57% male). Linear mixed effects models regressed NVIQ scores on age, while controlling for mother's education and sex. Participants' random intercepts and age slopes were clustered using K-means and Bayesian information criterion (BIC). Mean levels of total cerebral volume (TCV), total grey matter volume (GM), total white matter volume (WM), and total cortical surface area (SA) were estimated at each time point. Differences in these volumetric data were tested between the clusters using multiplicity-corrected repeated measures ANOVA.

**Results:** BIC identified a 4-cluster solution (n1 = 23, 9% ASD+; n2 = 55, 13% ASD+; n3 = 6, 67% ASD+; n4 = 39, 41% ASD+)(Figure 1). Several brain measures at school-age were significantly different between clusters 2 and 4: TCV ( $\bar{x}$  = -80,780 mm<sup>3</sup>, SE = 19,576,  $p$  = 0.0012); GM ( $\bar{x}$  = -43,598mm<sup>3</sup>, SE = 12,609,  $p$  = 0.0153); WM ( $\bar{x}$  = -36,915, SE = 8021,  $p$  = 0.0001), and SA ( $\bar{x}$  = -11,512 mm<sup>2</sup>, SE = 2242,  $p$  = < 0.0001) (Figure 2).

**Conclusions:** The clusters suggested three general patterns of cognitive development trajectories: Cluster 1: start above average and declining; Cluster 2: start at the average, with no change; and Cluster 3/4: start below average and improving. Across all brain volume measures, the largest cluster showing cognitive improvement (cluster 4) had the largest brain volumes at school-age compared to those with average, stable cognitive development (cluster 2). No significant differences were found between the clusters in brain measurement at the 12 or 24 month time points. This suggests that in familial high-risk siblings, regardless of ASD outcome, larger brain size may be related to a phenotype of improved cognitive functioning over time, however brain volume differences may not be evident until school age.

#### **522.006 (Virtual Poster) Phenotypic Correlates of Brain Morphometry in Young Children with Autism Spectrum Disorders**

**N. Kojovic<sup>1</sup>, B. Aurélie<sup>2</sup>, L. Ben Hadid<sup>3</sup>, E. Mullier<sup>2</sup>, P. Hagmann<sup>4</sup> and M. Schaer<sup>5</sup>,** (1)Developmental Imaging and Psychopathology Lab, UNIGE, Geneva, Switzerland, (2)University of Geneva, Geneva, Switzerland, (3)Department of Psychiatry, University of Geneva, Faculty of Medicine, 1211,

#### Background:

A growing body of literature suggests that neuroanatomic abnormalities such as increased cortical volume, thickness, and surface area, are evident in the first years of life in children with ASD.

#### Objectives:

The goal of this preliminary study is to characterize cerebral underpinnings of the behavioral phenotype in young children with ASD.

#### Methods:

A total of 113 scans were acquired from children with ASD (n=64, 10F), typically developing children (n=23, 8F). In children younger than 6 years, images were acquired in natural nocturnal sleep at Campus Biotech, Geneva (78 scans). Children of various developmental and sleep profiles were included, following the extensive and personalized behavioral training to adapt to the scanning environment.

Given the relatively large age span of the current sample we constrained these preliminary analyses to males younger than 6 with the diagnosis of ASD (n= 29, 3.24±0.92 years old). Cortical surfaces were reconstructed using the freesurfer 7.1 and were manually inspected and edited. Vertex-wise analyses were deployed to probe for the relation between brain morphology and behavioral phenotype. The supratentorial brain volume and age were used as covariates and results were corrected for multiple comparisons using Monte Carlo simulations.

#### Results:

Our preliminary results demonstrated a negative relationship between autism severity, as measured with the ADOS-2, and cortical thickness in the left lateral occipital area. The severity of symptoms in the Social Affect domain was negatively correlated with the cortical thickness of the left fusiform area. Moreover, a higher level of severity of social symptoms showed a negative association with the volume of a cluster in the left superior temporal lobe. Additionally, a higher level of repetitive behaviors negatively correlated with the cortical volume of the cluster in the left cuneus. No significant correlation was evidenced between the measure of cortical area and behavioral measures.

#### Conclusions:

Capitalizing on our rich database of phenotypic characteristics of children included in our cohort, we further intend to correlate differences in morphologic brain measures with behavioral measures of the processing of social information obtained using various eye-tracking paradigms.

#### **522.007 (Virtual Poster)** Use of Diffusion Tensor Imaging to Create Subgroups of Individuals with Autism Spectrum Disorder

**D. Y. Song<sup>1,2</sup>** and **S. Bisdas<sup>3,4</sup>**, (1)Department of Psychiatry, Seoul National University Bundang Hospital, Seongnam, Korea, Republic of (South), (2)Institute of Neurology, University College London, London, United Kingdom, (3)Lysholm Department of Neuroradiology, University College London Hospitals NHS Foundation Trust, London, United Kingdom, (4)Department of Brain Repair & Rehabilitation, University College London, London, United Kingdom

---

**Background:** Autism spectrum disorder (ASD) is a neurodevelopmental disorder with individualized trajectories in symptom manifestation. Such heterogeneous characteristics have called for subgroups that meet the individual's course, treatment, and outcome needs. While researchers believe that ASD stems from the associations of widespread white matter connectivity networks, previous studies creating subgroups have been limited to the use of observable behavioral data.

**Objectives:** The purpose of this study is (1) to explore the differences in the white matter microstructures between the ASD and their typically developing (TD) groups and (2) to create ASD subgroups by using the results from the voxel-wise comparisons.

**Methods:** A total of 229 individuals, aged 5-64 years, comprised of 134 ASD and 95 TD from the Autism Brain Imaging Data Exchange (ABIDE-II) dataset were included for analysis. Participants were divided into age groups to investigate potential effects by age (children n=67, adolescents n=108, adults=54). The Social Responsiveness Scale (SRS), a caregiver report with five subscales, was used to measure ASD-related traits. FMRIB Software Library (FSL) was used to pre-process and run the tract-based spatial statistics (TBSS) to perform the microstructural analysis. FSL Randomise with 5000 permutations was performed to examine between-group differences while covarying for age and intracranial volume (ICV). Multiple comparisons were corrected by threshold-free cluster enhancement. Fractional anisotropy (FA) and mean diffusivity (MD) values were used in the hierarchical cluster analysis of Euclidean distance and Ward's method to create subgroups. The number of subgroups was decided based on the distance presented in the agglomeration schedule. Univariate analysis of covariance (ANCOVA), while covarying for age, was performed to explore the clinical characteristics of each cluster group.

**Results:** There were no significant differences between the ASD and TD groups in white matter tracts when covaried with age and ICV. As a result, the findings from previous studies identified as the top key regions (e.g., corpus callosum, superior longitudinal fasciculus, fronto-occipital

fasciculus, cingulum) unique among individuals with ASD were chosen to be used as features in creating clusters. Two subgroups were made per age group, with the adolescent group differing in full-scale intelligent quotient and the adult group differing in the SRS attention subscale (Table 1).

Conclusions: There were no differences in FA and MD values between the two diagnostic groups. The clinical phenotypes per subgroup suggest the need for different treatment goals and approaches. Future studies with larger sample sizes and gold-standard diagnostic assessments to measure ASD-related traits are needed.

## Cognition: Attention, Learning, Memory

### PANEL — COGNITION: ATTENTION, LEARNING, MEMORY

#### 223 - Executive Functioning in Autistic Adolescents and Adults: Lived Experience, Relation to Outcomes and Response to Intervention

**Panel Chair:** Lauren Kenworthy, *Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC*

**Discussant:** Sharon daVanport, *Autistic Women & Nonbinary Network, Lincoln, NE*

**223.001 (Panel)** “When You’re Anxious, Planning Becomes Much More Painful”: Everyday Executive Function Difficulties from the Perspectives of Autistic Adolescents and Their Parents

**L. Kenny<sup>1</sup>**, A. Remington<sup>2</sup> and E. Pellicano<sup>3</sup>, (1)University College London, UK, London, United Kingdom, (2)UCL Centre for Research in Autism and Education, London, United Kingdom, (3)Macquarie School of Education, Macquarie University, Sydney, NSW, Australia

#### Background:

Researchers have long held that autistic people have executive function (EF) problems. Yet, despite decades of research on EF in autism, the existing literature remains contradictory and “confusing”, with, according to a recent meta-analysis, group differences of only moderate effect. Such effects are a far cry from the large effect sizes reported by autistic people and (more often) their caregivers on questionnaire measures of real-world EF. This discrepancy suggests that our current lab-based measures may lack sensitivity to the subtler, everyday experiences of autistic people. Yet, there is exceedingly little research eliciting such experiences and examining whether they map on to the construct as it is commonly assessed in the laboratory.

#### Objectives:

Understand in-depth the everyday EF experiences of autistic adolescents and their parents.

#### Methods:

Eighteen participants, including 11 autistic adolescents (10 young men, one young woman; aged 12 – 19 years) and seven of their parents completed semi-structured interviews about their EF abilities, including managing their time, multitasking, retaining information and adapting flexibly to changes in task demands. We adopted a critical incident technique, whereby participants were asked to recollect specific situations in which they (or their child) had excelled or had difficulties deploying EF. We followed Braun and Clarke’s method for reflexive thematic analysis using an inductive (bottom-up) approach to identify patterned meanings within the dataset.

Results: We identified four themes. Young people were adamant that their EF skills did not exist in a vacuum (Theme 1) but varied markedly depending on their motivation (“if it’s something in which I’m extremely focussed on in terms of interest, then I plan ahead of time quite well”) and mood (“when you’re anxious, planning becomes much more painful”) and could sometimes result in inertia. They also spoke of how their own (or their children’s) EF abilities were not fixed (Theme 2) but changed over time. Parents noticed that their children’s EF difficulties were becoming more apparent with age, which young people found frustrating as they longed for greater autonomy: “I do sometimes wish that they would leave me to make my own sort of decisions”. Young people were, however, divided about whether they viewed their EF difficulties as part and parcel of being autistic (Theme 3). While some felt that their executive difficulties “should not be planted at the door of autism”, others felt that they were intrinsic to who they are: “I have a one-track mind – it’s just the way I work”. Finally, while participants valued the strategies and accommodations to support their EF difficulties (Theme 4), they nevertheless felt that they often weren’t given sufficient opportunities “for me to do my own stuff” and thus exercise and develop these skills.

Conclusions: Participants’ phenomenological reports provide rare insights into their and their children’s executive difficulties – insights that do not straightforwardly map onto traditional theoretical models of EF. Future work on EF needs to take seriously the perspectives and subjectivity of autistic people themselves by triangulating quantitative, objective assessments with qualitative, subjective reports in complementary (controlled, uncontrolled) settings.

**223.002 (Panel)** Executive Function Problems Persist into Young Adulthood in Autism and Drive Psychopathology

#### Background:

Executive Function (EF) challenges are well established in autism and linked to key outcomes such as co-morbid psychopathology (Wallace et al., 2016; Hollocks et al., 2014). Longitudinal investigations of EF as measured by performance tasks have identified *gains in skills* with age (Kouklari, Tsermentseli, & Monks, 2018; Pellicano, 2010), while cross-sectional data on parent reported EF problems indicates *increasing difficulties* with age, perhaps reflecting a widening gap between autistic adolescents' EF capacities and environmental demands (Rosenthal et al., 2013). Assessment of parent reported EF problems across multiple time points is needed to better understand this apparent discrepancy and the impact of EF challenges on psychopathology in autism.

#### Objectives:

Explore trajectory of parent-reported executive function (EF) problems in autism from early childhood through young adulthood and the relationship of EF problems to psychopathology.

#### Methods:

Archival data (n = 941 data points) on 313 autistic people (79 female; mean age at first visit=9.5±4.6 years (range: 2.6-23.1 years) was extracted from a combined clinical/research database (see Figure 1). Inclusion criteria were: a DSM-5 autism spectrum disorder diagnosis, Full Scale IQ ≥70 at a time point when the participant was ≥5 years of age; and each participant had at least two assessments which were six or more months apart. Variables of interest were: age-appropriate Behavior Rating Inventory of Executive Function (BRIEF) Inhibit (inhibition), Shift (flexibility) and Working Memory scale scores, and parent-reported Child and Adult Behavior Checklist Affect, Anxiety and Aggression Scale scores.

Results: Growth curve modeling revealed that parent reported problems with flexibility and working memory are elevated and stable throughout childhood and young adulthood. Inhibition problems, while also elevated, decline significantly with age (0.5 T-score points/year of age,  $p<.001$ ). Level of parent education, sex-assigned at birth, visit type (clinical versus research) and child Full Scale IQ scores were not significant predictors of EF problems over time, a notable finding given the range of IQ scores observed in this sample across time points (64-145). The only exceptions to this were that females had significantly higher (3.45 T-score points) Inhibit scores across development than males, and research versus clinic visit predicted reduced (2 T-score points) Working Memory scores. Parent reported EF problems were significant predictors of psychopathology as reported on the Child and Adult Behavior Checklist. Flexibility (BRIEF Shift) was a consistent predictor of psychopathology across all three scales (Aggression, Affect, Anxiety) investigated ( $ts=3.5-6.2$ ;  $ps<.001$ ). In each case, higher levels of parent reported inflexibility predicted higher levels of psychopathology. Inhibition (BRIEF Inhibit) predicted Aggression scores ( $t=9.3$ ;  $p<.001$ ) and working memory predicted Affect scores ( $t=2.69$ ;  $p=.007$ ).

Conclusions: Parents report significantly elevated EF problems in their autistic children throughout childhood and into early adulthood. With the exception of inhibition, trajectories of change in EF problems do not indicate improvement over time. EF problems predict increased burden of psychiatric comorbidities over time, making them an important target for intervention.

Figure 1. Accelerated longitudinal structure of study participants. Each line is one participant (Male = blue, Female = black); each circle is a data collection time point.

#### **223.003 (Panel) Associations between Executive Functioning and Subjective Quality of Life in Autistic Adults**

**G. L. Wallace<sup>1</sup>, G. A. McQuaid<sup>1</sup> and N. R. Lee<sup>2</sup>**, (1)The George Washington University, Washington, DC, (2)Department of Psychological and Brain Sciences, Drexel University, Philadelphia, PA

---

Background: Executive function (EF), or the set of cognitive functions that serve self-regulatory roles in the service of problem solving and goal attainment, is a well-established marker of critical outcomes (e.g., adaptive skills and co-occurring psychopathology) in autism. To date, most of this work has focused on the developmental periods of childhood and adolescence, and the outcome metrics rarely prioritize subjective outcomes. Thus, whether EF is linked to subjective outcomes in autism during adulthood remains largely unknown.

Objectives: Examine associations between components of EF and various domains of subjective quality of life (QoL) in a large sample of autistic adults spanning a wide age range.

Methods: 805 autistic adults (447 assigned female at birth) aged 18-83 (M=40, SD=14) years were recruited via Simons Powering Autism Research Knowledge (SPARK) Research Match to complete online questionnaires. EF was assessed using the self-report versions of the Flexibility Scale-Revised and components of the Barkley Deficits in Executive Function Scale (inhibitory control and emotion regulation), while subjective QoL was evaluated across four domains (physical, psychological, social, environmental) using the World Health Organization Quality of Life (WHOQOL-BREF), and a fifth domain focused on autism-specific QoL (Autism Spectrum Quality of Life [ASQOL]). Five hierarchical linear regressions were conducted with age, sex assigned at birth, educational attainment, and autistic traits (Autism Spectrum Quotient-28) entered as covariates in the

initial step, and the three EF variables entered in the second step. To account for issues of multiple comparisons, a Bonferroni correction was calculated; thus,  $p < .01$  (.05/5) was considered statistically significant.

Results: All five regression models were consistent; after controlling for age, sex assigned at birth, educational attainment, and autistic traits, emotion regulation (unlike flexibility and inhibitory control) challenges contributed additional variance to subjective QoL (physical:  $\Delta R^2 = .08$ ; psychological:  $\Delta R^2 = .13$ ; social:  $\Delta R^2 = .04$ ; environmental:  $\Delta R^2 = .05$ ; autism-specific:  $\Delta R^2 = .07$ ; all  $ps < .001$ ).

Conclusions: These findings reveal for the first time that components of EF are selectively linked to aspects of subjective QoL in autism across adulthood. Specifically, emotion regulation, unlike flexibility and inhibitory control, challenges were associated with all five subjective QoL measures. Prior research has shown that emotion regulation difficulties are linked to increased risk for developing various forms of psychopathology (e.g., depression), which in turn detrimentally impact adult outcomes in autism. Therefore, EF in the form of emotion regulation, might directly and/or indirectly impact subjective QoL in autism during adulthood, though this possibility has yet to be tested. Regardless of the pathway of influence, these findings provide preliminary evidence for the importance of emotional regulation as a treatment target for future interventions that seek to optimize adult outcomes in autism.

**223.004 (Panel)** Developing Phenotype-Specific Interventions to Promote Meaningful Outcomes for Transition-Age Youth with ASD  
**C. E. Pugliese<sup>1</sup>, L. Anthony<sup>2</sup> and L. Kenworthy<sup>1</sup>**, (1)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (2)University of Colorado, Denver, Aurora, CO

Background:

Executive function (EF) impairment is pervasive in ASD and linked to poor adult outcome. Autistic people have unique perspectives, knowledge and skills, but are often prevented from sharing their gifts by EF weaknesses. EF problems are pivotal targets for intervention (Hume, Loftin & Lantz, 2009) because they are common (Hill, 2004), linked to independence (Pugliese et al., 2015), and responsive to treatment (Kenworthy et al., 2015). However, there are no evidence-based EF treatments for transition-age youth and youth have difficulty generalizing skills learned in the clinic to real-world settings. In response, we leveraged cognitive neuropsychological approaches to develop a novel EF intervention based on the unique cognitive phenotype in ASD to capitalize on EF strengths and teach skills to support/accommodate EF weaknesses. Unstuck & On Target: High School (UoT:HS) is a 25-lesson CBT delivered by trained teachers at school. Intervention content is directly relevant to the EF profile in ASD (e.g., emphasis on self-advocacy, flexible problem solving, planning, time management, and independent goal-setting). Intervention delivery capitalizes on the learning strengths in ASD (e.g., scripts and routines) and promotes application to real-world situations.

Objectives:

1) Discuss development process of UOT:HS informed by existing models of the cognitive phenotype in ASD that teaches teens to capitalize on cognitive strengths and accommodates challenges, and 2) test preliminary effectiveness on improving EF skills and more distal outcomes relevant to the autistic community (adaptive/classroom behavior).

Methods: UOT:HS content was developed by neuropsychologists, psychologists, and educators with input from the autistic community. To evaluate effectiveness, 10 schools were randomized to school supports as usual (SAU) or UOT:HS delivered by school staff. All participants ( $n=55$ ) were aged 14-20 ( $M=16.4$ ,  $SD=1.3$ ) and had an FSIQ  $\geq 80$  ( $M=105.8$ ,  $SD=14.7$ ). ASD diagnoses were verified via school classification of ASD supported by the Social Communication Questionnaire ( $n=37$ ) and/or ADOS ( $n=21$ ). Outcome measures included masked classroom observations, parent-report on the ABAS-II and BRIEF-2 Shift scale, and a semi-structured interactional task tapping flexibility and planning skills (EFCT). Group change was evaluated via linear mixed-effects models of change scores (Post-Pre, 5 month Follow Up-Post), controlling for baseline score of the outcome measurement and FSIQ. School was treated as a random effect to account for cluster variation.

Results:

There were no group differences on gender, age, race, IQ, ASD symptomatology, medication status, and parent education. The UOT:HS group improved more than SAU at endpoint on classroom behavior ( $t=-2.33$ ,  $p=.019$ ,  $d=0.65$ , med-large effect), ABAS global composite ( $t=-3.40$ ,  $p=.0007$ ,  $d=1.03$ , large), ABAS Practical ( $t=-2.92$ ,  $p=.004$ ,  $d=.85$ , large), BRIEF Shift ( $t=1.88$ ,  $p=.06$ ,  $d=.55$ , med), and EFCT ( $t=2.66$ ,  $p=.008$ ,  $d=.76$ , large). Controlling for endpoint scores and IQ, there were no significant differences on these measures at follow-up.

Conclusions:

Data support the effectiveness of the first contextually-based EF intervention for high school students with ASD. Students taught UOT:HS improved more than the SAU group on classroom observations, direct measures of EF, and parent-report measures of adaptive behavior and EF with medium-large effect sizes. Next steps include testing UOT:HS in a larger RCT and evaluating change mechanisms.

## ORAL SESSION - 8B — COGNITION: ATTENTION, LEARNING, MEMORY

### 320 - Perception, Attention, Learning and Decision Making

**320.001 (Oral)** Re-Investigating 'fast' and 'slow' Processing in Autism

**Background:** Following the popularity of dual-process models in social and cognitive psychology, there is major interest in the possibility that Autism Spectrum Disorder (ASD) is associated with impaired 'fast' intuitive thinking but enhanced 'slow' or 'rational' deliberative thinking (see Rozenkrantz et al., 2021, *Trends in Cognitive Sciences*). If correct, this has great potential to help understand various strengths and difficulties characteristic of autism. Previous empirical investigations of this phenomenon, however, are marred by concerns about the measurement of intuitive and deliberative processing, as well as broader problems in clinical psychological science (e.g., small underpowered studies, lack of replication).

**Objectives:** Making a step change to previous research, we conducted 4 large-scale studies to re-examine intuitive and deliberative thinking in autism. This included a pre-registered comparison of 200 autistic and non-autistic adults, as well as the recruitment of larger, diverse samples, which were carefully informed by power analyses (Overall N = 1192).

**Methods:** In Studies 1-3, participants completed the Autism-Spectrum Quotient (AQ; Baron-Cohen et al., 2001) as a measure of autistic traits. In Study 4, 200 participants had a clinical diagnosis of autism, either as a child or adult, from an independent UK or US-based healthcare professional in a well-recognized clinical setting. Autistic participants were closely matched to 200 non-autistic adults who had indicated, at multiple time-points during a screening process, that they did not i) have a clinically diagnosed ASD, ii) self-identify as autistic, or iii) suspect they had a diagnosable ASD.

All participants completed widely used cognitive (e.g., Cognitive Reflection Test; Toplak et al., 2014; Sirota et al., 2020) and self-report measures (Rational-Experiential Inventory; Pacini & Epstein, 1999) of numerical and verbal intuitive and deliberative processing. They also completed a psychometrically robust measure of general cognitive ability (International Cognitive Ability Resource; Condon & Revelle, 2014).

**Results:** Except for a link between autism and lower self-reported intuitive thinking (all  $p < .001$ , all  $BF_{10} > 100$ ), we found no unique contributions of autism to intuitive or deliberative thinking across all 4 studies, as evidenced by frequentist and Bayesian analyses. This pattern of results was clear when, i) measuring autistic traits in non-clinical samples from the general population (Studies 1-3), ii) comparing large groups of age-, sex- and general cognitive ability-matched clinically diagnosed autistic and non-autistic people (Study 4a: see Figure), and iii) applying inclusion criteria based on AQ thresholds after pooling datasets (Study 4b).

**Conclusions:** Overall, these studies indicate that intuitive and deliberative thinking is neither enhanced nor particularly impaired in relation to autism. We deliberate on the implications of these findings for theories of autism and future investigation of strengths and difficulties in autistic people. We also discuss the wider implications of our methodology (e.g., pre-registration) for enhancing the replicability of future autism research.

### **320.002 (Oral) Practice Makes Perfect or Make Practice Perfect: The Contextual Interference Effect Facilitates Motor Learning and Transfer in Autism Spectrum Disorders**

**N. C. Foster<sup>1</sup>, C. Ansuini<sup>1</sup>, K. Pullar<sup>2</sup>, F. Battaglia<sup>1,3</sup>, L. Nobili<sup>3,4</sup>, S. J. Hayes<sup>5</sup> and C. Becchio<sup>1</sup>,** (1)Cognition, Motion and Neuroscience, Istituto Italiano di Tecnologia, Genova, Italy, (2)Neural Coding, Istituto Italiano di Tecnologia, Genova, Italy, (3)IRCCS Istituto Giannina Gaslini, Ospedale Pediatrico, Genova, Italy, (4)Department of Neurosciences, Rehabilitation, Ophthalmology, Genetics and Maternal and Children's Science, University of Genoa, Genova, Italy, (5)Department of Psychology and Human Development, Institute of Education, University College London, London, United Kingdom

---

**Background:** The classic advice for anyone learning a new skill is "practice makes perfect". While this is a good general rule, it lacks any indication of what form of practice will efficiently maximize learning. Random practice (i.e., performing different skills) has frequently been shown to result in better retention and transfer compared to blocked practice (i.e., performing the same skill). This effect known as the contextual interference (CI) effect (Shea & Morgan, 1979) has been demonstrated on motor learning in numerous experiments in typical adults and children. Here we examined this effect in autistic children.

**Objectives:** (1) to examine CI in autistic children.

**Methods:** Thirty autistic (mean age: 11.3 (1.8) years.months; 6 female) and thirty matched neurotypical (mean age: 10.9 (1.6) years.months; 6 female) children volunteered for the study, which was approved by the local ethics committee. Children practised three different 3-segment motor sequences during an acquisition following either a HighCI (random) or LowCI (blocked) practice condition. Children then performed the practised sequences in two retention tests (random and blocked structures; 5 trials per sequence, 15 trials per test) and two transfer tests (novel 3-segment and 4-segment sequences; 5 trials per sequence). We quantified *reaction time (RT)*, *movement time (MT)* and *total time (TT)* from all children across the three phases. To examine the CI effect, children's motor behaviour (*RT/MT/TT*) during the retention and transfer tests was normalised by the final 5 trials of the acquisition phase. Retention data were submitted to separate 2 *diagnosis* (autism, neurotypical) x 2 *practice condition* (LowCI, HighCI) x 2 *test* (blocked, random) x 3 *phase* mixed design ANOVAs. Transfer data were submitted to separate 2 *diagnosis* (autism, neurotypical) x 2 *practice condition* (LowCI, HighCI) x 2 *test* (3-segment, 4-segment) mixed design ANOVAs.

**Results:** *RT* and *TT* were faster ( $ps < 0.05$ ) in retention following the HighCI practice condition regardless of diagnostic status. The LowCI practice condition specifically led to slower ( $p < 0.05$ ) *RT*, *MT* and *TT* in the random retention test. Whilst ASD children's *RT* were generally slower in the

transfer tests, *RT* and *TT* were faster in both tests following the HighCI practice condition for both ASD and neurotypical children. Overall, the added complexity of the 4-segment sequence was more impactful on ASD children, with them showing significantly greater *TT* on this test specifically.

**Conclusions:** ASD and neurotypical children that learned via the HighCI practice condition showed faster *RT* and *TT* in both retention and transfer. Whilst sensorimotor planning problems have often been reported (Rinehart et al., 2001) in autism, the present CI effect suggests that domain general elaborative cognitive planning processes are operational in autism and can be engaged (i.e., via random practice) to boost retention and flexibility to different task demands.

### **320.003** (Oral) Gender and Parent Reports of Childhood Joint Attention Related Symptoms

**S. L. Birkeneder**<sup>1,2</sup>, J. C. Bullen<sup>1,2</sup>, M. Solomon<sup>3</sup> and P. Mundy<sup>2,4</sup>, (1)UC Davis, Davis, CA, (2)The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, Sacramento, CA, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (4)University of California at Davis, Davis, CA

---

**Background:** Joint attention symptoms are present early in the development of Autism Spectrum Disorders (ASD) and reflect problems in coordinating attention with other people to share a point of reference and experience. Joint attention is conceptualized as an infant behavior domain, but joint attention symptoms may also characterize the childhood phenotype of ASD. One previous report suggests that the Childhood Joint Attention Rating Scale (C-JARS) provides a valid measure of joint attention beyond infancy and preschool (Mundy, Novotny, Swain-Lerro, McIntyre, Zajic & Oswald, 2017).

**Objectives:** To provide additional information on the validity and psychometrics of the C-JARS in a large sample of 9 to 14-year-old children with ASD ( $N = 89$ ) who were heterogeneous with respect to co-morbid intellectual disabilities (Mean FSIQ = 85.2,  $SD = 27.2$ ) and age matched typical controls ( $N = 62$ ). To examine four hypotheses: 1) the diagnostic groups would differ on C-JARS scales; 2) C-JARS scales would display discriminant sensitivity and specificity for ASD; 3) C-JARS would provide comparable scores for girls and boys with ASD; 4) the ADOS SA scores from age 3 – 4 would predict C-JARS scores.

**Methods:** C-JARS data was collected in an outcome battery of a longitudinal study of the phenotypic development of ASD. The C-JARS is a 60-items parent report measure that provides a 46-item Prosocial Scale Score (PSC) that measures children's verbal and nonverbal spontaneous sharing of a point or reference and experience and a 14-item Asocial Scale Score (ASC) that primarily measures non-verbal problems in sharing attention and experience. Reliability estimates exceed  $\alpha = .80$  for both ASD and typical samples.

**Results:** Hypo 1: MANCOVA with FSIQ as the covariate revealed large effect Diagnostic Group differences on both the average PSC and ASC scales, PSC  $F(1,146) = 169.4$ ,  $p < .001$ ,  $p\text{-}\eta^2 = .64$ ; ASC  $F(1,146) = 85.1$ ,  $p < .001$ ,  $p\text{-}\eta^2 = .37$ . Hypo 2: A diagnostic group discriminant function analysis of PSC and ASC was significant,  $p < .001$ , with 97% and 88% of the ASD and TD groups correctly classified respectively. Hypo 3: There was as anticipated significant but modest Gender by DX group interaction for PSC,  $F(1,146) = 9.91$ ,  $p < .002$ ,  $p\text{-}\eta^2 = .06$ , whereby ASD girls scored lower than ASD boys on PSC, but TD girls rated higher than TD boys (see Fig. 1). Hypo 4: Age 3-4 ADOS SA scores predicted C-JARS ASC scores,  $r = .24$ ,  $p < .02$  but ADOS RRB scores did not,  $r = .14$ . However, both SA and RRB scores negatively predicted C-JARS,  $r = -.54$ ,  $-.46$ ,  $p < .001$ , respectively, from preschool to school-aged children.

**Conclusions:** In combination with the initial study (Mundy et al., 2017), these longitudinal and diagnostic data provide additional support and validity for gathering parent report data on the childhood development of joint attention symptoms in ASD. Post-hoc the gender difference finding suggests that differences in prosocial spontaneous sharing of experience behavior versus peers may play a role in ASD identification in girls that warrant examination.

### **320.004** (Oral) Autistic People Show Higher Susceptibility to the Postdictive Illusion of Choice.

N. Greene, L. Wilkinson, S. Hagan and T. Karaminis, Department of Psychology, Edge Hill University, Ormskirk, United Kingdom

---

**Background:**

We often think we have made a conscious choice although, in reality, we have not. In experimental settings, this illusion occurs when we are asked to make a decision and we are presented with the outcome before the short interval that is required for the decision to become a conscious experience. As a result, we misperceive the outcome as a decision we have just made.

This so-called postdictive illusion taps on fundamental perceptual processes, such as attention, the formation of conscious percepts, the encoding of individual items into coherent ensembles, and confidence in judgements. Importantly, many theories suggest that these perceptual processes are different in autistic perception. It is, therefore, theoretically interesting to examine the susceptibility of autistic individuals to the postdictive choice illusion.

**Objectives:**

To examine the susceptibility of autistic individuals to the postdictive choice illusion.

**Methods:**

We tested 21 autistic people aged 20-62 ( $M = 43.58$ ,  $SD = 14.22$ ) and 20 neurotypical people of comparable age and cognitive ability. The participants completed a 162-trial experiment based on Bear & Bloom (2016). In each trial, participants chose between two options (two dots of different colour) and were presented with the choice outcome (a third dot which had the “correct” colour) after a short very time interval (50-1000ms). Subsequently, participants were asked to report whether or not they had chosen the dot with the correct colour (same as the outcome), with the option to report that they did not have time to make a choice. The participants also rated their confidence on their YES/NO responses (1-5 Likert scale). The postdictive illusion occurred when (i) participants reported they had chosen correctly more frequently than the 50% chance; and (ii) this effect manifested only in the shorter time intervals for the presentation of the outcome (i.e., it was not a uniform YES bias). The postdictive illusion effect was modeled with an asymptotic regression line ( $P(\text{YES}) = b \cdot (1/\text{time\_interval}) + a$ ) as a function of time interval, where  $P(\text{YES})$  is the probability of reporting a correct guess.

#### Results:

Both autistic and typical participants performed consistently with the postdictive illusion of choice, as the probability of reporting that they have made the correct choice was higher than 50% chance for shorter intervals, and converged to chance levels for longer intervals. Importantly, in the shorter time duration (50ms), the rate of these responses was higher for autistic than for typical participants ( $BF_{10} = 3.05$ , “moderate” evidence for a group difference). This effect could not be accounted for by overall number of YES ( $BF_{10} = 0.31$ , “moderate” evidence for no differences), NO ( $BF_{10} = 0.32$ ), and “NO TIME” ( $BF_{10} = 0.33$ ) responses, as well as confidence ratings ( $BF_{10} = 0.59$ ). The slope parameter (b) of the fitted regression lines were also different for autistic and typical participants (the 95% confidence intervals did not overlap).

#### Conclusions:

Our results suggest that autistic people are more susceptible to the postdictive choice illusion than neurotypical people. This finding has implications for theories of autistic perception.

## POSTER SESSION — COGNITION: ATTENTION, LEARNING, MEMORY

### 417 - Cognition: Attention, Learning, Memory

#### 417.065 (Poster) Inhibitory Control in Male and Female Adolescents with Autism Spectrum Disorder (ASD)

*M. N. Cissne<sup>1</sup>, K. R. Bellesheim<sup>2</sup> and S. E. Christ<sup>1</sup>, (1)Psychological Sciences, University of Missouri, Columbia, MO, (2)University of Michigan, Ann Arbor, MI*

**Background:** Recent research suggests that individuals with autism spectrum disorder (ASD) experience particular difficulty resisting interference from visual distractors (RIVD) relative to other aspects of inhibitory control (e.g., prepotent response inhibition and resistance to proactive interference). The literature further suggests that the ASD-related disruptions in inhibitory control may be age-related, such that RIVD difficulty may be more pronounced in young versus older adolescents. Much less is known, however, regarding potential sex-related differences in the inhibitory profile (i.e., strengths and weaknesses) in individuals with ASD.

**Objectives:** The present study was designed to further examine potential age- and sex-related differences in inhibitory ability in individuals with and without ASD.

**Methods:** A sample of 44 adolescents (25 males, 19 females) with ASD and 45 adolescents without ASD (22 males, 23 females) participated. Participants completed a computerized flanker visual filtering task and a go/no-go task, which assessed RIVD and prepotent response inhibition, respectively.

**Results:** No significant effect of group (ASD, non-ASD) was observed for the flanker task ( $F(1, 56) < 1$ ,  $p = 0.69$ ,  $\eta_p^2 = 0.003$ ) or the go/no-go task ( $F(1, 69) < 1$ ,  $p = 0.90$ ,  $\eta_p^2 < 0.001$ ). There was also no significant interaction between sex and group for either task ( $F < 1$ ,  $p > 0.43$ ,  $\eta_p^2 < 0.01$ , in both instances). However, a significant relationship between flanker performance and age was observed for the ASD group, with the older children showing smaller flanker effects (i.e., better inhibitory ability) as compared to the younger children ( $F(1, 24) = 9.57$ ,  $p = 0.005$ ,  $pr^2 = 0.29$ ).

**Conclusions:** Consistent with previous research (e.g., Christ et al., 2011), there was no evidence of ASD-related impairment in prepotent response inhibition as measured by the go/no-go task. Also consistent with past findings (e.g., Boland et al., 2019), age-related differences in RIVD ability were evident for the ASD group. Notably, we found no evidence of sex-related differences in the inhibitory profile of individuals with ASD.

#### 417.066 (Poster) Unexpected Salient Associations Prompt Attention Transfer to Subtler but More Predictive Cues: An Effect Influenced By Individual Differences

*F. Papastamou<sup>1</sup>, A. Destrebecqz<sup>2</sup> and M. Kissine<sup>3</sup>, (1)Université libre de Bruxelles, Bruxelles, Belgium, (2)Université libre de Bruxelles, Brussels, Belgium, (3)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium*

**Background:** In the present associative learning study, we investigate the extent to which a salient and highly predictive cue can overshadow a subtler, but more predictive one. In line with error-based theories of learning, we hypothesize that the onset of unexpected events within a salient cue – outcome association should progressively draw attention to, and increase the learning of the subtler but more predictive cues. Considering recent

Bayesian models of autism which suggest that autistic and non-autistic individuals process prediction errors differently, as well as the well documented preference towards local processing in autism, we explore how, socio cognitive traits frequently reported in the condition may influence participant's associative learning.

#### Objectives:

Remaining agnostic as to the existence of 'autistic traits' in the general population; this study investigates whether participants with high scores to the Autism-Spectrum Quotient questionnaire (AQ) would display different gaze behaviour than participants with lower scores, either by spontaneously focusing on the subtle cues or by showing a greater learning update when presented with salient unexpected associations.

#### Methods:

In this eye-tracking study, forty participants (age  $m=20$ , and a F/M ratio of 33/7) were each presented with two sounds, predicting the animation of one of two visual stimuli displayed on a computer screen. These visual stimuli contained a salient feature (a shape) and a subtler feature (a filling pattern). In 20% of the trials, we swapped the pattern filling both shapes and animated the visual stimulus containing the pattern associated with the sound. Every 16 ms the presence or the absence of anticipatory fixations towards each stimulus were recorded, before the onset of the animation.

Results: Generalized Linear Mixed Models set to binomial logistic regression revealed a greater number of anticipatory fixations on the salient compared to the subtle cue during the oddball trials in all participants ( $z = -27.81, p < .001$ ). However, as shown in Fig. 1, these erroneous gaze anticipations gradually prompted participants to explore the subtler cue, while disregarding the uncertain salient cue ( $z = 2.11, p < .05$ ). Interestingly, as presented in Fig. 2, while all participants were subject to this overshadowing effect, we observed that participants with a higher AQ score updated their predictions in favor of the subtler and more predictive cues ( $z = -33.11, p < .001$ ) while participants with lower scores kept their priors unchanged ( $z = -2.43, p = .072$ ).

#### Conclusions:

While all participants were spontaneously biased by the salient cue, those with higher AQ scores progressively anticipated the outcome based on the subtle but highly predictive cue, whereas participants with lower AQ scores kept their predictions based on salient uncertain cues throughout the task. In line with recent work showing a positive correlation between autistic traits and a preference for predictability, these results also echo important frameworks of autism research that propose that neurotypical participants place more weight to their prior learnings when faced with unexpected events, whilst autistic individuals accord more weight to their prediction errors and therefore update their learnings more frequently.

#### **417.067 (Poster)** Autistic Individuals Show Less Grouping-Induced Underestimation Bias in Numerosity Judgments.

A. Pomè<sup>1</sup>, T. Karaminis<sup>2</sup> and D. C. Burr<sup>3</sup>, (1)Heinrich-Heine-Universität Düsseldorf, Düsseldorf, Germany, (2)Department of Psychology, Edge Hill University, Ormskirk, United Kingdom, (3)Department of Neuroscience, Psychology, Pharmacology and Child Health, University of Florence, Florence, Italy

---

#### Background:

Recent studies on the perception of numerosity have shown that when people are asked to judge the numerosity of a cloud of dots in which pairs of dots are connected with thin lines, they underestimate numerosity. This effect is referred to as grouping-induced underestimation bias and is thought to arise as dot-pairs are processed as an integrated whole rather than as individual items. We have recently shown that neurotypical individuals with higher levels of autistic symptomatology (Autism Quotient scores) show lower levels of grouping-induced underestimation bias, suggesting a weaker propensity for active grouping strategies compared to individuals with low autistic symptomatology.

#### Objectives:

In this study we examined whether the reduced grouping-induced underestimation bias generalizes to autistic individuals.

#### Methods:

Twenty-four adults with ASD and 24 age and cognitive ability matched neurotypical adults (TD) controls judged the numerosity of clouds of dots, which optionally included 20% of dot-pairs connected by thin lines. We focused on numerosities of 15 (moderate) and 100 (high), similar to our earlier study with neurotypical adults.

#### Results:

There were no significant group differences in precision in numerosity discrimination, suggesting that both groups were equally capable performing the task. However, for moderate numerosities ( $N = 15$ ), connecting pairs of dots induced an underestimation bias in the neurotypical but not the autistic groups. Moreover, the magnitude of the effect covaried strongly with AQ-defined autistic traits in the neurotypical range.

#### Conclusions:

Our results reflect a major difference between autistic and neurotypical numerosity perception with regards to the role of grouping. Furthermore, our findings suggest that the strength of the grouping is predicted by autistic symptomatology. Our findings provide strong support for theories of autistic perception that emphasize differences in global versus local processing. Our approach enabled us to tap grouping mechanisms indirectly, by asking participants to report judgements on apparent numerosity (and not on grouping or perceptual organization).

**417.068 (Poster)** Black-and-White Style Predictions in Autism: Findings from Electroencephalography (EEG)

**S. Tikir<sup>1</sup>, M. J. Crosse<sup>2</sup> and S. Molholm<sup>1</sup>,** (1)Albert Einstein College of Medicine, Bronx, NY, (2)Trinity College Dublin, Dublin, NY, Ireland

---

**Background:** Top-down predictions play an integral role in perception and behavior. Typically, one flexibly updates the strength of their predictions in a context-dependent manner. In autism, however, there is a firm adherence to routines without regard for context. This is clinically referred to as "resistance to change"; however, the basis of this maladaptive behavior is unknown. Recent theories posit impairments in the brain's ability to make and update predictions as a major source of autistic behavior.

**Objectives:** A prominent feature of predictive processing is flexibly tuning the level of certainty associated with predictions based on changes in stimulus statistics. We hypothesized that this is impaired in autism. To test this, we investigated how autistic adults (n=19) and non-autistic controls (n=20) adjust the certainty of their predictions upon parametric manipulation of cue validity.

**Methods:** Using a novel probabilistic task accompanied by electroencephalography (EEG) measures of brain activity, we parametrically manipulated cue validity at four levels: 100%, 84%, 66%, and 33%. Multiple stages of predictive processing were unpackaged by examining different time windows of the stimulus-locked activity: 1) ~100 ms before targets (to measure anticipation of upcoming inputs), 2) ~350 ms after targets (to measure registration of target statistics), 3) ~700 ms after targets (to measure updating of statistical models).

**Results:** While the control group showed a systematically graded modulation of potentials proportional to the level of cue-target validity as measured by the CNV and P300, the autism group showed a remarkable difference between the entirely predictable and slightly predictable conditions, which is compatible with the clinical autistic behavior of over-reaction to small perturbations. On the other hand, they showed reduced differences between unstable conditions compared to controls. Furthermore, responses to violation of predictions revealed two phases of activity with different time courses in the control group, suggestive of the engagement of two distinct neural networks and sets of processes. Strikingly, the later response was not modulated by probability in autism while showing sensitivity to statistics in controls. We speculate that the earlier response may reflect response inhibition and the recognition of the incongruity, whereas the latter may represent the re-evaluation of the predictive model based on outcomes.

**Conclusions:** Our results on CNV and P300 indicate that autistic individuals adopt a black-and-white style of predictions, predicting outcomes in a highly confident manner in stable environments while failing to adjust the level of confidence with respect to statistics in unstable settings. Moreover, lack of modulation of responses upon violation of predictions may indicate that the autistic brain does not update internal models after observing the outcome of predictions, despite successfully registering them in the first place. Overall, our findings offer novel insights into neurophysiological mechanisms of impaired adaptation to changes in autism, which may underlie the social communication issues and insistence on sameness, behavioral hallmarks of the spectrum.

**417.069 (Poster)** Causal Modeling of Large Psychological Datasets to Evaluate Cognitive Theories of ASD

**J. B. Ewen<sup>1</sup>, B. Tang<sup>2</sup>, J. Adamek<sup>3</sup>, B. Caffo<sup>4</sup>, M. A. Levine<sup>5</sup> and E. Wodka<sup>6</sup>,** (1)School of Medicine, Johns Hopkins University, Baltimore, MD, (2)Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Kennedy Krieger Institute, Baltimore, MD, (4)Department of Biostatistics, Johns Hopkins University, Baltimore, MD, (5)Developmental Neurology, Kennedy Krieger Institute, Baltimore, MD, (6)Center for Autism and Related Disorder, Kennedy Krieger Institute, Baltimore, MD

---

**Background:** Nearly 80 years since autism was first described, the cognitive/psychological basis for key symptoms is still an area of active research, particularly in the service of developing rational and targeted interventions. One challenge to progress is siloing of research programs; investigators often test a single hypothesis alone, rather than testing multiple hypotheses in direct competition, within the same cohort.

**Objectives:** To evaluate >1 cognitive explanatory models of the ASD phenotype within a single, large cohort. Literature review identified several cognitive hypotheses of ASD.

**Methods:** The Simons Powering Autism Research for Knowledge (SPARK) database contains rater-scale responses around a variety of symptoms of ASD for 10,000s of individuals with ASD. Elements collected via SPARK were appropriate to test two hypotheses. The first, proposed by Rutter, claims that a primary, pervasive communication disorder (ie, limitations in both verbal and non-verbal [NV] communication) cause aloofness. The second hypothesis, proposed by Richter, claims that primary aloofness results in altered development of verbal and NV communication skills.

Psychological constructs (verbal language, NV communication, aloofness) were defined based on theory, and items from the SPARK data dictionary were investigator-selected, prior to any analysis. Covariates included age, sex, family history, annual household income, broad cognitive development, and age of onset, among others. We selected cases from the SPARK database based on absence of missingness for all studied items and covariates. Directed causal models of the two hypotheses were defined and evaluated using linear regression with appropriate interaction and mediation terms.

**Results:** N<sub>(ASD)</sub>=13,903. NV communication and aloofness were strongly correlated ( $r^2=0.65$ ), a non-directional result that is consistent with both hypotheses. Verbal language and aloofness correlated far less strongly ( $r^2=0.03$ ). To further test the Rutter model, we examined the interaction of NV with verbal language when predicting aloofness. There was a significant interaction effect, however many individuals with relative strong verbal

language showed severe aloofness. To assess directionality of the relationship between aloofness on one hand and both NV and verbal language on the other, we regressed out aloofness (and other covariates) from the relationship between NV and verbal language. The results were consistent with aloofness causing both NV and verbal language variation and inconsistent with communication causing aloofness: both aspects of communication were statistically independent from each other once aloofness was regressed out (72% confidence).

**Conclusions:** The results were inconsistent with the Rutter model of a pervasive communication deficit causing aloofness. Results were however consistent with the Richter model showing aloofness causing deficits to a large degree in NV communication and, to a lesser degree, verbal communication. Significant limitations of the dataset for the current purpose should be considered: the data are not longitudinal; rater (rather than experimental/performance) data are likely associated with confounds that could spuriously increase covariance among the variables; these analyses only use data from individuals with ASD and therefore only assess inter-individual variation within the ASD spectrum rather than genesis of the ASD phenotype; analyses do not allow for the possibility that different causal paths are present in different individuals.

**417.070 (Poster)** Effects of Age on Verbal Memory and the Hippocampus in Adults with Autism Spectrum Disorder: Longitudinal Versus Cross-Sectional Findings

**B. A. Pagni<sup>1</sup>, M. Walsh<sup>1</sup>, E. Ofori<sup>2</sup>, K. Chen<sup>2</sup>, G. Sullivan<sup>1</sup>, J. Alvar<sup>3</sup>, L. Monahan<sup>1</sup>, N. Guerithault<sup>1</sup>, S. Delaney<sup>1</sup> and B. B. Braden<sup>3</sup>,** (1)Arizona State University, Tempe, AZ, (2)Banner Alzheimer's Institute, Phoenix, AZ, (3)College of Health Solutions, Arizona State University, Tempe, AZ

---

**Background:** Research aimed at understanding aging in adults with autism spectrum disorder (ASD) is growing, but critical longitudinal work in middle-age and older adults has yet to emerge. Adults with ASD have difficulty with tasks involving verbal memory compared with neurotypical (NT) adults. This may be related to differences in volume or integrity of the hippocampus and its primary structural connectivity pathway, the fornix.

**Objectives:** The aim of this study was to explore cross-sectional and longitudinal age-related differences in verbal learning, and short-term and long-term verbal memory, the volume of hippocampus, and fornix fractional anisotropy (FA) in adults with ASD, compared with a matched NT group.

**Methods:** Participants were 194 adults with (n=106; 74 male, 32 female) and without (n=88; 52 male, 36 female) ASD, ages 18-71. Participants who were 40-70 years of age (n=45; 37 male, 8 female) were evaluated at two time points two to three years apart. Hippocampal volume was measured via T1-weighted MRI with FreeSurfer. Fornix FA was measured from diffusion tensor imaging (DTI). Verbal learning and memory were measured with the Rey Auditory Verbal Learning Test (AVLT). For cross-sectional relationships with age, multi-variable regression analyses were conducted with diagnosis, age, diagnosis by age interaction, and sex as a covariate. For longitudinal analyses in middle-age and older adults, repeated measures ANCOVA were conducted with sex as a covariate.

**Results:** Cross-sectional analyses revealed short-term verbal memory and total word learning diagnosis main effects, with adults with ASD recalling fewer items than NT adults. For short-term verbal memory there was also a diagnosis by age interaction, with increasing age associated with worsening recall in NT adults only. However, in longitudinal analyses only middle-age and older adults with ASD declined in short-term verbal memory performance. Middle-age and older adults with ASD also had faster hippocampal shrinkage, compared to matched NT adults.

**Conclusions:** These preliminary longitudinal findings suggest age-related vulnerabilities in short-term verbal memory and hippocampal volume in middle-age and older adults with ASD, while cross-sectional findings suggest ASD protection from age-related declines in short-term verbal memory. Divergent cross-sectional versus longitudinal aging results could be due to cohort effects, underscoring the importance of longitudinal aging research in adults with ASD.

**417.071 (Poster)** Executive Functioning and Sleep in Children with ASD and Neurotypical Development

**H. K. Schiltz<sup>1</sup>, R. M. Fenning<sup>2</sup> and J. K. Baker<sup>3</sup>,** (1)Psychology, Marquette University, Milwaukee, WI, (2)Center for Autism, Child and Adolescent Studies, California State University, Fullerton, Fullerton, CA, (3)Center for Autism; Dept. of Child & Adolescent Studies, California State University, Fullerton, Fullerton, CA

---

**Background:** In children with autism spectrum disorder (ASD), sleep disturbance is highly prevalent and related to multiple areas of daytime functioning (Souders et al., 2017). Executive functioning (EF) is frequently impaired in ASD (Eylen et al., 2015) and is thought to be particularly sensitive to sleep disturbance in childhood due to its prolonged developmental maturation (Turnball et al., 2013). Empirical examination of sleep quality and executive functioning in ASD is sparse and mixed, and studies have predominantly relied on parent-report metrics (Cremone-Caira et al., 2019; Holingue et al., 2021). Research is needed to better understand these links using a multimethod approach, and to explore whether such associations may be unique to ASD.

**Objectives:** This study sought to 1) replicate higher levels of sleep problems and EF difficulties in children with ASD compared to neurotypical development (NTD) 2) examine associations between sleep and EF across children with ASD and NTD using a multi-method approach (i.e., parent report and direct testing) and 3) determine whether sleep-EF associations differ for children with or without ASD.

**Methods:** Participants included children with diagnoses of ASD (n=26; Age M=7.50, SD=2.18; 23% female; IQ M=83.31, SD=19.82) and NTD (n=21; Age M=5.67, SD=1.68; 33% female; IQ M=110.43, SD=12.14). Sleep problems were measured using the Children's Sleep Habits Questionnaire, Abbreviated. Executive functioning was captured with the Behavior Rating Inventory of Executive Functioning, Global Executive Composite (BRIEF-GEC) and the Tower of London, Total Score (ToL).

**Results:** The ASD and NTD groups differed on age and IQ, which were both related to variables of interest (Table 1); therefore, IQ and age were controlled in subsequent group-based analyses. Analysis of covariance (ANCOVA) controlling for age and IQ, revealed that on average, compared to the group with NTD, the group with ASD had higher levels of sleep problems ( $p < 0.05$ ) and greater EF difficulties on the BRIEF-GEC ( $p < 0.05$ ), but not significantly different ToL performance. Bivariate correlations indicated that more sleep problems were significantly related to greater reported EF difficulties (BRIEF-GEC) and demonstrated a marginal inverse association with poorer EF performance on the ToL across all participants (Table 1). Regression analyses predicting the BRIEF-GEC indicated direct effects of group and sleep problems, controlling for child IQ and age; the interaction between group and sleep problems was not significant (Table 2). For the model predicting ToL, effects of group, sleep problems, and their interaction were not significant (Table 2).

**Conclusions:** Parent-reported EF, but not direct testing of EF, revealed significant impairment in ASD and was associated with sleep problems similarly for both children with and without ASD. Sleep problems may have more meaningful implications for broad EF challenges observed by parents in daily life than maximal performance on a direct EF test of organization, planning, and inhibitory control. Improving child sleep quality may be an important avenue to support such EF difficulties for children who struggle in these areas. These findings will be discussed in relation to measurement and discrepancies in EF assessments. Future work should explore other metrics and specific domains of EF.

**417.072 (Poster)** Executive Functioning in Everyday Life in Children and Adolescents with Attention-Deficit/Hyperactivity Disorder and Autism Spectrum Disorders: A Two-Year Longitudinal Study

*E. W. Skogli<sup>1</sup>, P. N. Andersen<sup>2</sup>, S. Orm<sup>3</sup>, K. T. Hovik<sup>4</sup> and M. G. Øie<sup>1</sup>, (1)Innlandet Hospital Trust, Lillehammer, Norway, (2)Inland Norway University College of Applied Sciences, Lillehammer, Norway, (3)Innlandet Hospital Trust, Lillehammer, Norway, (4)Department of Psychology, University of Oslo, Oslo, Norway*

---

**Background:** Problems with everyday executive functions (EF) are considered a hallmark of Attention-Deficit/Hyperactivity Disorder (ADHD) and Autism Spectrum Disorder (ASD). Little is known, however, about the developmental pathway of everyday EF in these two groups, and whether the two groups follow a similar or different course.

**Objectives:** To examine and compare the developmental trajectories of parent-reported EF problems from childhood into adolescence among children and adolescents with ADHD, ASD, and typically developing children and adolescents (TDC).

**Methods:** In this longitudinal study, children and adolescents with ADHD ( $n = 84$ ,  $M_{age} = 11.6$ ,  $SD = 2.0$ ), ASD ( $n = 38$ ,  $M_{age} = 12.0$ ,  $SD = 2.3$ ), and TDC ( $n = 50$ ,  $M_{age} = 11.6$ ,  $SD = 2.0$ ) were diagnosed and assessed with parent-ratings of everyday EF at baseline and two-year follow-up (97% retention). Between baseline and follow-ups, the groups received treatment as usual. We conducted Linear Mixed Models for analysis of the developmental trajectories of everyday EF.

**Results:** The youth with ADHD and those with ASD displayed elevated levels of everyday EF problems relative to the TDC at baseline (Hedges  $g = 1.99$  to  $2.99$ ). Over the two-year period, everyday EF improved in the children and adolescents with ADHD relative to the TDC, whereas those with ASD displayed no improvement relative to the TDC. At two-year follow-up, both those with ADHD and those with ASD continued to display elevated levels of everyday EF problems relative to the TDC (Hedges  $g = 1.61$  to  $3.19$ ).

**Conclusions:** Despite improved everyday EF in the ADHD group across time, both the ADHD and the ASD groups continued to display elevated levels of everyday EF compared to TD youth. These findings suggest that everyday EF could be an important treatment target in children and adolescents with either ADHD or ASD. Assessment of everyday EF should be routine when diagnosing and treating children with ADHD or ASD, and the results should be shared with their caregivers and teachers.

**Keywords:** Attention-Deficit/Hyperactivity Disorder, Autism Spectrum Disorder, Children, Adolescents, Executive Functions, BRIEF.

**417.073 (Poster)** Executive Functions As Predictors of ASD Youth Mental Health during COVID-19

*C. Romero, University of Miami, Coral Gables, FL*

---

## **Background:**

Children with autism spectrum disorder (ASD) are at an increased risk for experiencing adverse psychosocial consequences of COVID-19 lockdown and social distancing. Recent research suggests that disruptions to routines necessitated by pandemic response have led to significant increases in the prevalence of psychopathology among youth with ASD.

Executive function (EF) skills are impaired in children with ASD, however, the profile of EF in autism is characterized by extensive heterogeneity. EF, a collection of cognitive processes that direct one's attention and behavior, has been identified as a predictor of mental health problems among youth. Children with ASD who have greater EF and cognitive flexibility ability show reduced anxiety and depression. Consistent with the impaired disengagement hypothesis, EF deficits may heighten the risk for psychopathology by inhibiting disengagement from negative thoughts and compromising one's ability to redirect behavior in a positive manner.

## **Objectives:**

The current study sought to explore the extent to which pre-pandemic levels of EF are associated with psychosocial outcomes in TD children and children with ASD during the COVID-19 pandemic. It was hypothesized that EF deficits would be associated with adverse psychosocial outcomes.

## Methods:

57 participants between 10 and 16 years of age ( $n_{ASD} = 25$ ,  $n_{TD} = 31$ ), underwent neuropsychological assessments before the onset of the pandemic including the Wechsler Abbreviated Scale of Intelligence (WASI II), Autism Diagnostic Observation Schedule (ADOS-2), Behavior Assessment System for Children (BASC-2), and the Behavior Rating Inventory of Executive Function (BRIEF). In July 2020, at the height of South Florida stay-at-home orders, participants completed the Social Psychological Measurements of COVID-19, The Perceived Stress Scale for Children (PSS-C), Screen for Child Anxiety and Related Emotional Disorders (SCARED), Mood and Feeling Questionnaire (MFQ) and The Child and the Youth Resilience Measure (CYRM). Multiple linear regressions were performed to investigate if pre-existing EF abilities predict anxiety and depressive symptoms during COVID-19. In each regression the covariates of age, IQ, and SES were entered in the model as fixed effects

## Results:

Examination of baseline symptoms in youth with ASD, compared with matched controls, demonstrate significantly elevated depression symptoms for children with ASD. Additionally, children with ASD experienced significantly elevated anxiety ( $F(1,54)=14.42$ ,  $p=0.003$ ) and depressive symptoms ( $F(1,54)=7.45$ ,  $p=0.009$ ) during the pandemic.

Pre-COVID working memory, inhibition, and emotional control EF abilities did not significantly predict COVID-related anxiety or depression. However, multiple regression analysis used to test if baseline cognitive flexibility, as assessed with the BRIEF Shift subscale, significantly predicted parent ratings of child anxiety. The results of the regression indicated that baseline cognitive flexibility explains 82.24% of the variance ( $R^2 = .82$ ,  $F = 1.46$ ,  $p = 0.24$ ). It was found that cognitive flexibility skills predicted anxiety ( $\beta = 1.04$ ,  $p = 0.02$ ) and depression ( $\beta = 1.04$ ,  $p = 0.09$ ) during COVID-19 lockdown.

## Conclusions:

In line with previous research associating greater cognitive flexibility with resilience, this study suggests that the Shift component of EF is associated with mental health status during the pandemic. Specifically, cognitive flexibility may be a factor contributing to resilient mental health outcomes in children with ASD.

**417.074 (Poster)** How Reliable Are the Parental Reports on Academic and Attention Performance of Children with Autism Spectrum Disorder? *C. S. Paula<sup>1</sup>, C. Mevorach<sup>2</sup>, R. Lowenthal<sup>3</sup>, J. Magalhães<sup>4</sup>, M. C. Teixeira<sup>1</sup> and M. Muller Spaniol<sup>5</sup>, (1)Developmental Disorder Program, Universidade Presbiteriana Mackenzie, São Paulo, Brazil, (2)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (3)Santa Casa Hospital, Sao Paulo, Brazil, (4)Mackenzie Presbyterian University, São Paulo, Brazil, (5)Developmental Disorders Program, Mackenzie Presbyterian University, Sao Paulo, Brazil*

**Background:** In low and middle-income countries, most diagnoses for Autism Spectrum Disorder (ASD), surveys, and evaluation of intervention outcomes use subjective measures from reports and questionnaires filled out by parents. However, parents' ratings and child performance were not correlated, and parents view can be influenced by a variety of aspects.

Besides, one aspect that appears less researched in ASD is attention skills, although attention is often atypical in this population and is closely linked to academic attainment, one of the main priorities for parents of children with ASD.

**Objectives:** to assess the concordance of parents' subjective evaluations of academic and attention performance in ASD children and adolescents with objective evaluations.

**Methods:** 32 children and adolescents (8-14 years) with ASD and their parents participated in the study. All participants were users of a public outpatient clinic in São Paulo city, Brazil. The children/adolescents completed the (1) School Performance Test (SPT), measuring performance in math, writing, and reading, and the (2) Attention Cancellation Test (ACT), measuring selective and alternating attention. Parents responded to three questionnaires related to to measure their children: (a) autistic symptoms and severity (Autism Behavior Checklist [ABC]), (b) school and attentional performance (a structured 5-point Likert-scale interview), (c) attentional deficits (Swanson, Nolan and Pelham questionnaire [SNAP-IV]). Spearman correlation coefficients were calculated to determine the degree of relationship between variables. Significance level was set at  $p < .05$ .

## Results:

Results show that overall academic performance from the SPT was significantly correlated with parents' ratings: in math ( $r = .553$ ;  $p = .001$ ), reading ( $r = .546$ ;  $p = .001$ ) and writing ( $r = .455$ ;  $p = .009$ ). In contrast, there was no clear association between children/adolescent's attention performance and parental reports (SNAP-IV) (all  $p$ -values higher than .05).

**Conclusions:** Overall academic parental rates were good predictors for child/adolescent performance in school which indicates that parents are involved and accurately alert of their children's activities in the school environment. On the other hand, it seems that parents have difficulties in perceiving attention deficits in their children. Thus, our results point to the need for direct measures with children/adolescents to assist in the diagnosis and treatment of ASD, particularly related to attention.

**417.075 (Poster)** Longitudinal Development of Real-World Executive Function Skills in Preschoolers with Autism Spectrum Disorder

**R. Foster<sup>1</sup>**, K. Alf<sup>1</sup>, C. Banarjee<sup>2</sup>, E. Diamond<sup>3</sup>, A. Boxberger<sup>2</sup>, B. Gordon<sup>2</sup>, V. Donthireddy<sup>2</sup>, K. K. Powell<sup>1</sup>, E. Brennan-Wydra<sup>2</sup>, A. Vermetti<sup>2</sup>, S. Macari<sup>2</sup> and K. Chawarska<sup>2</sup>, (1)Child Study Center, Yale School of Medicine, New Haven, CT, (2)Child Study Center, Yale University School of Medicine, New Haven, CT, (3)Child Study Center, Child Study Center, Yale School of Medicine, New Haven, CT, (4)Yale University, New Haven, CT

---

**Background:** Executive functioning (EF) skills such as remembering multiple steps in a task, adjusting to new environments, and staying organized are impacted in children with autism spectrum disorder (ASD). Parent-reported concerns begin as young as preschool (Smithson et al., 2013) and increase during school-age (Rosenthal et al., 2013). Given that there are important changes in EF during preschool (Zelazo, 2011), longitudinal measurement during this time can reveal when and in what domains real-world EF concerns emerge for children with ASD relative to their peers with developmental delays (DD) and typical development (TD).

**Objectives:** 1) Assess the stability of real-world EF as measured by the Behavior Rating Inventory of Executive Function – Preschool Version (BRIEF-P; Gioia et al., 2003) from early to late preschool in a sample of preschoolers with ASD, DD and TD; 2) compare the proportion of children with clinically significant EF concerns by age and diagnosis; and 3) determine which EF domains are subject to change over preschool in children with ASD.

**Methods:** Primary caregivers completed the BRIEF-P at Time 1 ( $M_{age}=38.7mo$ ) and Time 2 ( $M_{age}=61.6mo$ ) for 68 preschoolers with ASD ( $n=40$ ), DD ( $n=12$ ) and TD ( $n=16$ ). We examined T-scores ( $M=50$ ,  $SD=10$ ) from the Global Executive Composite (GEC) and the five BRIEF-P subscales: Inhibit, Shift, Working Memory (WM), Plan/Organize (PO), and Emotional Control (EC). Pearson's  $r$  correlations examined the association between Time 1 and Time 2 T-scores for the full sample and ASD group. Proportions of children with clinically significant EF difficulties (GEC T-score $>65$ ) were compared using tests of proportion. Within-subjects t-tests assessed change in T-scores over time in the ASD group.

**Results:** GEC and all subscale scores were positively correlated from Time 1 to Time 2 in the full sample (all  $r>.46$ ,  $p<.001$ ) and in the ASD group (all  $r>.43$ ,  $p<.01$ ). The proportion of children with clinically significant EF scores differed between ASD and TD at each time (Time 1:  $p<.001$ ,  $h=1.47$ ; Time 2:  $p<.001$ ,  $h=1.22$ ), but not between ASD and DD, nor were within-group changes in these proportions significant across time (Table 1). Within-subjects t-tests revealed significant increases (indicating greater difficulties) from Time 1 to Time 2 in GEC scores ( $p=.045$ ,  $d=.328$ ) and several subscales: PO ( $p=.014$ ,  $d=.405$ ), EC ( $p=.002$ ,  $d=.522$ ), and a marginal increase in Inhibition ( $p=.058$ ,  $d=.308$ ; Figure 1).

**Conclusions:** These findings suggest that individual differences in real world EF skills are stable from early to late preschool in children with TD, DD and ASD. In both early and late preschool, approximately 50% of children with ASD fell in the clinically significant range, complementing prior findings which collapsed across preschool (Smithson et al., 2013). The extent of EF difficulties increased for children with ASD compared to the normative sample across preschool, driven by changes in planning, organizing and emotional control skills. Given that preschool EF skills are predictive of children's school readiness (Pellicano et al. 2017), designing specific supports for children with ASD to develop planning, organizing, inhibition, and emotional control skills may help mitigate any worsening and prepare children for school entry.

**417.076 (Poster)** Preliminary Results on the Role of Emotional Difficulties in the Academic Success of Adolescents with ASD

A. P. Costa<sup>1</sup>, L. Morais dos Reis<sup>2</sup> and M. Franco<sup>2</sup>, (1)University of Luxembourg, Esch sur Alzette, LUXEMBOURG, (2)University of Luxembourg, Esch-sur-Alzette, Luxembourg

---

**Background:** There is significant variability in the academic achievements of young people with autism spectrum disorder (ASD; Keen et al., 2016). Some perform as expected, given their symptomatology and IQ and might perform better in some tasks such as visual reasoning (Mayes-Dickerson & Calhoun, 2003). Many, however, perform worse academically than their IQ would predict (Manti et al., 2011). For those with ASD with high IQs, the variability in academic achievement is even higher, some perform well in mainstream schools, while others need to attend special education settings (Church et al., 2000). This variability in the academic success of people with ASD might be due to several external factors such as pedagogical practices and curriculum type (Keen et al., 2016) but may also be due to internal factors such as emotional difficulties. Indeed, emotional ability is closely linked to academic readiness (Blair, 2012) and even though not all people with ASD have emotional impairments, these are far more common among those with ASD than among typically developing (TD) people (Nuske et al. 2013).

**Objectives:** To analyze the relationship between the emotional ability of adolescents with ASD and their academic achievement.

**Methods:** 39 German-speaking parents (38 mothers) reported online on the emotional ability and academic achievement of their adolescent children (29 ASD, 10 TD). The adolescents were aged between 10 and 19 years ( $M_{age}=14.36$ ;  $SD_{age}=2.03$ ), 25 were male and 14 female. Parents indicated the diagnosis of their children and reported autistic traits using the Autism Spectrum Quotient (AQ) Adolescent version (Baron-Cohen et al., 2006). Parents reported on a 6-point Likert scale their children's academic performance in German (mother tongue), arithmetic or mathematics, general knowledge, history or social studies, science, and foreign languages. To assess the adolescents' emotional ability, parents answered the Emotionale-Kompetenz-Fragebogen (EKF; Rindermann (2009) [eng. Emotional Competence Questionnaire] and a German version of the Children's Alexithymia Measure (CAM; Way et al. 2010).

**Results:** The analyses showed that adolescents with ASD were reported by their parents as having more autistic traits [ $t(37)=9.64$ ,  $p<.001$ ], less overall emotional competence [ $t(37)=4.31$ ,  $p<.001$ ], and scoring higher in alexithymia [ $t(37)=3.10$ ,  $p<.001$ ] than TD adolescents. However, they did not differ in academic performance [ $t(35)=0.28$ ,  $p=.78$ ]. Regression analyses conducted to understand the contribution of emotional difficulties to academic performance revealed that alexithymia was the only significant predictor: being reported by the parents as having higher alexithymia significantly predicted lower academic performance (Table 1).

Conclusions: Adolescents with ASD were reported by their parents as having more emotional difficulties than TD adolescents but they did not differ in terms of academic performance. However, looking at predictors of academic performance, alexithymia revealed to be a significant contributor. These preliminary results, based on a small sample of parent reports suggests that difficulties with emotional awareness, which are common among people with ASD, might be an important aspect to consider in regards to understanding the academic achievement of youth with ASD and their frequently encountered difficulties in school.

**417.077 (Poster)** Puppets Facilitate Attention to Social Cues in Children with ASD

**S. Macari<sup>1</sup>, X. E. Chen<sup>2</sup>, L. Brunissen<sup>1</sup>, E. Yhang<sup>1</sup>, E. Brennan-Wydra<sup>1</sup>, A. Vernetti<sup>1</sup>, F. R. Volkmar<sup>1</sup>, J. Chang<sup>2</sup> and K. Chawarska<sup>1</sup>,** (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Statistics and Data Science, Yale University, New Haven, CT

---

**Background:**

Diminished visual attention to faces of social partners represents an early characteristic of ASD. Early intervention programs incorporate enhancing attention to social partners as one of their goals (Kasari et al., 2010; Rogers et al., 2012). Anecdotally, children with ASD are thought to be attracted to puppet characters, though visual attention to puppets has never been studied empirically. Here we examined how attention to puppets as social agents may differ from attention to human social agents in young children with ASD.

**Objectives:**

1) Examine attention to faces as a function of a speaker (puppet versus human) and diagnosis (ASD vs. typical development (TD)) in response to a video-recorded interaction between a puppet and a human speaker; 2) Evaluate links between speaker preference and severity of autism symptoms.

**Methods:**

Young children with ASD (N=37; M<sub>age</sub>=49.44 months) and TD (N=27; M<sub>age</sub>=40.66 months) viewed a video of a puppet and a human engaged in a conversation (Figure 1). Dwell time on these faces (%HumanFace, %PuppetFace) was quantified via eye-tracking and analyzed using group (2) by speaker identity condition (Human Speaker, Puppet Speaker) (2) linear mixed models (LMM). Speaker preference proportions were calculated and correlations with autism symptom severity (ADOS) were computed.

**Results:**

LMM analysis of %HumanFace indicated a significant group x condition interaction ( $p < 0.01$ ). The speaker effect on %Human Face was lower in ASD than in TD ( $p < 0.01$ ). In contrast, analysis of %PuppetFace showed only the expected speaker effect ( $p < 0.001$ ), but no significant group effect or interaction (Fig2b). These results suggest that attention to a human speaker's face was diminished in ASD but attention to a puppet speaker's face was comparable to that observed in TD peers. Furthermore, TD children showed a preference for both speakers' faces ( $ps < .001$ ); children with ASD only showed a preference when the puppet spoke ( $p < .001$ ) (Figure 2). In the Human Speaker condition, lower attention to the human's face was associated with higher autism symptom severity ( $r = 0.37, p = 0.024$ ) while in the Puppet Speaker condition, there were no significant associations between speaker preference proportion and ADOS severity.

**Conclusions:**

Unlike humans, expressive and verbal puppets attracted the attention of children with ASD at levels comparable to that of TD controls. There was no evidence that the preference for the puppet speaker was associated with severity of autism symptoms, suggesting that children more severely impacted by autism are just as likely to attend to puppets as those with less severe autism symptoms. Considering that puppets can engage in reciprocal interactions and deliver simplified, salient social-communicative cues, they may facilitate therapeutic efforts in children with ASD. Puppets could enhance motivation to engage in social exchanges and provide a bridge to understanding human social cues for all children with ASD, regardless of their level of impairment.

**417.078 (Poster)** Self-Regulation, Academic Learning Rates, and School Performance in Preschoolers with Autism Spectrum Disorder

**Y. Chen<sup>1</sup> and L. B. Jahromi<sup>2</sup>,** (1)Department of Health and Behavior Studies, Boston University, New York, NY, China, (2)Teachers College, Columbia University, New York, NY

---

**Background:** Delay in self-regulation represents a significant challenge for children with autism spectrum disorder (ASD). They also demonstrate academic difficulties and underachievement compared to typically developing peers. It has been well-documented that typical children with greater self-regulation have better academic achievement (e.g., Blair & Razza, 2007). However, few studies have examined this association in individuals with ASD. Moreover, most previous work solely relied on standardized assessments to reflect children's temporary learning *outcomes* rather than their dynamic learning *process*. Little is known about how children's self-regulation is related to how they learn.

**Objectives:** This study examined how self-regulation in children with ASD, including executive function (EF) and effortful control (EC), was linked to their academic learning process and investigated the mechanisms underlying this association. Long-term school data of multiple literacy and mathematics programs were derived to reflect the dynamic learning process of children with ASD.

**Methods:** Thirty-two preschoolers with ASD from two specialized preschools in New York participated in this study ( $M_{age} = 51.35$  months,  $SD = 7.59$ , range from 36–68 months). Each participant had a clinical diagnosis of autism that was confirmed with the Autism Diagnostic Observation Schedule (Lord et al., 2012). Participants' EF skills were measured directly through the NIH Toolbox Cognition Battery (Gershon et al., 2013) and were reported by parents on the Behavior Rating Inventory of Executive Function-Preschool Version (Gioia et al., 2000). Parents also reported children's EC through the Child Behavior Questionnaire-Short Form (Putnam & Rothbart, 2006) and reward sensitivity through the Sensitivity to Punishment and Reward Questionnaire for Children (Colder & O'Connor, 2004). Teachers reported participants' school engagement on the Teacher Rating Scale of School Adjustment (Birch & Ladd, 1997) and adaptive behavior through the Vineland-3 Teacher Form (Sparrow et al., 2016).

**Results:** Children with higher overall EF levels demonstrated greater behavior engagement in school activities ( $r = .40$ ,  $p = .02$ ) and better adaptive behavior at school ( $r = .44$ ,  $p = .02$ ). Those with better inhibitory control and attention had better communication and reciprocal social interaction ( $r = .40$ ,  $p = .03$ ). Similarly, participants with better EC demonstrated better adaptive behavior ( $r = .45$ ,  $p = .02$ ) and socialization ( $r = .43$ ,  $p = .02$ ) at school. In terms of literacy learning, children with better emotional control achieved literacy learning objectives faster ( $r = -.42$ ,  $p = .03$ ). Those with better inhibitory control and attention learned new words faster ( $r = .60$ ,  $p = .02$ ). In terms of mathematics learning, children with higher overall EF levels achieved mathematics learning objectives faster ( $r = -.54$ ,  $p = .01$ ). Specifically, those with better working memory learned math concepts and mastered problem-solving skills faster ( $r = -.54$ ,  $p = .01$ ). See Table 1. Further analyses showed that the relation between self-regulation and academic learning was moderated by behavior school engagement and reward sensitivity. See Figure 1.

**Conclusions:** Self-regulation emerged as a potential protective factor for children with ASD in their school success in terms of engagement and adaptive level as well as academic learning rates. School engagement and reward sensitivity were two main factors that facilitated academic learning in children with ASD. Future interventions are recommended to focus on these areas to promote academic learning and school success in children with ASD.

**417.079 (Poster)** Short- and Long-Term Melodic Memory of Children on the Autism Spectrum of Varying Mental Ages.

**S. T. S. Wong, S. Stanutz, S. Sivathasan, E. Stubbett, J. Burack and E. M. Quintin, Educational & Counselling Psychology, McGill University, Montreal, QC, Canada**

**Background:** Children on the autism spectrum (AS) display typical or better levels of music perception on tasks of pitch and melodic discrimination and identification, indicating strong processing of local-level information (pitch) without impairment of global processing (melody). These findings are congruent with the Enhanced Perceptual Functioning theory. The aim of the current study was to extend the long-term music memory findings from single notes (Heaton et al., 1998) and the long- and short-term music memory findings by Stanutz et al. (2014) on a pitch discrimination and melodic memory task. We tested participants' long-term ability to remember a melody in a specific key to differentiate between local and global processing in a melodic context.

**Objectives:** Investigate and compare pitch and melodic memory children on the AS with varying mental ages (MAs) and among typically developing (TD) children.

**Methods:** Three groups of children, aged 7–13 years, participated in this study. They included groups of children on the AS with lower ( $N = 9$ ) and higher ( $N = 10$ ) verbal, nonverbal, and auditory working memory MAs, and one comparison group of TD children ( $N = 14$ ) matched on verbal, nonverbal, and auditory working memory MAs to the AS subgroup with higher MAs. In the first session (Melodic Learning Task), the participants learned four melodies in specific keys that were each paired with a picture of a specific animal. One week later (Music Memory Task), they were presented each of the four melodies in the original key and two new transposed keys. The participants were then asked to identify 1) the key in which they originally learned each melody; and 2) the animal with which each melody was paired. MA was derived from WASI-II and WISC-V. Musical experience of participants was accounted for. Participants with AS were assessed with the Autism Diagnostic Observation Schedule, 2<sup>nd</sup> edition (ADOS-2) to confirm diagnosis. The parents completed the Social Responsiveness Scale, 2<sup>nd</sup> edition (SRS-2) and the Social Communication Questionnaire Lifetime version (SCQ-L) to describe the autism symptomatology among the participants on the AS and to ensure that the TD children did not present with signs of autism (below cut-off T-score of 60 on the SRS-2, or 11 on the SCQ).

**Results:** The analyses revealed 1) comparable accuracy at different points in the learning task and between groups, indicating comparable ability for all three groups to learn melodies (Figure 1); and 2) comparable performance in the retention of pitch and melody in long-term memory across all three groups (Figure 2).

**Conclusions:** We found comparable short-term melodic memory and melodic learning and long-term pitch and melodic memory between children on the AS and TD children. These findings also extend to children on the AS with lower MA, especially when verbal demands are minimized as in our long-term pitch memory task. The findings that children on the AS process music well supports both the increasing popularity of music education with this population and the importance of the inclusion of groups of different MAs in research on persons on the AS.

**417.080 (Poster)** The Relationship between Repetitive Behaviors and Concurrent Executive Function Demands in Children with Autism Spectrum Disorder

**S. E. Christ<sup>1,2</sup>, M. N. Cissne<sup>1</sup>, L. E. Kester<sup>1</sup>, A. J. Moffitt<sup>2</sup>, K. E. Bodner<sup>3,4</sup> and J. H. Miles<sup>2,5</sup>, (1)Psychological Sciences, University of Missouri, Columbia, MO, (2)Thompson Center for Autism & Neurodevelopmental Disorders, University of Missouri, Columbia, MO, (3)Case Western Reserve University School of Medicine, Cleveland, OH, (4)MetroHealth System, Cleveland, OH, (5)Child Health, University of Missouri, Columbia, MO**

**Background:** It has been previously theorized that impairments in executive function (EF) contribute to the manifestation of repetitive behaviors and restricted interests (RBRI) symptomatology in individuals with autism spectrum disorder (ASD). Past research examining this issue, however, has yielded mixed results. Prior studies that have utilized broad measures of EF have generally yielded positive results; whereas studies that employed measures thought to primarily tap an isolated component of EF often have not.

**Objectives:** Presently, we tested the hypothesis that the strength of the relationship between EF task performance and day-to-day manifestations of RBRI is moderated by the degree to the task places concurrent demands on multiple aspects of EF.

**Methods:** An eye movement task was used to evaluate inhibitory control and task switching ability (both together and in isolation) in a sample of 22 children and adolescents (mean age: 14.4 years) with ASD. The severity of RBRI symptoms exhibited by participants was assessed using the Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al., 2000).

**Results:** A significant relationship was seen between RBS-R scores and task performance under conditions that placed simultaneous demands on multiple EF processes (both inhibitory control and task switching) [ $p^2 = 0.25$ ,  $t(16) = 2.32$ ,  $p = 0.03$ ]. No relationship, however, was seen between RBS-R scores and task performance when demands were placed on only one EF process, in the switching only condition [ $p^2 = 0.09$ ,  $t(16) = 1.27$ ,  $p = 0.22$ ] or inhibition only condition [ $p^2 = 0.04$ ,  $t(16) < 1$ ,  $p = 0.42$ ].

**Conclusions:** The present findings provide support for the theory that impairments in EF contribute to the manifestation of RBRI symptoms in individuals with ASD. Furthermore, they suggest that the strength of the relationship between these two phenomena is dependent on the multiplicity, rather than the magnitude, of the demands under which EF is assessed.

#### **417.081 (Poster)** The Role of Autism Core Features and Inhibitory Control in Parent-Child Interactions across FXS Versus ASD

**E. Hunt<sup>1</sup>**, E. A. Will<sup>2</sup> and J. Roberts<sup>1</sup>, (1)Department of Psychology, University of South Carolina, Columbia, SC, (2)Psychology, University of South Carolina, Columbia, SC

**Background:** Fragile X syndrome (FXS) is a single gene disorder characterized by high prevalence of autism spectrum disorder (ASD) and inhibitory control (IC) deficits. IC deficits are also indicated in individuals with idiopathic ASD. Both ASD symptoms and IC deficits contribute to difficulties with interpersonal communication. Our previous work has demonstrated child ASD symptoms and poor IC interact to predict dysfunctional parent-child interactions in families of children with FXS.

**Objectives:** This study examined whether ASD symptom domains, namely atypical social affect (SA) and restricted and repetitive behaviors (RRB), and IC differentially predict parent-child dysfunctional interactions (PCDI) in children with FXS compared to children with idiopathic ASD with developmental delay. Additionally, we explored the relation between IC and each ASD symptom domain in both groups.

**Methods:** Participants included 51 children with FXS (14 females;  $M(SD)$  age = 44.96(11.93) months) and 46 chronological age-matched children with idiopathic ASD (7 females;  $M(SD)$  age = 44.96(11.61) months) and their mothers. IC was measured via the Early Childhood Behavior Questionnaire (18-36 months) or the Children's Behavior Questionnaire (>36 months). PCDI was assessed via Parenting Stress Index-SF. SA and RRB domains were assessed via the Autism Diagnostic Observation Schedule-2. PCDI was log transformed and RRB was cubed. Three multiple linear regression models predicting PCDI were tested with group, child variable (i.e., IC, SA, RRB), and group\*child variable terms and FXS as the reference group. Nonverbal developmental quotient, derived from the Mullen Scales of Early Learning, was included in initial models however did not significantly predict PCDI and was therefore excluded from final models. Pearson's correlations between child variables were tested across groups separately.

**Results:** Results from the model testing whether IC predicted PCDI showed a significant main effect of IC, ( $t(88) = -5.29$ ,  $p < .001$ ,  $b = -0.22$ ), and a significant IC\*group interaction, ( $t(88) = -2.32$ ,  $p = .023$ ,  $b = -0.15$ ), accounting for 24% of variance in PCDI. Results from the model testing the effects of SA on PCDI indicated a significant main effect of SA ( $t(92) = 2.82$ ,  $p = .006$ ,  $b = 0.05$ , adjusted  $R^2 = .06$ ). Results from the model testing whether RRB predicted PCDI also identified a significant main effect of repetitive behaviors ( $t(92) = 4.17$ ,  $p < .001$ ,  $b = 0.0005$ , adjusted  $R^2 = .17$ ). Pearson's correlations indicated significant associations between IC and atypical social affect, ( $r(46) = -.42$ ,  $p = .003$ ), and IC and repetitive behaviors, ( $r(46) = -.54$ ,  $p < .001$ ), for the FXS group only.

**Conclusions:** Associations between greater IC with lower atypical social affect, repetitive behaviors, and parent-child dysfunctional interactions were specific to the FXS group, whereas greater repetitive behaviors were associated with greater parent-child dysfunctional interactions across FXS and ASD groups. These findings suggest that interventions targeting IC may be associated with broader positive outcomes for children with FXS and their families, including potential reduction of ASD symptoms and dysfunctional interactions. Rather, treatment focused directly on reduction of repetitive behaviors may contribute to more harmonious family dynamics in both groups. Findings suggest IC may have an important role in the characterization of ASD in FXS, though it may be less central to the expression of ASD symptoms in the general population.

### **VIRTUAL POSTER SESSION — COGNITION: ATTENTION, LEARNING, MEMORY**

#### **517 - Cognition: Attention, Learning, Memory --- (V)**

**517.062 (Virtual Poster)** A Follow-up Study on School-Age Outcomes of Children Born Very Preterm

#### Background:

An elevated likelihood to develop autism spectrum disorder (ASD) or the broader autism phenotype (BAP) has been observed in children born very preterm (VP; Vermeirsch et al., 2021). In addition, prevalence rates of cognitive impairment (Roze et al., 2021), executive dysfunctions (Mulder et al., 2011) and internalizing and externalizing problem behavior (Bhutta et al., 2002) are higher in VP- than in term-born (TB) children. It could be expected that these difficulties are even more pronounced in VP-children with more severe levels of ASD symptoms. Although prospective studies could provide valuable knowledge on this association and other early markers of school-age difficulties, longitudinal studies on the broad functioning of VP-children, while taking symptoms of ASD into account, have not yet been conducted.

#### Objectives:

To examine the cognitive-, behavioral and social-emotional functioning of VP-children at school-age, and to explore the predictive value of autism symptom severity at age three.

#### Methods:

67 VP-children and 36 TB-children without first-degree relative with ASD were previously followed from 5 to 36 months old. To date, 24% of them participated in a follow-up moment at school-age. More specifically, the current school-aged sample includes 16 VP-children (6 girls; mean age=8.90 years, sd=.30; mean gestational age=26.69 weeks, sd=1.25; mean birth weight=1028.44 g, sd=274.81) and 9 TB-children (6 girls, mean age=8.89 years, sd=.24). At the age of three, 2 of the VP-children (12.5%) had a BAP outcome, while 2 others (12.5%) received a best-estimate research diagnosis of ASD and/or had a clinical diagnosis at follow-up.

At school-age, the WISC-V intelligence test was administered and questionnaires on social-emotional wellbeing were filled out by the child. Executive functioning (planning, flexibility, inhibition and sustained attention) was assessed through the Color-Word Interference Test of the Delis-Kaplan Executive Function System (D-KEFS) and subtests of the Cambridge Neuropsychological Test Automated Battery (CANTAB).

#### Results:

First, the two groups were compared on all school-age outcomes. Preliminary results showed no significant differences in terms of depression, anxiety, self-esteem, number of friends, inhibition, total IQ or index scores (Verbal Comprehension, Visual Spatial index, Fluid Reasoning, Working Memory and Processing Speed). However, (marginally) significant differences in favor of the TB-group were detected on the CANTAB, more specifically on sustained attention (Rapid Visual Information Processing subtest;  $p=.025$ ), planning (Stockings of Cambridge subtest;  $p=.095$ ) and flexibility (Intra-Extra Dimensional Set Shift subtest;  $p=.057$ ). VP-children also reported to be bullied more often than TB-children ( $p=.079$ ).

Second, associations between ADOS-2 Calibrated Severity Scores of the VP-group at age three and the different school-age outcome variables were investigated. No correlations, however, could be observed.

#### Conclusions:

Although the VP-group scored slightly less favorable on all cognitive, social-emotional and behavioral outcomes, only the differences on executive functioning as assessed with the CANTAB were (marginally) significant. In this preliminary sample, severity of early autism symptoms was not predictive for school-age functioning.

At the conference, results of the full sample of 77 participants will be presented and clinical implications will be discussed. The results of the VP-children with ASD/BAP will furthermore be compared to those of the VP-children without ASD/BAP.

#### **517.063** (Virtual Poster) Category Learning Strategy in Autism Spectrum Disorders (ASD)

**J. R. Linde<sup>1</sup>, R. Handsman<sup>2</sup>, X. You<sup>3</sup>, D. Zeithamova<sup>4</sup>, A. Missner<sup>1</sup>, A. Verbalis<sup>5</sup>, C. E. Pugliese<sup>5</sup>, L. Kenworthy<sup>5</sup> and C. Vaidya<sup>6</sup>,** (1)Georgetown University, Washington, DC, (2)Center for Autism Spectrum Disorders, Childrens National Medical Center, Washington, DC, (3)Center for Neuroscience, Children's National Hospital, Washington DC, DC, (4)University of Oregon, Eugene, OR, (5)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (6)Psychology, Georgetown University, Washington, DC

---

#### Background:

Learning concepts that generalize to novel information, such as categories, is important for adaptive functioning. Difficulty with generalization in ASD has been attributed to a preference for detailed processing over integration or to rigidity in behavior; whether it is due to atypical learning has received less attention. While few, studies of category learning in ASD reveal mixed results, and provide little insight into why some children acquire generalizable category knowledge and others do not. Here, we explored variation in learning strategy by applying formal categorization models to

individual accuracy data in a perceptual category learning task, to fit models for representation of individual instances (exemplar-based) and their central tendency (prototype-based) in typically developing (TD) youth and those with ASD.

#### Objectives:

To characterize category learning strategies in autistic and typically developing youth.

#### Methods:

Participants were 46 youth with (n=24; males = 21) and without (n=22; males = 15) ASD, who were 14-18 years old (ASD M=15.77, SD=1.05; TD M=15.73, SD= .96) with normal intelligence (ASD M=105.92, SD=16.17; TD M=107.93, SD=10.14). Participants with autism met DSM-5 criteria based on the SCQ and/or ADOS-2, and those without autism had no diagnoses or active treatment for developmental or mental health conditions.

Over zoom, participants classified cartoon fish, bugs, or butterflies, into two “families” through feedback over 5 blocks in a training phase followed by a generalization phase with new exemplars. Training exemplars differed from prototypes by 2 features, whereas generalization exemplars differed from prototypes by 0, 1, 2, or 3 features. Accuracy was assessed with ANCOVAs including gender and age as covariates and between-subjects factor of group and within-subjects factor of block (1-5) at training and feature-away-from-prototype (0, 1, 2, 3) at generalization. For each participant, categorization models were fit to the generalization phase according to Bowman & Zeithamova (2018; J Neurosci, 38, 2605-2614). and superiority of prototype or exemplar fit was tested using Monte Carlo simulation; chi square assessed whether the number of participants with an exemplar, prototype, or no reliable strategy differed by group.

#### Results:

At training, accuracy was above chance in both groups for each block, and did not differ significantly between groups or by block. At generalization, Group X feature-away interaction approached significance ( $F(3, 39)= 3.91, p=.055$ ) such that the magnitude of group difference in accuracy was largest in the prototype condition – 0-feature-away (ASD M=72.1%; TD M=86.6%,  $t(44)=1.6, p=.049, d=.14$ ) and smallest in the 3-feature-away condition (ASD M=54.1%; TD M=59.3,  $p=.12, d=.05$ ); no other effects were significant. Further, 17 TD had a prototype-based learning strategy while only 10 ASD had a prototype-based strategy, these differences were shown at a significant level (chi square = 6.00,  $df=1, p=.01$ ).

#### Conclusions:

Results are suggestive of atypical prototype-based category learning in ASD based on qualitative observation of lower accuracy for prototype stimuli and fewer number of youth with superior model fits. This study is ongoing and larger samples will determine whether our observations are reliable.

#### **517.064** (Virtual Poster) Contextual Information Modulates Pupil Size in Autistic Children

**M. Turi<sup>1</sup>, C. Tortelli<sup>2</sup>, D. C. Burr<sup>3</sup>, R. Igliozzi<sup>4</sup> and P. Binda<sup>5</sup>**, (1)Department of Translational Research on New Technologies in Medicine and Surgery, University of Pisa, Department of Translational Research on New Technologies in Medicine and Surgery, Pisa, Italy, (2)university of pisa, pisa, Italy, (3)Department of Neuroscience, Psychology, Pharmacology and Child Health, University of Florence, Florence, Italy, (4)IRCSS Fondazione Stella Maris, Pisa, Italy, (5)Department of Translational Research on New Technologies in Medicine and Surgery, University of Pisa, Pisa, Italy

#### Background:

Recent Bayesian models suggest that perception is more “data-driven” and less dependent on contextual information in autistic individuals than others. However, experimental tests of this hypothesis have given mixed results, possibly due to the lack of objectivity of the self-report methods typically employed. Here we introduce an objective no-report paradigm based on pupillometry to assess the processing of contextual information in autistic children and a comparison clinical group.

#### Objectives:

In the present study, we used a no-report pupillometry paradigm to assess processing of contextual information in autistic children and a comparison group. Specifically, we tested whether a pictorial representation of the sun would lead to pupillary constriction when compared with control images.

#### Methods:

After validating (in a group of neurotypical adults) a child-friendly pupillometric paradigm, in which we embedded test images within an animation movie that participants watched passively, we compared pupillary response to images of the sun and meaningless control images in children with autism versus age- and IQ-matched children presenting developmental disorders unrelated to the autistic spectrum.

#### Results:

Both clinical groups showed stronger pupillary constriction for the sun images compared with control images, like the neurotypical adults. There was no detectable difference between autistic children and the comparison group (in spite of a significant difference in pupillary light responses, enhanced in the autistic group).

#### Conclusions:

Our report introduces an objective technique for studying perception in clinical samples and children. The lack of statistically significant group differences in our tests suggests that autistic children and the comparison group do not show large differences in perception of these stimuli. This opens the way to further studies testing contextual processing at other levels of perception.

#### **517.065 (Virtual Poster)** Executive Function As a Generalized Determinant of Psychopathology and Functional Outcome in School-Aged Autism Spectrum Disorder

**O. Wong<sup>1</sup>, R. Barzilay<sup>2,3,4</sup>, A. Lam<sup>1</sup>, S. Chan<sup>1</sup>, M. E. Calkins<sup>3,4</sup>, R. E. Gur<sup>3,4</sup> and R. C. Gur<sup>3,4</sup>,** (1)Department of Psychiatry, The Chinese University of Hong Kong, Hong Kong, Hong Kong, (2)Department of Child and Adolescent Psychiatry and Behavioral Science, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Lifespan Brain Institute (LiBI), Children's Hospital of Philadelphia and Penn Medicine, Philadelphia, PA, (4)Neurodevelopment and Psychosis Section, Department of Psychiatry, Perelman School of Medicine, University of Pennsylvania, Philadelphia, PA

**Background:** Individuals with autism spectrum disorder (ASD) are challenged not only by the defining features of social-communication deficit and restricted repetitive behavior, but also by a myriad of psychopathology varying in severity that causes functional impairment. Different cognitive deficits mediate the development of psychopathology, which could be subjected to intervention to alter the course of the disorder. Understanding domain-specific mediating effects of cognition is essential to develop targeted intervention strategies. However, the high degree of inter-correlation among different cognitive functions hinders elucidation of individual effects.

**Objectives:** To investigate domain-specific mediating effects of neurocognition on dimensional psychopathology and functional level in school-aged ASD.

**Methods:** In the Philadelphia Neurodevelopmental Cohort (PNC), 218 individuals with ASD were identified to match with 872 non-ASD controls on sex, age and socioeconomic status. The participants of this cohort were deeply and broadly phenotyped on neurocognitive abilities and dimensional psychopathology. Using structural equation modelling, inter-correlation among cognitive domains were adjusted before mediation analysis on outcomes of multi-domain psychopathology and functional level.

**Results:** While social cognition, complex cognition and memory each had a unique pattern of mediating effect on psychopathology domains in ASD, none had a significant effect on functional level. In contrast, executive function was the only cognitive domain that exerted a generalized negative impact on every psychopathology domain (P factor, Anxious-Misery, Psychosis, Fear and Externalizing), as well as functional level (measured by Children's Global Assessment Scale).

**Conclusions:** Relative to other cognitive domains, executive function has a unique role in determining severity of comorbid psychopathology in ASD and could be a target of intervention. As executive dysfunction occurs variably in ASD, our result also supports the clinical utility of assessing executive function for prognostic purposes.

#### **517.066 (Virtual Poster)** Executive Function As a Predictor of Academic and Social Outcomes in Kindergarteners with ASD

**E. P. McKernan, A. M. Viggiano and S. H. Kim, Psychiatry, Center for Autism and the Developing Brain, White Plains, NY**

**Background:** Executive function (EF) refers to the ability to self-monitor and flexibly adapt one's behavior in response to changes in the internal or external environment. Previous studies have suggested that elements of EF, including response inhibition, predict later mathematics and reading performance. Investigating how the trajectories of EF affect the development of functional skills such as academic and social skills can inform interventions targeting EF skills as early as the preschool years.

**Objectives:** Examine how kindergarten-entry EF is associated with academic and social skills across the kindergarten year in young children with ASD.

**Methods:** Participants included 62 cognitively able children with ASD assessed at kindergarten-entry (13 females;  $M_{age} = 63.8$  months;  $SD_{age} = 5.1$  months). EF was measured using a child-friendly, tablet-based battery of executive function tasks (EF Touch; Willoughby et al., 2010), including Spatial Conflict Arrows (SCA; inhibitory control), Something's the Same (STS; attention shifting), and Pick the Picture (PTP; working memory). Subtests of the Woodcock Johnson III Tests of Achievement (WJ; Woodcock et al., 2001) were used to measure children's reading and math skills (i.e., Passage Comprehension; Applied Problems). Children's peer play interactions (i.e., Play Interaction) were assessed via caregiver report on the Penn Interactive Peer Play Scale (PIPPS; Fantuzzo & McWayne, 2002). Generalized linear mixed models were performed to evaluate the effects of EF as a predictor of academic achievement and social functioning over time while controlling for baseline cognitive ability (i.e., nonverbal IQ [NVIQ]). When significant predictors emerged, we subsequently conducted separate analyses for each EF construct and its interaction with time.

**Results:** Passage Comprehension performance was significantly predicted by time ( $F[1, 119]=69.08, p < .001$ ) and SCA ( $F[1, 119]=5.79, p=.018$ ). Performance on Applied Problems was significantly predicted by time ( $F[1, 119]=77.72, p < .001$ ), SCA ( $F[1, 119]=.006, p=.006$ ), STS ( $F[1, 119]=10.25, p=.002$ ), and baseline NVIQ ( $F[1, 119]=7.62, p=.007$ ). Play Interaction was significantly predicted by time ( $F[1, 117]=4.65, p=.033$ ). In

subsequent models with interaction terms included, we found a significant interaction between SCA and time ( $F[1, 118]=4.07, p=.046$ ) for Play Interaction; post hoc investigation with low vs. high SCA group (based on a median split) showed that children with lower SCA at kindergarten entry still made improvements in Play Interaction while children with higher SCA showed stability in their play skills over time.

**Conclusions:** Lower EF skills at kindergarten entry predict lower academic skills across the kindergarten year, even when accounting for baseline cognitive ability. The results suggest that targeting EF prior to school entry may encourage greater success in kindergarten for cognitively-able children with ASD. Furthermore, examining other protective factors for social development in children with ASD over the kindergarten year will be crucial as children with lower levels of inhibitory control at kindergarten entry still showed improvements over time with regard to play interaction.

**517.067 (Virtual Poster)** Gaze Behaviors in Children with Autism Spectrum Disorder and the Impact of Parental Gaze Behaviors on Joint Attention  
*E. S. Perkovich<sup>1</sup>, S. S. Mire<sup>2</sup>, L. Sun<sup>1</sup>, A. L. Laakman<sup>2</sup>, G. J. Sakyi<sup>2</sup>, U. Sakhuja<sup>1</sup>, S. Lagbenro<sup>1</sup> and H. Yoshida<sup>1</sup>, (1)Psychology, University of Houston, Houston, TX, (2)Psychological, Health, and Learning Sciences, University of Houston, Houston, TX*

---

**Background:** Social communication difficulties in autism spectrum disorder (ASD) include limited attention to referential cues (including social gaze, gaze/point following, joint attention (JA), and gestures). Attentional behavior differences between children with ASD and typically-developing (TD) children are often studied during screen-based tasks without parental involvement; however, some researchers have suggested that child attentional experiences are scaffolded by parents' behaviors and should be studied in the context of this interaction. Limited research has examined this possibility, but parent-worn eye-trackers during play-sessions with their child may reveal subtle scaffolding behaviors that facilitate child attention.

**Objectives:** This study aims to assess 1) similarities and differences in attentional behaviors to targets between children with ASD and TD children, 2) similarities and differences in attentional behaviors to targets between parents of children with ASD and parents of TD children, and 3) to what extent parental gaze impacts child's JA during a natural task with head-mounted eye-trackers.

**Methods:** Thirteen ASD ( $M=68.26$  months,  $SD=20.61$  months, 3 females) and thirteen TD ( $M=53.41$  months,  $SD=11.75$  months, 7 females) parent-child dyads participated in 5.33-minute semi-naturalistic play-sessions while wearing head-mounted eye-trackers, generating 9804.837 frames on average for children and 10,006.919 frames on average for parents for statistical analyses. Gaze-to-target (objects, hands, face) data was coded for frequency and duration and annotated for saccades (<200 milliseconds), fixation (200-2000 milliseconds), and sustained attention (>2000 milliseconds), JA, and attention-shifting. Group comparisons were analyzed via t-tests and predictiveness between parent attention and child's JA was analyzed via linear regression.

**Results:** Child Attention: No significant group differences. Both groups distributed their attention similarly to the targets with that frequency order; objects>parent hands>parent face>child hands. Children in both groups most frequently exhibited saccades and spent the most time in fixation.

Parent Attention: TD parents demonstrated more fixations ( $p=0.025$ ), particularly to objects ( $p=0.011$ ), and longer looking time at objects ( $p=0.025$ ); they also made more attention shifts between their children's faces and objects ( $p=0.010$ ). ASD parents had a higher frequency of attention shifting between their own hands and their children ( $p=0.044$ ), particularly their children's faces ( $p=0.037$ ).

Parental Impact: Parents' target- ( $\beta=3.11, p=0.038$ ) and hand- ( $\beta=1.04, p=0.012$ ) looking frequency and object-looking ( $\beta=668.59, p=0.007$ ) duration are significantly predictive of their children's JA frequency; hand-looking frequency ( $\beta=.0059, p=0.030$ ) and object-looking duration ( $\beta=4.36, p=0.004$ ) are significantly predictive of their children's JA duration. ASD parents' child-looking frequency is significantly predictive of the frequency ( $\beta=.2, p=0.040$ ) and duration ( $\beta=24.94, p=0.027$ ) of their children's JA. TD parents' object-looking duration is significantly predictive of both the frequency ( $\beta=.0011, p=0.010$ ) and duration ( $\beta=.18, p=0.021$ ) of their children's JA.

**Conclusions:** While previous work on screen-based tasks suggests differences in gaze behaviors of children with ASD and TD children when using naturalistic interactive context, we observed similar gaze behaviors and that parental attention supports children's visual experiences. Specifically, we observed that ASD parents focused more on their children's faces and TD parents focused more on objects. Our work sheds light on the impact of social context and parental involvement on children's early attention, a facilitator of learning.

**517.068 (Virtual Poster)** Müller-Lyer Illusion Susceptibility Is Conditionally Predicted By Autistic Trait Expression  
*G. Tailor<sup>1</sup> and C. M. Glazebrook<sup>2</sup>, (1)Kinesiology and Recreation Management, University of Manitoba, Winnipeg, MB, Canada, (2)University of Manitoba, Winnipeg, MB, CANADA*

---

**Background:** The Müller-Lyer Illusion (ML) is a visual illusion that biases size estimation. ML figures feature central lines where each figure has two inward pointing, or two outward pointing arrows, on either end. Inward pointing arrows impose a perceptual bias where the line appears shorter, whereas outward pointing arrows impose a lengthening bias. Illusory bias can be assessed using a variety of methods inducing different degrees of bias. There is also some evidence that autistic individuals are less likely than neurotypicals to perceive illusory biases when the bias relies on environmental experience. It has also been suggested that autistic individuals, relative to neurotypicals, tend to rely on present stimuli more heavily over past stimuli. Varying levels of autistic trait expression have also been proposed to modulate susceptibility to illusions. The Autism Quotient (AQ) and Systemizing Quotient (SQ) questionnaires are validated self-report measures quantifying autistic trait expression and systemizing ability in neurotypicals.

**Objectives:** Taking the perspective that human perception and (inter)actions reciprocally influence one another, the current study aimed to determine if perceptions of illusory size bias in the ML negatively correlate with autistic trait expression in neurotypicals, and the extent to which varying methods of illusion presentation change both that relationship and the magnitude of illusory bias.

**Methods:** Thirty neurotypical adults (15 cis-female; 15 cis-male) completed both questionnaires and four size estimation tasks through a computer-based remotely conducted experiment. Tasks 1 and 2 featured 144 trials each and involved perceptual discrimination of ML figure sizes with concurrent and successive presentation. In Task 3, participants adjusted the length of a non-illusory line to match its length to an illusory target ML figure's central line over 128 trials. For Task 4, participants adjusted a composite ML figure to match its line size to a target ML figure's over 128 trials.

**Results:** Task 1 and 2 performance was determined by forced-choice biased selections, response time, and variability of response time. A stronger bias was found in the concurrent compared to successive figure presentation, with more biased figure selections and longer response times. Performance measures in Task 3 and 4 were magnitude of constant and variable error in figure adjustments. A stronger bias was found in composite ML figure adjustments compared to non-illusory figure adjustments. Task performance was generally not correlated with AQ or SQ. Two exceptions were positive correlations of constant and variable error to AQ when adjusting a composite illusory ML figure in Task 4. Participant sex was not a significant factor determining performance.

**Conclusions:** Simultaneous presentation of composite ML figures increases illusory size bias more than when figures are presented and perceived individually. Illusion susceptibility to the ML was reduced with increases in AQ, but only when the method of illusion measurement was adjustment of concurrently presented illusory figures. Thus, considering task details, including differences in the stimuli, instructions, and responses, can help explain the diversity of perceptual experiences that shape human (inter)actions. Future research will examine perceptual experiences across the autism spectrum(s) and the impact of perception on actions specifically.

**517.069 (Virtual Poster)** A Link between the Profiles of Attention and the Clinical Presentation of Autistic Females

**T. Del Bianco<sup>1</sup>, L. Mason<sup>1</sup>, M. C. Lai<sup>2,3,4</sup>, E. Loth<sup>5</sup>, J. Tillmann<sup>6,7</sup>, T. Charman<sup>8</sup>, H. L. Hayward<sup>8</sup>, T. Jones<sup>1</sup>,** (1)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (2)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom, (3)Centre for Addiction & Mental Health, University of Toronto, Toronto, ON, Canada, (4)Department of Psychiatry, National Taiwan University Hospital and College of Medicine, Taipei, Taiwan, (5)Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Neuroscience and Rare Diseases (NRD), Pharma Research & Early Development, Roche Innovation Center Basel, F. Hoffmann-La Roche AG, Basel, Switzerland, (8)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (9)Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom, (10)Department of Cognitive Neuroscience, Donders Institute for Brain, Cognition and Behaviour, Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands, (11)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, & Stockholm Health Care Services, Region Stockholm, Stockholm, Sweden

**Background:** Recent evidence has shown distinct profiles of autistic features in females, including domains such as social communication, with a more relevant use of social attention (i.e., the tendency to look at other people and parts of the body expressing social cues) compared to autistic males. Establishing a link between social attention in females' and clinical characteristics may help the implementation of diagnostics, procedures and interventions tailored for autistic females.

**Objectives:** We aimed to examine whether socio-communicative traits are linked to profiles of social attention in autistic females, based on the degree of difference from autistic males (sex differences) and neurotypical females (diagnostic differences).

**Methods:**

453 (123 females) autistic and 311 (107 females) non-autistic people participated in the Longitudinal European Autism Study (LEAP; see Table 1).

We built growth curve mixed models for females/males and autistic/non-autistic participants separately, with the proportional looking time (PLT) to the face across 3 eye-tracking tasks featuring static and dynamic social and nonsocial content (see Fig. 1A) as dependent variable, with sex, age and proportion of missing data as predictors. We extracted a) the random effects - i.e., individual coefficients and b) a difference score representing the degree to which social attention in an autistic female was more influenced by sex or diagnostic effects by subtracting/differencing the random effects of female participants in from the model that compared them to autistic males from that comparing them to and neurotypical females; both were used them as dependent variables in multiple linear regressions with ADOS Social Affect (SA) Calibrated Scores (CSS) and ADOS Repetitive Behaviour (RRB) CSS as predictors, in interaction with sex, with stimulus and age as covariates.

**Results:** In females only, higher ADOS SA-CSS (Coef. = -0.18, 95% CI = -0.28~-0.07) and ADOS RRB-CSS significantly linked to lower average PLT (Coef. = -0.22, 95% CI = -0.32~-0.11). A steeper decline of PLT linked to more symptoms in females, reflected in a distinct association between quadratic change and ADOS that differed from males (ADOS SA-CSS, Contr.=-0.28, SE=0.06, p-value<0.01; ADOS RRB-CSS, Quadratic, Contr.=-0.19, SE=0.06, p-value=0.01). In females, PLT was more influenced by sex than diagnosis when socio-communicative symptoms were lower, as indicated by the inverse relationship between ADOS SA-CSS and the difference score, both for average (Coef. = -0.001, 95% CI = -0.002~-0.0008) and quadratic change (Coef. = 0.0006, 95% CI = 0.00004~-0.001).

**Conclusions:** In females, more pronounced social attention and a relatively greater influence of sex-related differences relative to diagnostic group-related differences was related to fewer social communication difficulties. This finding suggests that the relation between social attention and social communicative function is stronger in autistic females. Social attention may provide autistic females with a tool for cultivating desired social interactions, and/or avoiding stressful ones, calling for longitudinal research investigating socio-communicative functions and autistic female experiences, such as camouflaging.

**517.070 (Virtual Poster) Adults with More Autistic Traits Are More Willing to Pay for “Useless” Information**

**H. Lu<sup>1,2</sup>, H. Zhang<sup>2,3,4</sup> and L. Yi<sup>3,4,5</sup>**, (1)Academy for Advanced Interdisciplinary Studies, Peking University, Beijing, China, (2)Peking-Tsinghua Center for Life Sciences, Peking University, Beijing, China, (3)School of Psychological and Cognitive Sciences, Peking University, Beijing, China, (4)PKU-IDG/McGovern Institute for Brain Research, Peking University, Beijing, China, (5)Beijing Key Laboratory of Behavior and Mental Health, Peking University, Beijing, China

---

**Background:**

Actively sampling information from the environment reduces uncertainty and is thus often instrumental for future outcomes, increasing the probability that a better action can be chosen. However, even when a piece of information is non-instrumental (i.e. does not influence future outcomes) and merely reduces uncertainty earlier, humans and non-human primates are still willing to pay for the information (Bennett et al., 2016), probably due to aversion to prolonged uncertainty. We hypothesize that as a consequence of intolerance of uncertainty (Hwang et al., 2019), the seeking of such “useless” information would be more common for people with autism spectrum disorders (ASD) or higher autistic traits.

**Objectives:**

The present study investigates whether and how autistic traits influence the willingness to pay for non-instrumental information in different outcome domains (i.e., loss vs. gain).

**Methods:**

Participants were 133 college students, who performed a non-instrumental information sampling task adapted from Bennett et al. (2016) on a computer with their eye movements recorded by a 300 Hz Tobii Spectrum. In each of 144 trials, participants faced a monetary lottery. In the beginning, they could choose between two decks of cards. An informative deck would cost 0, 1, or 3 game credits, and the other is always free but noninformative. Both decks consisted of five face-down cards that participants could click to flip them over to see. When participants chose the informative deck, the cards were predictive of winning or loss; when the noninformative deck, the cards were irrelevant to the lottery result. After participants flipped all five cards or decided to stop early, they must wait for five seconds before the final reveal of the result. In the gain domain, winning earned participants 20 credits and losing cost none; in the loss domain, winning gained them 0 credits but losing took 20 credits. Winning or losing was equiprobable and pseudo-randomly determined before the beginning of a trial. Two domains were pseudo-randomly assigned to 6 blocks, and three information costs were pseudo-randomly mixed within each block.

**Results:**

Bayesian multilevel models showed that participants with higher AQ scores were more willing to pay for costly information, specifically the most expensive one (3 credits), to foretell the good news (i.e., the gain domain) compared with the bad news (Fig. 1a). High AQ participants also made faster information choice decisions particularly in the high-cost condition compared to the zero-cost condition (Fig. 1b). Consistent with the behavioral results, the time-course analysis of eye-tracking data revealed that participants with higher AQ tended to look more at the costly informative choice for expectedly rewarding prediction (Fig. 1c), specifically from around 967 to 1267 ms from the onset of the choice stimuli (i.e., two decks of cards).

**Conclusions:**

Participants with different levels of autistic traits differed in their preference and valuation for non-instrumental information. To summarize, participants with higher AQ were less sensitive to the monetary cost of the information, especially for the possible good news.

**517.071 (Virtual Poster) Evaluating Gender Differences in Perceptual Profiles of Individuals with Autism Spectrum Disorder**

**E. Marcil and A. Bertone**, McGill University, Montreal, QC, Canada

---

**Background:** Autistic perception is traditionally characterized by a superior ability to process detailed, spatial visual information non-social in nature, with difficulties with social information, such as that conveyed by faces. Two main theories have been developed to explain this phenomenon: the Weak Central Theory and the Enhanced Perceptual Functioning. While both acknowledge a tendency to favour local analysis in Autism Spectrum Disorders (ASD), the former postulates deficits in global processing whereas the latter does not. Although the aforementioned perceptual profiles are typically used to describe strengths and weaknesses in ASD, it remains unknown whether they are comparable in both males and females with ASD. The reason for this void in knowledge is that the neurocognitive theories in ASD are based on studies assessing a disproportionate number of male participants.

**Objectives:** The aim of this study was to assess whether non-social perceptual profiles are equivalent in both males and females with ASD and comparable to that of neurotypicals, as measured by the performance on a visuospatial cognitive task. The first hypothesis was that individuals with ASD would show a performance peak with local processing compared to neurotypicals. The second hypothesis, pertaining to possible gender differences, was that males with ASD would show a more pronounced cognitive peak than females.

**Methods:** Forty-two participants with ASD (21 females, 21 males) and 38 typically developing (TD), neurotypicals (19 females and 19 males) matched on age and Full-Scale IQ, completed a reversed, match-to-sample block design task on a touch-sensitive screen. Response time (RT; in seconds) for correct responses was calculated as the dependent variable of interest. Conditions included block designs defined by either low or high perceptual cohesiveness (PC) that favoured a local or global processing strategy, respectively, as well as different matrix sizes (4, 9, or 16 blocks).

**Results:** As expected, RTs were significantly shorter in high PC conditions. However, no effect of gender was reported between PC conditions. The interaction of diagnosis and gender was also not significant, indicating that RTs were not significantly different across diagnosis and gender groups. The interaction of diagnosis and PC was found to be significant for the high PC condition at the nine- and 16-block matrix sizes, but not at the four-block matrix size or in the low PC condition.

**Conclusions:** ASD and TD groups performed similarly in a reversed block design task targeting both local (low PC) and global (high PC) visuospatial processing. This pattern of results indicates that the ASD group had access to both local and global analyses and could switch between the two modes depending on the situation, leading to the conclusion that individuals with ASD exhibit neither an enhanced local visual processing nor a deficit in global visual processing, compared to neurotypicals. Cohesiveness condition manipulations did not result in gender differences in ASD either, as they had the same effect on female and male ASD groups. This suggests no significant gender differences in non-social perceptual profiles in ASD, although a follow-up with a larger sample size may be warranted.

#### **517.072 (Virtual Poster)** Outcomes of Online Executive Functioning Support Videos for Caregivers of Children with Executive Function Difficulties during COVID-19

**T. Dahlman<sup>1</sup>, J. V. Smith<sup>2</sup>, E. Grinstein<sup>3</sup>, J. Holmes<sup>4</sup>, A. Verbalis<sup>5</sup>, A. C. Armour<sup>6</sup>, L. Cannon<sup>6</sup>, M. A. Werner<sup>7</sup>, K. C. Alexander<sup>8</sup>, A. B. Ratto<sup>4</sup>, K. Hardy<sup>9</sup>, B. J. Anthony<sup>10</sup>, L. Kenworthy<sup>4</sup> and L. Anthony<sup>10</sup>,** (1)Department of Psychiatry, University of Colorado Anschutz Medical Campus, Aurora, CO, (2)Psychology, The University of Alabama, Tuscaloosa, AL, (3)University of Colorado Anschutz Medical Campus, Aurora, CO, (4)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (5)Children's National Hospital, Rockville, MD, (6)Ivymount School, Rockville, MD, (7)Program Development and Training, Ivymount School, Rockville, MD, (8)The Occupational Therapy Institute, La Mesa, CA, (9)Children's National Health System, Washington, DC, (10)University of Colorado, Denver, Aurora, CO

#### **Background:**

Autism Spectrum Disorder (ASD) and ADHD are both neurodevelopmental disorders associated with executive functioning (EF) challenges and increased caregiver strain. The COVID-19 pandemic further increased caregiver strain as caregivers found themselves managing their child's EF difficulties at home with few supports.

#### **Objectives:**

This project aims to better understand the viability of basic and brief videos to support caregivers managing their child's EF difficulties at home during COVID-19. The series consists of 12 short videos (e.g., animations, expert, and caregiver interviews), that describe child EF and skills caregivers could use and model.

#### **Methods:**

Participants were comprised of caregivers ( $N = 73$ ) of children with symptoms consistent with ASD and/or ADHD and flexibility or planning/organizational problems. Caregivers were majority female (90.4%) and had an average age of 41.4 years ( $SD = 6.3$ ). Their children were between 8 and 11 years old ( $M = 9.7$ ,  $SD = 0.96$ ). A 5-point Likert scale assessed helpfulness and value of the videos, and another measure assessed knowledge of video content. Caregivers reported their child's observed EF with two global executive function questions, which assess the degree of interference from child EF behaviors at home and frequency of EF difficulties on a 10-point Likert scale; higher scores indicate greater EF problems. Caregiver strain was assessed using the Caregiver Strain Questionnaire-Short Form 7, a 7-item questionnaire gauging child-related caregiver strain with a 6-point Likert scale; higher composite scores indicate greater strain. Change scores were calculated for pre- and post-video series for child EF interference and frequency, and caregiver strain. Paired t-tests were used to evaluate pre- and post- outcome scores in order to capture the magnitude of the videos' effect.

#### **Results:**

Results indicate a significant reduction in both interference of child EF behaviors ( $t = 2.18$ ,  $p = .03$ ) and their frequency ( $t = 4.37$ ,  $p < .001$ ), with small to medium effect sizes (Cohen's  $d$ s: 0.22–0.49) after viewing the videos. Caregivers also reported that child-related strain decreased ( $t = 3.08$ ,  $p = .003$ ,  $d = 0.31$ ) with a medium effect size, and caregiver knowledge significantly increased ( $t = -13.19$ ,  $p < 0.001$ , 95% CIs [-2.93, -2.16],  $d = 1.54$ ) with a large effect size. Furthermore, caregivers found the videos helpful ( $M = 3.88$ ,  $SD = 0.81$ ) and valuable ( $M = 4.17$ ,  $SD = 0.82$ ).

#### **Conclusions:**

Caregivers report modest reductions in the interference and frequency of observed child EF difficulties, reductions in caregiver strain, and an increase in knowledge following a series of caregiver support videos. Caregivers also find the support the videos offer helpful and valuable. These findings suggest that even brief, online, and asynchronous caregiver support videos may be effective in improving both caregiver and child outcomes and offer valuable support to parents managing their child's EF difficulties at home. All outcomes were based on caregiver self-report and there was no control condition; thus, these are preliminary findings that require replication in a randomized-controlled trial. The findings, nonetheless, suggest that low-cost, highly accessible caregiver support tools may yield important benefits for both caregivers and children.

**517.073 (Virtual Poster)** Processing Speed, Executive Function and Social Impairment in a Puerto Rican Sample of Children with Autism Spectrum Disorder.

R. E. Oliveras<sup>1</sup>, J. L. Baez-Morales<sup>2</sup>, W. Rodriguez<sup>1</sup> and E. Rosario<sup>1</sup>, (1)Behavior & Brain Sciences, Ponce Health Sciences University, Ponce, PR, (2)Behavior & Brain Sciences, PONCE HEALTH SCIENCES UNIVERSITY, Ponce, PR

---

**Background:** Autism spectrum disorder (ASD) is characterized by a myriad of strengths and weaknesses. Among those weaknesses, the literature has found deficits in cognitive domains such as processing speed and executive functions. However, it has not been studied how processing speed and executive function may relate to social impairment, particularly in a culturally diverse sample, such as a Puerto Rican sample of children with ASD. Following Mundy and Newell (2007) social cognition model, it is expected to find a significant relationship between these cognitive constructs and social impairment.

**Objectives:** Five main objectives were studied: 1) describe the pattern of scores in measures of intellectual skills, metacognition component of executive functions, and social impairment, 2) determine if processing speed index score is lesser than the other cognitive indices, 3) determine if there is a correlation between the processing speed index and metacognitive abilities of executive functions, 4) determine if there is a correlation between processing speed and social impairment symptoms, and, 5) determine if there is a correlation between metacognitive abilities of executive functions and social impairment symptoms.

**Methods:** The study followed a non-experimental transversal design correlational and exploratory type. A secondary data analysis was performed using a clinical database completed with previous neuropsychological assessment reports with a sample of Puerto Rican children. The sample consisted of 68 Puerto Rican children (57 [83.1%] males) with an ASD clinical diagnosis. The Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV), and the Behavior Rating Inventory of Executive Function (BRIEF), and Social Responsiveness Scales (SRS) parent forms inventories, respectively were analyzed. The Processing Speed Index (PSI) of the WISC-IV, the metacognitive index of the BRIEF and the SRS scores were analyzed following a partial least squares structural equation modeling (PLS-SEM).

**Results:** Consistent with the literature, the PSI appeared as the most affected measure when comparing other WISC-IV indices. The most significant Cronbach's Alpha are for the measures of executive function (.82) and social impairment (.88), while processing speed was within acceptable range (.60). The processing speed construct had a negative significance to social impairment ( $\beta = -.165$ ,  $p < .037$ ) and to executive function impairment ( $\beta = -.197$ ,  $p < .050$ ). However, executive function impairment had a positive significant relation to social impairment ( $\beta = .653$ ,  $p < .001$ ). When assessing the direct effect mediation of executive function impairment between processing speed and social impairment, the former mediated the relation in a negative significant way ( $-.165$ ,  $p < .045$ ). Regarding the indirect mediation effect of processing speed on executive function and social impairment, results showed a negative and significant mediation ( $-.129$ ;  $p < .045$ ). However, effect sizes for processing speed in relation to executive function ( $f^2 = .041$ ) and social impairment ( $f^2 = .052$ ) were small suggesting limited practical implications.

**Conclusions:** There appears to be a relationship between processing speed, executive functions, and social impairment in a Puerto Rican sample of children with ASD. Following Mundy and Newell (2007) social cognition model, deficits among cognitive abilities could impact social functionality, and processing speed could be mediating these weaknesses. Limitations and future directions are discussed.

**517.074 (Virtual Poster)** Role of Alpha Power during Selective Attention in Children with Autism Spectrum Disorder: A QEEG Study

A. Ahmad<sup>1</sup>, S. Sharma<sup>2</sup>, S. Soni<sup>3</sup>, S. Kaur<sup>3</sup>, P. Tayade<sup>3</sup>, B. Chakrabarty<sup>4</sup>, S. Gulati<sup>5</sup> and R. Sharma<sup>6</sup>, (1)Department of Physiology, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (2)Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, New Delhi, India, (3)Physiology, All India Institute of medical sciences, New Delhi, India, NEW DELHI, India, (4)Pediatrics, All India Institute of medical sciences, New Delhi, India, NEW DELHI, India, (5)Centre of Excellence and Advanced Research for Childhood Neurodevelopmental Disorders, Child Neurology Division, Department of Pediatrics, All India Institute of Medical Sciences, New Delhi, India, (6)Department of Physiology, All India Institute of Medical Sciences, New Delhi, India

---

**Background:**

Attention is a process of selecting a relevant stimulus from available infinite number of objects/events, filtering out the irrelevant information. Previous researchers studied evoked potentials and reported impaired attention in individuals with Autism spectrum disorder (ASD). Differential attentional capacities and variation in sensitivity to cue types have also been suggested in ASD. Further, task related alpha power modulation has been suggested to predict performance on attention tasks in healthy individuals. Therefore, in the present study an attempt was made for the first time to investigate the alpha band power during attention task i.e. digit span forward task (DSFT) in children with ASD compared to typically developing children (control) by analyzing single trial EEG

**Objectives:**

To compare EEG alpha power between children with ASD and control during DSFT.

## Methods:

**DSFT task:** First examiner speaks a sequence of two numerical digits, then child was asked to repeat the sequence correctly and immediately, with increasingly longer sequences being tested in each trial to assess attention. The score was determined by the length of the longest correctly repeated sequence, ranging from zero to nine numbers. A total of three blocks of the task was performed.

## QEEG recording:

EEG was recorded during DSFT task using 128 channels sensor net in 61 children with ASD diagnosed by DSM 5 criteria and 48 age matched control. Raw EEG data were filtered (1-100 Hz band pass, 50Hz notch) followed by segmentation into 5 epochs of 1 second duration from each block i.e. total of 15 epochs of 1 second duration. Artifacts were removed using independent component analysis and average referencing was computed for the data. After exclusion of files with artifacts or corrupt files, EEG data of 19 children with ASD were analyzed. For comparison EEG data of 20 age matched control were used. Individual alpha frequency (IAF) was calculated using "Spectopo" EEGLAB function with window size of 256 data points and overlapping windows of 50% in order to classify the EEG frequency bands. Further, for spectral power analysis Fast Fourier Transform was performed in MATLAB using a custom made script. Results were plotted using EEGLAB topoplot function.

## Results:

Mean age of children with ASD ( $6.12 \pm 2.4$  years) and control ( $7.24 \pm 2.3$  years) was not significantly different. Changes in Alpha power during DSFT were computed and compared between children with ASD and control. Twenty-three electrodes showed significantly higher activity ( $p < 0.05$ ) in alpha band which was mainly distributed over frontal and temporal regions in children with ASD compared to control. Additionally, significant decrease in DSFT task score ( $p < 0.05$ ) was also observed suggesting impaired attention in children with ASD compared to control.

## Conclusions:

Higher alpha power during DSFT in children with ASD might reflect the role of alpha band in flexible recruitment of functional networks in order to meet cognitive demands. Previous studies have also reported a higher alpha power in regions processing the relevant stimulus and lower power in regions processing irrelevant stimuli in individuals with ASD suggesting a role of alpha power in attention allocation.

**517.075 (Virtual Poster)** The Association between Rhythm Perception and Phonological Awareness for Children on the Autism Spectrum  
**C. Rimmer<sup>1</sup>, H. Dahary<sup>1</sup> and E. M. Quintin<sup>2</sup>, (1)McGill University, Montreal, QC, Canada, (2)Educational & Counselling Psychology, McGill University, Montreal, QC, Canada**

---

**Background:** Exploring non-linguistic predictors of early literacy, such as musical rhythm perception, is valuable for students who present with language difficulties and diverse support needs. Studies on the musical abilities of children on the autism spectrum show average or above-average musical production and auditory processing abilities.

**Objectives:** This study aims to investigate the use of a non-verbal stimuli (musical rhythm) as a potential screening tool for the early literacy skills of children on the autism spectrum by exploring the relationship between musical rhythm perception and phonological awareness skills.

**Methods:** A total of 21 participants on the autism spectrum between the ages of 6 to 11 years old ( $M = 8.9$ ,  $SD = 1.5$ ) completed a rhythm perception task, an adapted version of the Beat Alignment Test (BAT; Iversen & Patel, 2008). Phonological awareness skills were measured using the Phonological Processing subtest of the NEPSY-II (Korman et al., 2007).

**Results:** Results revealed that phonological awareness and rhythm abilities are positively correlated for children on the autism spectrum. Higher scores in phonological awareness skills were associated with a more accurate performance on the rhythm perception task, and that this relationship was strongest for the most challenging trials of the rhythm perception task.

**Conclusions:** Phonological awareness and rhythm perception may underlie a common auditory mechanism in the typical population, which seems to also be the case for children on the autism spectrum. The association between rhythm perception and phonological awareness holds significant clinical implications for the assessment of phonological awareness skills, as typical screening tools rely heavily on linguistic stimuli. Findings thus lend support to the use rhythm perception as a screening tool for early literacy skills for children with diverse support needs as an alternative to traditional verbal tasks that tend to underestimate the potential of children on the autism spectrum.

**517.076 (Virtual Poster)** Use and Compliance of a Computer Assistant Learning Program (Lexia) in Children with Autism Spectrum Disorder and Learning Disabilities in Reading in an Ethnically Diverse Community.  
**M. Valicenti-McDermott, E. Rivelis, M. J. Cardin, C. Bernstein and L. Shulman, Rose F. Kennedy Center, Children's Evaluation and Rehabilitation Center; Montefiore Medical Center, Bronx, NY**

---

**Background:** Children with Autism Spectrum Disorder (ASD) often present with co-morbid developmental disabilities such as language impairment and learning disabilities(LD). Learning disabilities(LD) are lifelong conditions and with intervention, people with LD in reading can improve their abilities. Intensive individualized instruction, remediation, accommodations, and modifications are used as techniques for improving LD in reading but are not easy to access. In recent years, technology-based remedial approaches and blended learning have become increasingly popular, but

research to support its use with children with autism and LD is sparse. We are conducting a study to examine the impact of computer-assisted learning (CAL Lexia Learning, Concord, MA; [Lexialearning.com](http://Lexialearning.com)), to the treatment of children with ASD and LD in reading in the Bronx, NY in a rigorous way. As a first step, we examined feasibility and compliance with virtual use of Lexia, following publisher recommendations.

**Objectives:** to examine compliance and use of a CAL with children and adolescents with autism and LD in reading who attend an urban, multidisciplinary University affiliated center

**Methods:** Children and adolescents with LD in reading, who were on a waitlist for a remediation program at a multidisciplinary center were invited to participate in February, March, and April 2021. Families and patients met with a psychologist, who explained how the online Lexia program works. If needed, an iPad was lent to the family. If the child lived in a bilingual English/Spanish household, then the visit was done by a bilingual English/Spanish psychologist. Families were contacted on the phone 1 week, 2 weeks and 2 months after starting, and patients were encouraged to contact clinicians if difficulties arose. Initial assessment included reading measures (Woodcock-Johnson IV) and assessment of behavior (BASC-3); demographic and developmental data was also collected along with time spent engaged with the program. Statistics included chi-square, t-test.

**Results:** 54 children with LD in reading signed up for the program, 31 (57%) boys and 23 (43%) girls, age  $11 \pm 2$  y.o., 26 (50%) came from bilingual English/Spanish households. Of the 54, 4 (7%) children had a previous diagnosis of ASD, 3 boys/1 girl, mean age  $11 \pm 2$  y.o., Overall, children participated in the program for  $605 \pm 132$  minutes and of the 54, 23 (42%) discontinued the program before 6-month assessment. Children with autism were more likely to continue the program for at least 6 months (4/4 100% vs. 27/50 54%  $p=0.07$ ) and used it for more minutes ( $1136 \pm 726$  min vs.  $388 \pm 780$  min  $p=0.02$ ) than children without autism. There were no significant difference in demographics and academic skills, but, as expected, children with autism scored higher on the BASC-3 withdrawn subscale ( $76 \pm 19$  vs.  $55 \pm 13$   $p=0.008$ ) and development/social ( $69 \pm 9$  vs.  $56 \pm 10$   $p=0.03$ ) than children without autism.

**Conclusions:** In an urban, ethnically diverse group, a small sample of children and adolescents with autism and LD in reading were compliant with an online computer-assisted reading program. As a next step, information on efficacy of these programs in academics is needed, as it may represent a positive intervention for children with autism.

#### **517.077 (Virtual Poster) Vocabulary, Decoding, and Memory in Autistic Children with a Discrepant Reading Profile**

**M. E. Beckerson<sup>1</sup>, G. N. Miller<sup>2</sup>, J. A. Trapani<sup>3</sup>, M. Martino<sup>4</sup>, S. E. O'Kelley<sup>4</sup> and R. K. Kana<sup>1</sup>,** (1)Department of Psychology, University of Alabama, Tuscaloosa, AL, (2)University of Alabama, Tuscaloosa, AL, (3)University of Alabama at Birmingham, Birmingham, AL, (4)The University of Alabama at Birmingham, Birmingham, AL

**Background:** Children's baseline vocabulary and word reading (i.e., *decoding*) capabilities play a significant role in their reading comprehension. However, constructing a cohesive representation of read information also requires integrating and recalling both visual and verbal material (Wooley, 2010; Cain, 2006). Many autistic children excel at decoding but struggle to integrate the words into context (Huemer & Mann, 2010; Nation et al., 2006), leading to reading comprehension deficits. This is described as the *discrepant poor comprehender* reading profile (Davidson, 2021). Verbal and visual *working* memory have been shown to predict reading comprehension beyond vocabulary and decoding in typical development (Pham & Hasson, 2014; Cain, Oakhill & Bryant, 2004), while vocabulary is suggested to be a stronger predictor in autism (Davidson et al., 2018). However, the role of *general* visual and verbal memory on reading comprehension has not been examined within the discrepant poor comprehender profile in autism.

**Objectives:** The aim of this study is to investigate whether general verbal and visual memory predict reading comprehension beyond vocabulary and decoding within a group of autistic children categorized in the discrepant poor comprehender reading profile.

**Methods:** Fifteen autistic children with the discrepant poor comprehender reading profile (GORT-5 < 37<sup>th</sup> percentile and SORT-R3 > 36<sup>th</sup> percentile) between the ages of 7 and 13 years ( $M=10.95$ ) participated in this study (data collection is ongoing). Participants completed a battery of assessments including the Gray Oral Reading Test (GORT-5), the Slosson Oral Reading Test (SORT-R3), the Peabody Picture Vocabulary Test (PPVT-4), the Expressive Vocabulary Test (EVT-2), and the Wide Range Assessment of Memory and Learning (WRAML-2). Hierarchical linear regression was conducted with GORT-5 Comprehension Scaled Score as the dependent variable. SORT-R3 Scaled Scores were entered at stage one to control for word decoding ability. PPVT-4 and EVT-2 Standard Scores were entered at stage two to control for vocabulary. Finally, verbal and visual memory index scores on the WRAML-2 were entered at stage three to determine the contribution of general memory abilities beyond decoding and vocabulary.

**Results:** Decoding significantly predicted reading comprehension scores,  $F(1,13)=6.30$ ,  $p=.026$ , and accounted for 32.6% of the variance in performance on a reading comprehension task. The contribution of expressive and receptive vocabulary beyond word reading was trending toward significance,  $F(2,11)=3.56$ ,  $p=.064$ , accounting for 26.5% of the variance. Visual and verbal memory did not significantly predict reading comprehension above and beyond the other variables,  $F(2,9)=1.23$ ,  $p=.338$ .

**Conclusions:** These preliminary results suggest that decoding and vocabulary, rather than general memory, play vital role in predicting reading comprehension in autistic children with the discrepant poor comprehender profile. Therefore, children with this reading profile may benefit from interventions focused on building vocabulary and word-reading skills. Additionally, the relationship between memory and reading comprehension might depend on the type of task and whether the comprehension questions require inferencing (Lucas & Norbury, 2015; Tirado & Saladaña, 2016). As data collection is ongoing, we plan to examine this relationship after children complete the Visualizing and Verbalizing (V/V) intervention (Bell, 1991), which teaches children to use visual imagery to improve reading comprehension.

#### **517.078 (Virtual Poster) Working Memory in Preschool Children with Autism Spectrum Disorder: An Eye-Tracking Study**

**Background:** Older children with Autism Spectrum Disorder (ASD) have been shown to exhibit difficulties with working memory (WM). Research conducted on preschool children with ASD has generated inconsistent findings. One of the reasons may be that the WM tasks are either too demanding for preschoolers or that children's developmental level has surpassed the task's requirements and the performance is at or near ceiling.

**Objectives:** The aim of the current study is to investigate and compare the WM performance of preschool age typically developing (TD) children and children with ASD on the novel eye-tracking A-not-B task. In addition, the current study examined whether there is a relationship between nonverbal mental age (NVMA) and the ASD and TD children's performance on the A-not-B task.

**Methods:** Twelve children (M = 53.08 months, SD = 11.59, range = 31 – 68, 83.3 % boys) with a confirmed ICD – 10 diagnosis of ASD and twenty-three TD children (M = 49.50 months, SD = 6, range = 37 – 59, 45.8 % boys) viewed animations of the moving train. The A-not-B task is purported to measure WM. The "A" trials consisted of the train moving into the left tunnel. The "B" trials had two conditions (short = 10200msec, long = 15200msec). During the "B" trials the train was moving into the right tunnel. The comparison statistics were performed on "B" trials only. The dependent variables were the looking times (in milliseconds) at the left and the right tunnels during a 5-second period before the reappearance of the train. Mullen Scales of Early Learning was used to measure NVMA.

**Results:** The ASD and TD groups spent more time looking at the right tunnel (ASD: M = 2036, SD = 1110; TD: M = 2020, SD = 868) than the left tunnel (ASD: M = 1069, SD = 471; TD: M = 975, SD = 620) during the "B" trials with short waiting period. The groups did not differ in looking times at the right tunnel ( $t(34) = 0.044$ ,  $p = 0.965$ , 95% CI[-320 – 507]). The ASD and TD groups spent more time looking at the right tunnel (ASD: M = 1720, SD = 1109; TD: M = 1788, SD = 992) than the left tunnel (ASD: M = 987, SD = 1028; TD: M = 839, SD = 487) during the "B" trials with long waiting period. The groups did not differ in looking times at the right tunnel ( $t(34) = -0.186$ ,  $p = 0.853$ , 95% CI[-809 – 673]). NVMA was lower in the ASD group (M = 31.58, SD = 10.26) as compared with TD group (48.96, SD = 8.57) ( $t(34) = -5.37$ ,  $p < 0.001$ , 95% CI[-23.95 – -10.79]). No correlations between NVMA and the performance on two "B" trial types were found for ASD and TD groups.

**Conclusions:** The results suggest that despite the large NVMA variation in ASD group, the current task may not be suitable for the age range of the current sample and may better suit even younger children with ASD.

**517.079 (Virtual Poster) Cognitive Heterogeneity in School-Aged Children with High-Functioning Autism Spectrum Disorder: Theory of Mind and Executive Function**

*C. H. Chiang<sup>1</sup> and Y. L. Chen<sup>2</sup>, (1)Department of Psychology, National Chengchi University, Taipei City, Taiwan, (2)Child and Adolescent Psychiatry, Kaohsiung Chang Gung Memorial Hospital, Kaohsiung, Taiwan*

---

**Background:** 'Theory of Mind' (ToM) deficits, 'Executive Functions' (EF) deficits were the two most widely discussed accounts to the impairment of Autism Spectrum Disorder (ASD). Happé, Ronald, and Plomin (2006) proposed the concept of "multiple cognitive atypicalities" and emphasized that the combination of the core cognitive abilities could better depict the cognitive profile of ASD, and explained the distinct aspects of the behavioral phenotype.

**Objectives:** The aim of this study was to portray the cognitive atypicalities of ToM and EF in school-aged children with High-functioning Autism Spectrum Disorder (HFASD) and to investigate their relationships with autism severity and adaptive function.

**Methods:** Sixty-six children with HFASD and 41 children with typically development (TD) aged 7-12 years were recruited in large Taipei area of Taiwan and matched on chronological and verbal mental ages. Participants were assessed on a battery of tasks measuring (1) irony and metaphor tasks in ToM, developed by Deng (2018); (2) inhibition control (using Flanker task) and cognitive flexibility (using Animal Sorting in NEPSY-II) in EF; (3) IQ using Wechsler Intelligence Scale for Children- Third Edition in Traditional Chinese Version (WISC-III); (4) autism severity (using ADOS and ADI-R); and (5) adaptive function (using Vineland adaptive behavior scales, 2<sup>nd</sup> Edition).

**Results:** The results showed that (1) The means and standard deviations of the TD were used to calculate the Z score of ToM and EF measures. The Z scores of the reaction time and error rate were reversed to obtain a higher Z score, indicating a better performance on the task. Following the criteria of Pellicano (2007), cognitive atypicality is defined as one standard deviation higher/lower than the average TD. Based on this criterion, 38% children demonstrated intact on both of ToM and EF, 18% children were atypicality on both of ToM and EF, while 22% children were either atypicality on ToM or EF; (2) the children with double cognitive atypicalities showed significant higher score on communication than the children with single cognitive atypicality and no atypicality in ADOS ( $p < .01$ ), however, no difference were revealed among the three groups on adaptive function in VABS-II.

**Conclusions:** Considering ToM and EF concurrently would give a better portray of the heterogeneity of ASD at cognitive level. The clinical implications could be addressed in the assessment and intervention for the school-aged children with HFASD.

**517.080 (Virtual Poster) Intact Self-Bias on Perception in Adults with Autism**

*L. Amodeo<sup>1</sup>, J. Goris<sup>2</sup>, A. D. Nijhof<sup>3</sup>, M. Brass<sup>4</sup> and J. R. Wiersema<sup>5</sup>, (1)Department of Experimental-Clinical and Health Psychology, Faculty of Psychology and Educational Sciences - Ghent University, Ghent, Belgium, (2)Department of Experimental Psychology, Ghent University, Ghent, Belgium, (3)Institute of Psychiatry, King's College London, London, United Kingdom, (4)Research group EXPLORA, Ghent University, Ghent, Belgium, (5)Department of Experimental Clinical and Health Psychology, Ghent University, Ghent, Belgium*

---

Background: Self-related information is consistently processed more quickly and accurately than other-related information. This effect – known as the *self-bias* – has a critical role for social functioning. An altered self-bias can hamper the ability of understanding one's own social surroundings (Nijhof & Bird, 2019). Studies have reported decreased or absent self-bias in individuals with autism, however findings are not conclusive, as intact self-bias has also been reported. Williams et al. (2018) used the “shape-label matching task” task developed by Sui and colleagues (2012), to test self-prioritization effects on perception, in which participants have to judge whether shape-label pairings matched. Self-related pairings were prioritized, but equally in both groups. More research is warranted to test the robustness of this finding.

Objectives: The main goal of our study is to investigate the impact of the self-bias on perception using the shape-label matching task in both adults with autism and neurotypicals.

Methods: Thirty-six participants with an ASD diagnosis and thirty age- and IQ-matched neurotypicals performed a shape-label matching task. In a first ‘association’ phase, participants learned to associate three distinct shapes (i.e. circle, square, triangle) with three different labels (i.e. self, close other, stranger). In a second ‘matching’ phase, participants were presented with a series of shape-label pairings, and asked whether the shape matched or mismatched the label in question. In addition, participants completed two self-report questionnaires (i.e. AQ and SRS-A) to measure the extent of autistic traits. EEG was also recorded, in order to test which information processing stages are affected by the self-bias.

Results: We replicated the findings by Williams et al. (2018). Self-related pairings were prioritized, but equally in both groups. For both groups, repeated measures ANOVAs revealed faster and more accurate responses for self-related than either close other- or stranger-related associations. Adults with autism responded slower in general, yet this did not interact with condition. Results from correlational analyses further showed no significant relationship between ASD symptomatology and the size of the self-bias effect in either group. Findings from the EEG data analysis will be presented at the conference.

Conclusions: In line with prior research, no atypical behavioural pattern in making perceptual judgments involving self-related information was observed in individuals with autism, and no significant association between ASD symptomatology and self-bias magnitude was found within our sample. This suggests an intact self-bias on perception in autism. Further studies are warranted to directly compare different types of self-biases in autism.

## Combined Topics

### PANEL — COMBINED TOPICS

#### 203 - The Lancet Commission on the Future of Care and Clinical Research in Autism

**Panel Chairs:** Catherine Lord, *UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA*

**Tony Charman**, *Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, Department of Psychology, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

**Discussant:** James Cusack, *Autistica, London, United Kingdom of Great Britain and Northern Ireland*

**203.001 (Panel)** A New Stepped Care and Personalised Health Model for Delivering Services and Monitoring Effectiveness

**C. Lord**, *UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA*

Background: Autism is a heterogeneous condition that affects people across the lifespan in different ways at different times. Interventions and services often involve not only the autistic person but the entire family and depend on the individual's and families' preferences and resources. Most treatments do not work for everyone; some treatments are inappropriate or unnecessary for some people and helpful for others. However, goals of happiness, purpose, health and greater independence are obtainable for all autistic people.

Objectives: We need cost-effective ways of prioritizing interventions and services for autistic persons that begin with the person and the family, and that consider the particular needs from a person-centered point of view that also includes families and what is possible within a community, not just from the perspective of the health and social support systems.

Methods: We propose a stepped-care, personalized health model that begins with a needs assessment, but also requires consideration of specific aspects of individual and family functioning. A diagnosis of autism is only the beginning. Information about the individual's and family's preferences and specific strengths and difficulties, including co-occurring conditions is critical. With better data about what interventions are most beneficial for whom, when and with what intensity, and with systems that obtain individualized information about the autistic child, adolescent or adult and the family and community in which they live, we could build probabilistic models, combined with individual and family preferences, that would allow us to better design individual service plans.

Results: A stepped care, personalized health model is outlined, including both an example of assessment data and examples of how such a model might work in intervention and service planning for a young, minimally verbal boy with autism in a LMIC and an adolescent girl with autism and

severe social anxiety with strengths in academic skills in a HIC. Such models could use existing and new research about effectiveness to address needs of autistic individuals in both LMIC and HIC and support integration across systems of services and support.

**Conclusions:** We need planful systematic research across systems that allows comparisons of different interventions for different needs within autism. The Lancet Commission presented a model of stepped care, personalized health that we hope can be used as a start in the development of a more person-centered, cost-effective approach to service provision within different cultural contexts.

### **203.002 (Panel) Care of Co-Occurring Medical and Mental Health Conditions**

**P. Carbone**, *Univeristy of Utah, Salt Lake City, UT*

---

**Background:** An important aspect of the heterogeneity of autism is the presence of co-occurring medical, behavioral and psychiatric conditions. These conditions vary in presentation throughout the lifespan and have profound effects on life outcomes. Common co-occurring conditions seen in individuals with autism include sleep disorders, gastrointestinal conditions, overweight/ obesity, epilepsy, attention-deficit hyperactivity disorder, anxiety and depression. Robust evidence for most of these co-occurring conditions indicate that rates are higher in autistic people compared with the general population. Profound autism can be associated with the same co-occurring conditions, but they may be more complex with regards to identification and treatment.

**Objectives:** Early and timely identification of co-occurring conditions is important because evidence-based treatment can result in increased wellbeing for autistic people and their families and can enable better access to other services and supports. Symptoms of these conditions might be missed because of an atypical presentation in autistic individuals. Specifically, clinicians should avoid either attributing all maladaptive behaviors to autism or, on the other hand, neglect to take into account the role of core aspects of autism in identifying co-occurring conditions.

**Methods:** Therefore, a clinical environment with a knowledgeable provider, that is culturally appropriate, adapted to the needs of the stakeholders, and that allows sufficient time for assessment, discussion, and participatory decision making is necessary to support a successful diagnostic evaluation of co-occurring conditions.

**Results:** Once identified, a stepped care and personalized healthcare model can be effective in addressing co-occurring conditions. Use of this model can adapt existing treatment guidelines to account for the widely varying needs, skills, circumstances, and preferences of the autistic child, adolescent and respective family. Modification to existing evidence-based treatments helps to optimize behavioral, psychological and medical approaches for co-occurring conditions in autism and improves effectiveness and participation.

**Conclusions:** Access to functioning systems of care is necessary to address co-occurring conditions. Successful treatment of co-occurring conditions often will involve collaboration between caregivers and providers across environments. Treatment interventions for co-occurring conditions cannot depend on delivery only by autism experts. Yet, poor knowledge regarding the health care of autistic children and adults among primary care providers, especially in rural or low resource settings, threatens their long-term health outcomes. Furthermore, many community mental health systems are not sufficiently equipped to assist people with both mental health issues and autism, which again leaves people with autism deprived of support from existing systems of care. Therefore, we call for systematic efforts to reach primary care providers and non-autism specialty therapists and mental health providers with information about identification and treatment of co-occurring conditions in order to ensure equitable access to needed healthcare services across the lifespan.

### **203.003 (Panel) Global and Cultural Diversity: Addressing the Needs of Autistic People in LMICs, Low Resource Settings and Those Social Excluded**

**G. Divan**, *Child Development Group, Sangath, New Delhi, India*

---

**Background:** Assuming a minimum prevalence of 1% an estimated minimum of 78 million individuals worldwide have autism. Outside urban areas in most countries, families have virtually no access to either assessments or evidence-based interventions. The assessment and intervention gap seen across the world is compounded by a knowledge gap in LMICs and other low-resource settings. 95% of all children under the age of 5 years with developmental disabilities (including autism) live in LMICs; and yet, little research is done outside of HICs. The needs of families who live with autism worldwide are universal: to understand their child's developmental differences; to seek support that can improve and optimise outcomes; to be included as active members of society; and to receive appropriate support to empower their child's journey into and throughout adulthood.

**Objectives:** Cultural diversity encompasses broad social constructs including sex, race and ethnicity, class, income, language, religion, sexual orientation, and gender identity. Many autistic individuals will have a so-called minority or non-dominant status across several of these social and cultural factors, and recognition is growing that the intersectionality of these factors makes individuals vulnerable to both discrimination and exclusion from appropriate services.

**Methods:** Making services scalable should not compromise standards of evidence, meaningful outcomes, and efficacy. In LMICs, there is a great need for task-sharing approaches where specialists train and supervise community-based healthcare and education workers to optimise their inputs to individuals with more complex support needs.

**Results:** Research about what is colloquially described as home-grown versus transported models of intervention in children's mental health generally suggests that transported models can be adapted and implemented in different cultural contexts with good clinical outcomes. However, such implementation requires sustained attention to adaptation processes, supervision to maintain fidelity over time, and a clear understanding of implementation challenges. Capacity building and implementation of evidence-based programmes of care in LMICs is crucial to support the rights of

people with autism and other neurodevelopmental disorders to have their needs met within the context of the Universal Declaration of Human Rights, UN Convention on the Rights of the Child, and Sustainable Development Goals.

**Conclusions:** Many of the priorities for global action have been highlighted during this Commission. These priorities include engaging families as key stakeholders; remembering that most autistic people are adults; addressing the need, particularly in LMICs, to find scalable models to raise awareness, identification, assessment, and care that will, in most cases, take place across a lifetime; recognising the importance of systems and economic implications; and acknowledging the continual need to take into account heterogeneity and diversity not just in individuals with autism but in their cultures, contexts, and personal preferences.

#### **203.004** (Panel) Neurodiversity and Valuing Autism

**A. Plank**, *Wrong Planet, Los Angeles, CA*

---

**Background:** Neurodiversity refers to the natural variability within human brains and minds. Recognition of human diversity helps us to better understand autistic individuals in ways that have far-reaching effects. These effects cut across issues as broad as human rights, equity and social justice, respect for difference, and the need to take individual and family preferences into account. Valuing neurodiversity has the potential to create stronger and wiser communities and positive social values.

**Objectives:** N/A

**Methods:** N/A

**Results:** The concept of neurodiversity is also the basis of an international civil rights movement that arose primarily as a response to the marginalisation of autistic people. The neurodiversity movement considers autism as a neurological difference rather than a disorder and is sometimes associated with opposition to efforts to find a cause or cure. Individuals prefer to self-identify as a member of the neurodiverse community rather than with psychiatric and medical diagnoses that highlight impairment and disorder. Not all autistic people and stakeholders identify with the neurodiversity movement. Controversy exists about how those with the highest support needs, including those with substantial intellectual disabilities and limited functional communication and who are unable to advocate for themselves are represented by a non-medical model. Many autistic people struggle with their difficulties and feel excluded from society; some might seek a cure whereas others embrace autism as part of their identity, thankful for some aspects of who they are despite the challenges that come with difference; most are somewhere in the middle. A sometimes overlooked aspect in ongoing debates about neurodiversity in the autism community is that experiences, views, and attitudes vary across stakeholder groups. In fact, holding a plurality of views at one time is possible. Another consideration is that the current debates on medical versus social models of disability can be quite different across social, cultural, and global communities.

**Conclusions:** Individuals with autism and other neurodevelopmental disorders are a valued part of our society and represent a prototype of neurodiversity. At the same time, many individuals with autism have high levels of need and are vulnerable, and societal attitudes to difference, inclusion and equity will impact their life experiences and outcomes. Autistic individuals and their families can show amazing strengths and persistence, patience and perception that can change development as well. Respect for this diversity and heterogeneity is key, as well as respect for the power of development and the possibility of change. All developmental conditions induce society to reflect on the degree to which those with the highest levels of need are supported, on including people who are different, and on making an effort to build communities and institutions that function well for all citizens. Valuing autism and neurodiversity benefits society as a whole.

#### **203.005** (Panel) Policy and Research Priorities and Implications

**T. Charman**, *Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom*

---

**Background:** At least 78 million people worldwide have autism; the majority do not receive support from, or have access to, adequate health-care, education, and social care services.

**Objectives:** We call for governments and funding organisations to prioritise systematic research that goes beyond biology and small-scale studies of single short-term interventions, to address the issues of for whom, when, how much, how long and when interventions can change outcomes in ways that acknowledge the heterogeneity of families, cultural contexts and autistic individuals and the need to integrate care across systems and time. People with autism have complex needs; meeting these needs requires government coordination between health-care, education, finance, and social sectors across the life span, and active inclusion and participation of autistic people and their families.

**Methods:** Research that will result in immediate improvements in the lives of people with autism and their families should be prioritised. National and international infrastructures should be developed to help such projects to move beyond single investigator-led (albeit multi-site) studies to more integrated attempts that take into account individual differences within autism. Infrastructures should also support studies that build on each other and provide evidence for broader community implementation and effectiveness, rather than simply showing that an intervention is better than a waiting list or treatment as usual. High-quality research in LMICs is possible; support for such studies is crucial and should address implementation and feasibility as well as outcomes

**Results:** Governments and services should monitor access to provision to ensure that underserved groups, including those who are minimally verbal, girls and women, minority ethnic groups, from socially disadvantaged backgrounds, or with severe co-occurring conditions, have equitable access to appropriate services.

Conclusions: Our message is one of hope in that research has shown us that there is great potential for change, which can be built upon through future research and policies for autistic people and their families across the globe.

## ORAL SESSION - 5B — COMBINED TOPICS

### 311 - Biomarkers and Intervention Trials

**311.001** (Oral) Identification of Metabolic Dysregulation Associated with Autism Spectrum Disorder (ASD) through Continued Development of a Precision Medicine Approach to Blood Plasma Based Metabolic Tests

**A. M. Smith<sup>1</sup>**, E. Donley<sup>1</sup>, M. Ludwig<sup>1</sup>, L. Feuling<sup>1</sup>, M. Natowicz<sup>2</sup>, D. G. Amaral<sup>3</sup> and R. Burrier<sup>1</sup>, (1)Stemina Biomarker Discovery, Madison, WI, (2)Pathology & Laboratory Medicine Institute, Cleveland Clinic, LL-3, Cleveland, OH, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA

#### Background:

Individuals with ASD display a diverse array of behaviors and co-occurring conditions leading to a heterogeneous disorder that complicates diagnosis and interventions. Discovery of biochemical phenotypes (metabotypes) based on quantification of blood plasma metabolites can be used to stratify individuals with ASD into subpopulations based on shared mechanisms of metabolic dysregulation. Previously we reported on metabolic stratification of ASD participants enrolled in the Children's Autism Metabolome Project (CAMP, ClinicalTrials.gov Identifier: NCT02548442) based on ratios of plasma metabolites that may identify dysregulation of metabolism. This can lead to the development of laboratory tests useful in precision medicine-based approaches to screening and treatment of ASD. In this work, we assayed metabolites associated with the microbiome and acylcarnitine metabolism to identify novel metabotypes. The novel metabotypes were then clustered and optimized into a test battery that included previously identified metabotypes.

#### Objectives:

Stratify CAMP ASD participants into distinct metabotypes based on alterations of a wide array of biochemical processes that can be used to develop clinically actionable biomarker-based tests and paired therapies.

#### Methods:

CAMP enrolled children, age 18-48 months, from 8 centers across the USA and employed the Autism Diagnostic Observation Schedule, Second Edition performed by research reliable clinicians to confirm ASD diagnoses. Three quantitative mass spectrometry-based assays were used to measure the concentrations of 54 metabolites from plasma samples of 499 children with ASD and 209 typically developing (TYP) children. Metabotype tests were created by setting a diagnostic threshold to identify a subpopulation of CAMP participants primarily composed of children with ASD. Metabotype tests that identified subpopulations with a sensitivity  $\geq 5\%$  and specificity  $\geq 95\%$  following 4-fold repeated cross validation were clustered based on the common participants in the subpopulations. These metabotype tests were then used to create a test battery to increase sensitivity of the overall screening approach.

#### Results:

Metabotyping of CAMP participants identified 153 metabotype tests where 83% of ASD participants were identified by at least 1 metabotype. The metabotype tests had average sensitivities of 5-11% and specificities of 97-100%. Metabotypes associated with ratios of metabolites containing an acylcarnitine as a numerator or denominator identified 30 novel tests. Clustering of metabotype tests identified three novel clusters primarily associated with ratios of metabolites with a numerator or denominator that was a medium chain acylcarnitine. The medium chain acylcarnitine associated metabotypes clusters had two distinct patterns of distributions where acylcarnitines were either increased or decreased relative to the participants lacking a metabotype. These metabotype tests could be optimized into a battery of tests that identified CAMP participants with 71% sensitivity and 90% specificity.

#### Conclusions:

Discovery of metabolic biomarkers associated with ASD can lead to the development of laboratory tests useful in screening children with ASD for altered metabolism. This approach has identified novel metabotypes associated with dysregulation of medium chain acylcarnitine metabolites. This research provides a pathway for precision medicine in diagnosing and treating autism by pairing subjects with metabolically characterized subtypes of autism with targeted therapies that address the specific biochemistry of the dysregulation.

**311.002** (Oral) Metabolic Support Therapy with Q10 Ubiquinol, Vitamin E and Polyvitamin B: Results of a Retrospective Chart Review in Neurodevelopmental Disorders and of a Double-Blind, Randomized Cross-over Study in Phelan-McDermid Syndrome

**A. M. Persico<sup>1</sup>**, A. Ricciardello<sup>2</sup>, L. Turriziani<sup>3</sup>, F. Cucinotta<sup>4</sup>, G. Calabrese<sup>3</sup>, P. Tomaiuolo<sup>3</sup>, A. Mancini<sup>3</sup>, T. Di Bella<sup>3</sup>, F. Bellomo<sup>3</sup>, M. Boncoddò<sup>3</sup>, G. Turturo<sup>3</sup>, S. Mirabelli<sup>3</sup>, R. Keller<sup>3</sup>, V. Porcelli<sup>3</sup> and L. Palmieri<sup>3</sup>, (1)Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy, (2)Villa Miralago, Center for the treatment of eating disorders, Cuasso al Monte, Italy, (3)Interdepartmental Program "Autism 0-90", "G. Martino" University Hospital, University of Messina, Messina, Italy, (4)IRCCS Centro Neurolesi "Bonino-Pulejo",

**Background:** Defective mitochondrial functioning and increased oxidative stress have been well documented in ASD and in neurodevelopmental disorders (NDDs). Studies of antioxidants and supplements are often limited by the co-administration of several dozen compounds.

**Objectives:** (1) To study the efficacy of a “metabolic support therapy” (MST) including Q10 ubiquinol, vitamin E and polyvitamin B, in NDDs and in Phelan-McDermid syndrome (PMS), a syndromic form of ASD; (2) to begin dissecting the selective contribution of Q10 ubiquinol vs vitamins.

**Methods:**

(1) Retrospective chart review: records of patients with any NDD (2016-2020), treated with MST for a minimum of three months were reviewed by a Child Neuropsychiatrist not involved in their clinical management, scoring CGI-S and CGI-I.

(2) Double-blind, randomized, active comparator-controlled, cross-over study: patients with PMS received Q10 ubiquinol (50/100 mg b.i.d.) + Vit.E (60 mg/d) + polyvitamin B for 4 months (active drug) vs only Vit. E and B for 4 months (active comparator). Primary outcome measures include VABS, CARS, CGI-I and VAS; secondary outcome measures include measures of cognitive function, autism, problem behaviors, quality of life (QoL), communication, comorbidities, and measures of oxidative stress (clinicaltrials.gov id. NCT04312152).

**Results:**

(1) records of 53 patients with NDDs (16 ASD, 13 ID/DD, 16 ASD+ID/DD, 5 PMS, 3 ADHD) identified 40 (75.5%) responders and 13 (24.5%) non-responders to MST. Most frequently improved were adaptive function and cognition (41-43% of cases), followed by social interaction, motor coordination, attention and language (20-32%). Mild hyperactivity and early insomnia were observed in 11-17% of patients. In two MST responders with ID, pre-/post-treatment IQ testing documented a 20 pt improvement;

(2) We recruited 31 PMS patients, (3-37 yrs, M:F ratio=1.06:1), all but one with ID and 13 (39.4%) with co-morbid ASD. Q10+vit. yielded “much” or “minimal” CGI improvement in 10/31 (32.3%) and 14/31 (45.2%) cases, respectively, vs 6/31 (19.4%) and 16/31 (51.6%) with vitamins only. Non-responders to either treatment were 7/31 (22.6%). VABS motor skills, VAS stereotypies and shared play improved more with Q10+vit. over vit. only ( $P<0.05$ ). CGI-I scores were superimposable when Q10+vit was administered during the first quadrimester, but significantly better when administered during the second quadrimester (time x treatment interaction in Fig. 1). Maternal WHO-QOL scores displayed a striking 4.7 pt improvement with Q10+vit. over vit. only ( $P=0.0079$ ), and paternal scores showed a similar trend ( $P=0.075$ ). Side effects (hyperactivity, insomnia and irritability) were mild, rare and did not differ between treatments.

**Conclusions:** MST seemingly produces small-to-moderate improvement especially in cognitive and adaptive skills, in up to 70% of cases with ASD, ID, DD or PMS. This improvement is sufficient to improve parental QoL. Vitamins E and B seemingly exert some beneficial effect (Fig. 1, left panel) and promote greater efficacy by Q10 over time (Fig. 1, right panel). A targeted confirmatory cross-over RCT contrasting [Q10+vit] vs placebo can now be undertaken.

### **311.003 (Oral)** Phenotypic Characterization of Individuals with Autism Spectrum Disorder Based upon Serotonin Blood Levels.

**A. M. Persico<sup>1</sup>, F. Cucinotta<sup>2</sup>, A. Ricciardello<sup>3</sup>, L. Turriziani<sup>4</sup>, P. Tomaiuolo<sup>4</sup>, G. Calabrese<sup>4</sup>, F. Bellomo<sup>4</sup>, M. Boncoddo<sup>4</sup>, G. Turturo<sup>4</sup>, S. Mirabelli<sup>4</sup>, R. Sacco<sup>5</sup>, S. Gabriele<sup>5</sup> and M. Canali<sup>5</sup>,** (1)Department of Biomedical, Metabolic and Neural Sciences, University of Modena and Reggio Emilia, Modena, Italy, (2)IRCCS Centro Neurolesi "Bonino-Pulejo", Messina, Italy, (3)Villa Miralago, Center for the treatment of eating disorders, Cuasso al Monte, Italy, (4)Interdepartmental Program "Autism 0-90", "G. Martino" University Hospital, University of Messina, Messina, Italy, (5)Service for Neurodevelopmental Disorders & Laboratory of Molecular Psychiatry and Neurogenetics, University "Campus Bio-Medico", Rome, Italy

---

**Background:** Hyperserotonemia was the first biomarker identified in autism research. Platelet serotonin (5-HT) is elevated in approximately 25% of autistic children, but displays a broad distribution in ASD. Its neurochemical basis, behavioral correlates and underlying mechanisms remain unclear.

**Objectives:** To characterize the phenotypic and behavioral correlates of serotonin blood levels in a large sample of ASD patients.

**Methods:** Serotonin levels were measured from platelet-rich plasma by HPLC in triplicate and categorized in two ways, either as “low/normal/high” applying thresholds at 102 and 279 ng/ml, or by quartiles. Significant results using both approaches are reported and additional multivariate analyses are under way. A total of 667 patients with non-syndromic ASD were analyzed, following the exclusion of 21 SSRI-treated patients. Phenotypic variables include (a) demographic and parent-reported patient/family-history, (b) medical, neurological, behavioral and comorbidities derived from direct observation, and (c) tests/questionnaires. Some phenotypic variables are available only for a subgroup including 232 of the 667 patients.

**Results:** Significantly associated with high 5-HT and less frequent in low 5-HT patients are “difficulties at weaning” ( $P<0.05$ ,  $N=242$ ), “delayed motor development” ( $P<0.05$ ,  $N=244$ ), “presence of facial dysmorphisms” ( $P<0.05$ ,  $N=243$ ). On the contrary, significantly associated with low 5-HT and less frequent in high 5-HT patients are “self-injurious behavior” ( $P<0.001$ ,  $N=604$ ), “presence of sleep disorders” ( $P<1.5 \times 10^{-4}$ ,  $N=602$ ), “pediatric or infectious disease coincident with autism onset” ( $P=5.9 \times 10^{-5}$ ,  $N=634$ ), “autoimmune disorders in II degree relatives” ( $P=6.5 \times 10^{-9}$ ,  $N=589$ ) with a similar trend for I degree relatives.

Conclusions: Increased 5-HT blood levels appear associated with deficits in weaning and motor development, consistent with known roles of 5-HT in development and control of rhythmic movements like chewing and locomotion. Also a greater incidence of facial dysmorphisms appears compatible with 5-HT roles in craniofacial morphogenesis. Instead, low 5-HT blood levels are associated in our sample with self-injurious behavior and with sleep disorders, in line with 5-HT involvement in impulse control and sleep regulation. The surprising and strongly skewed distribution of “pediatric or infectious disease observed at autism onset” and familial loading for autoimmune diseases points toward protective effects of 5-HT against both peripherally-triggered neuroinflammation and autoimmunity, in line with known 5-HT influences in keeping microglia in a resting, anti-inflammatory state, and in preventing autoimmunity by promoting the expansion of Tregs cell. Importantly, these data confirm that platelet 5-HT does not merely represent a peripheral biomarker, but rather reflects both peripheral and central phenomena. These results thus spur further interest into elucidating the mechanisms underlying serotonergic imbalances in ASD.

**311.004 (Oral)** Long-Term Safety and Sustained Efficacy of ZYN002 Cannabidiol Transdermal Gel in Children and Adolescents with Fragile X Syndrome (ZYN2-CL-017)

N. Tich<sup>1</sup>, A. Thibodeau<sup>1</sup>, T. Sebre<sup>1</sup>, T. Dobbins<sup>2</sup>, J. M. Palumbo<sup>1</sup> and S. O'Quinn<sup>1</sup>, (1)Zynerba Pharmaceuticals, Devon, PA, (2)The Griesser Group, Conshohocken, PA

Background: ZYN002 is a pharmaceutically produced transdermal cannabidiol gel in development for the behavioral symptoms in Fragile X syndrome (FXS). ZYN2-CL-017 is an ongoing, long-term, open-label extension (OLE) of CONNECT-FX (ZYN2-CL-016). CONNECT-FX was a randomized, double-blind trial assessing safety and efficacy of ZYN002 in children and adolescents with full *FMR1* gene mutation. Patients with complete, 100% *FMR1* gene methylation treated with ZYN002 had significant improvements as compared to placebo on multiple endpoints.

Objectives: To assess the long-term safety and efficacy of ZYN002 in patients age 3 through 17 years with FXS.

Methods: Interim analyses of data collected through 21-May-2021. Safety data for all patients, up to 30 months, and efficacy data through 6 months of treatment for patients with 100% *FMR1* gene methylation who completed CONNECT-FX are reported. Patients screened for CONNECT-FX were eligible for entry, including patients ineligible to continue in the trial, and patients who were randomized to 12-weeks of ZYN002 (250 mg or 500 mg daily [weight-based]) or placebo. Patients from an earlier open-label trial (ZYN2-CL-009) also entered the OLE trial. Patients who completed CONNECT-FX remain blinded to the treatment received in CONNECT-FX. Safety assessments included adverse events, vital signs, laboratories, and electrocardiograms (ECGs). The primary efficacy endpoint was change in the Social Avoidance (SA) subscale of the Aberrant Behavior Checklist–Community FXS (ABC–CFXS).

Results: 240 patients were enrolled; 197 who completed CONNECT-FX, 12 screen failures and 21 patients ineligible to continue from CONNECT-FX and 10 patients from ZYN2-CL-009. 110 patients received ZYN002 prior to entry. Mean age was 9.7 years and 76.3% were male. 156 patients (70.3%) for whom methylation status was determined had 100% *FMR1* methylation. 210 patients completed at least 6 months of open-label treatment (median of 21 months). 131 patients were continuing at this interim analysis. Treatment emergent adverse events (TEAEs) were reported by 62.2% of patients; 97.7% were mild to moderate severity. TEAEs reported by  $\geq 5\%$  of patients included: upper respiratory infection (15.4%) and application site pain (6.6%). 13.3% of patients reported a TEAE possibly related to treatment. Six patients experienced 7 serious adverse events; none were considered treatment-related. Seven patients discontinued due to an adverse event. No clinically significant changes in vital signs, laboratories or ECGs were reported. At the end of CONNECT-FX, completely methylated patients treated with ZYN002 had a median improvement of 40% in SA versus 20% ( $p=0.027$ ) in patients treated with placebo. After six months of treatment with ZYN002, patients reported a median improvement of 50% in SA whether originally treated with ZYN002 in CONNECT-FX (3 months OLE) or newly treated with ZYN002 in the OLE trial.

Conclusions: ZYN002 was safe and well tolerated when administered over a median of 21 months. In patients with complete *FMR1* gene methylation, ZYN002 led to sustained improvement in Social Avoidance, a key behavioral symptom of Fragile X syndrome, following initial improvement seen after 12 weeks of double-blind therapy. The results from this OLE trial continues to support the effectiveness of ZYN002 in patients with complete *FMR1* gene methylation.

## POSTER SESSION — COMBINED TOPICS

### 407 - Combined Topics

**407.167 (Poster)** Effects of a Whole-Body General Movement and Exercise Intervention on Social Communication and Behavioral-Affective Skills of Children with ASD

A. Delskey<sup>1</sup>, M. Spearing<sup>2</sup>, C. Cleff<sup>3</sup>, W. C. Su<sup>4</sup>, N. Amonkar<sup>1</sup>, A. N. Bhat<sup>5</sup> and S. Srinivasan<sup>6</sup>, (1)University of Connecticut, Storrs, CT, (2)University of Delaware, Newark, DE, (3)Physical therapy, University of Delaware, Newark, DE, (4)Physical Therapy, University of Delaware, Newark, DE, (5)Department of Physical Therapy, University of Delaware, Newark, DE, (6)Kinesiology, University of Connecticut, Storrs, CT

Background: Children with Autism Spectrum Disorder (ASD) demonstrate poor verbal and non-verbal communication, impaired affective regulation, and repetitive and maladaptive behaviors. Our past work has demonstrated that rhythmic movement interventions provided in a small group can promote motor skills, joint attention, spontaneous communication, and on-task behaviors in children with ASD.

Objectives: The current study extends our work by comparing the effects of a whole-body general movement (GM) intervention compared to a conventional seated play (SP) intervention on social communication and behavioral-affective skills of children with ASD. The study will also allow a

comparison between face-to-face and telehealth-based intervention delivery, since this research team had to transition from in-person to virtual research in the midst of the COVID-19 pandemic.

**Methods:** 30 children with ASD between 6 and 14 years were seen as part of this 10-week study. Pretests and posttests were conducted in the first and last weeks and training was provided 2 times/week in the intermediate 8 weeks. Training sessions involved interactions between the child, an expert trainer, and an adult model. Specifically, the GM group engaged in turn taking-based, goal-directed, movement games and exercises with an emphasis on promoting muscle strength (upper, lower, and trunk), endurance, movement speed, agility, bilateral coordination, and executive function. In contrast, the SP group engaged in seated activities such as reading, building, and art-craft that focused on promoting fine motor and academic skills. Outcome measures included the standardized Joint Attention Test (JTAT) assessed at pretest and posttest as well as training-specific measures of the amount of socially-directed verbalization, duration of positive/interested affect, and frequencies of repetitive and maladaptive behaviors measured during early and late training sessions.

**Results:** Preliminary data from 5 children seen via telehealth in the GM group suggest a trend for improvement in overall JTAT scores from pretest to posttest. Moreover, all children showed an increase in socially-directed verbalization (Mean(SE) - Early:7.4(1.0), Late: 12.4(2.2)) from an early to a late training session. Engaging in movement games in a turn taking format afforded greater spontaneous, socially-directed speech (7.8(1.3)) compared to responsive verbalization (2.2(0.5)) during sessions. Moreover, children increased the amount of spontaneous speech as well as appropriate responding towards the trainers across training weeks. All children generally showed high levels of compliance with the training and in fact decreased the frequencies of negative/maladaptive behaviors from an early (5.2(3.0)) to a late (3.5(2.7)) training session. We hypothesize that overall the GM training will afford higher levels of engagement, socially-directed speech, and task compliance as well as lower levels of repetitive behaviors compared to the SP training.

**Conclusions:** Our preliminary findings suggest that whole-body movement interventions focused on promoting strength, agility, coordination, and motor planning in small group formats provide excellent opportunities to facilitate social communication and behavioral-affective skills in children with ASD. Goal-directed movement games foster social monitoring, turn taking, cooperation, rule following, imitation, and motor planning, all of which are impaired in children with ASD.

**407.168 (Poster)** Comparing Telehealth and Face-to-Face (F2F) Videos of Standardized Motor Assessments from a Pilot Randomized Controlled Trial in Children with Autism Spectrum Disorder (ASD)

C. Myers<sup>1</sup>, C. Cleff<sup>2</sup>, W. C. Su<sup>3</sup>, S. Williams<sup>4</sup>, N. Amonkar<sup>5</sup>, A. N. Bhat<sup>6</sup> and S. Srinivasan<sup>6</sup>, (1)University of Connecticut, Storrs, CT, (2)Physical therapy, University of Delaware, Newark, DE, (3)Physical Therapy, University of Delaware, Newark, DE, (4)University of Delaware, Newark, DE, (5)Department of Physical Therapy, University of Delaware, Newark, DE, (6)Kinesiology, University of Connecticut, Storrs, CT

**Background:** In the past, we have established preliminary evidence for creative movement (CM) interventions to promote solo/social-motor skills in children with Autism Spectrum Disorder (ASD) (Srinivasan et al., 2015, 2016, 2018). This study builds on past studies to compare the effects of a whole-body, play intervention versus a seated play intervention in children with ASD.

**Objectives:** At the onset of the pandemic, our ongoing randomized controlled trial design transformed from a face-to-face (F2F) intervention to a virtual/telehealth (TH) format for both intervention types (Play, Seated play). By the end of the study, we will have an equal number of children observed in both groups (F2F and TH, N=15 per group, 30 total). The poster will compare F2F versus TH-based administration of standardized motor assessments. We will obtain feedback from caregivers, test administrators, and test coders regarding their experiences with both delivery modes.

**Methods:** 30 children with ASD between 6 and 14 years participated over 10 weeks with pretests and posttests conducted during the first and tenth weeks. We administered several standardized tests of motor performance including the Bruininks Oseretsky Test of Motor Proficiency, Test of Gross Motor Development, Sensory Integration and Praxis Tests, Timed Up and Go test, and 2-minute walk test as well as custom-developed paradigms to assess imitation and interpersonal synchrony during the tests. All testing sessions were videotaped for further coding. Following pretests, children were randomly assigned to receive either play or seated play training. While the play training focused on whole-body music, dance, and yoga-based activities, the seated play involved table-top activities such as reading, building, and art-craft. Each stakeholder group completed a survey with 5-point, Likert type questions (too difficult to too Easy, etc.). Caregivers were asked about the testing burden with regard to prep time, their efforts to engage the child during sessions, ease of equipment and space setup, etc. Test administrators were asked to compare their experience with F2F vs. TH delivery in terms of ease of instruction and setup, time required for tests, and communication with child/family. Coders were asked about ease of scoring tests and challenges faced in scoring due to delivery mode.

**Results:** Preliminary analysis of surveys suggest that irrespective of mode of test delivery, caregivers found the test preparation optimal, test supplies easy to use, and tester instructions/demonstrations appropriate and clear. Over 75% caregivers said that the test sessions were slightly long and a little over 30% felt that the sessions were somewhat demanding for caregivers in terms of time and effort. We hypothesize that while both formats will be acceptable, TH-based testing barriers include space-related constraints associated with test administration, need for greater caregiver efforts, more tester prompting, audio-visual lags that impair synchrony/imitation testing and coding, as well as greater variability in test administration compared to the F2F mode.

**Conclusions:** We will add to the pre-pandemic evidence on efficacy of telehealth-based clinical assessments and their feasibility, acceptability, challenges, and test validity. In the future, OTs/PTs may consider conducting certain types of clinical motor assessments via telehealth.

**407.169 (Poster)** Effects of a Whole-Body General Movement Interventions on Motor Performance, Agility, and Locomotor Skills of Children with ASD

**N. Amonkar<sup>1</sup>, C. Cleff<sup>2</sup>, W. C. Su<sup>3</sup>, A. N. Bhat<sup>4</sup> and S. Srinivasan<sup>5</sup>,** (1)University of Connecticut, Storrs, CT, (2)Physical therapy, University of Delaware, Newark, DE, (3)Physical Therapy, University of Delaware, Newark, DE, (4)Department of Physical Therapy, University of Delaware, Newark, DE, (5)Kinesiology, University of Connecticut, Storrs, CT

---

**Background:** Conventional treatment approaches for Autism Spectrum Disorder (ASD) focus primarily on addressing core impairments in social communication & behavioral domains. However, it was recently reported that 87% of children with ASD are at risk for motor impairments (Bhat, 2020, 2021). Our past work suggests that rhythm and yoga-based interventions can help promote motor performance, social communication, and behavioral-affective skills in children with ASD (Srinivasan et al., 2015; Kaur & Bhat, 2019).

**Objectives:** The present study expands this work by comparing the effects of a whole-body General Movement (GM) intervention to a standard-of-care, Sedentary Play (SP) intervention on gross motor performance, agility, and locomotor skills of children with ASD. A subset of the children in the study were seen via telehealth due to the ongoing COVID-19 pandemic.

**Methods:** The study lasted for 10 weeks with pretests and posttests conducted during the first and the tenth weeks respectively. 30 children between 6-14 years were matched on age, gender, and level of functioning and then randomly assigned to the GM or SP groups. Each child received 8 weeks of training with 2 sessions conducted per week. The GM group engaged in dynamic, whole-body activities that promoted visuo-motor, bilateral, and dual-limb coordination, strength, and agility skills. The SP group engaged in tabletop activities such as reading, building, and art-crafts to promote social interactions and fine motor skills. The balance, bilateral coordination, upper limb coordination, and running speed subtests of the Bruininks-Oseretsky Test of Motor Proficiency (BOT-2) and the locomotor subtest of the Test of Gross-motor development (TGMD) were administered at pretest and posttest. In addition, task-specific games involving locomotor skills such as hopping, leaping, sliding, running, etc. were assessed during early and late training sessions to evaluate changes in movement form and accuracy.

**Results:** Preliminary data from the GM group suggest that 8 out of 11 children showed improvements in locomotor skills as assessed using standard scores on the TGMD (Mean(SE): Pretest= 5.72(1.02), Posttest= 7.81(0.95)). Moreover, 86% children also showed improvements in raw scores on the balance (Pretest= 24.28(2.17), Posttest= 32(1.35)), upper-limb coordination (Pretest= 25.71(3.14), Posttest= 30.57(2.43)), and running speed (Pretest= 19(4.68), Posttest= 23.81(3.73)) subtests of the BOT-2. In terms of task-specific tests, around 70% children improved in movement form on multiple locomotor skills such as fast feet running, hop-skotch, sliding, bunny jumps, and side stepping from an early to a late training session. Moreover, 86% children also reduced the amount of prompting required to complete the task-specific tests during sessions. We hypothesize that irrespective of the mode of intervention delivery the GM group will demonstrate greater improvements in gross motor performance, agility, and locomotor skills compared to the SP group.

**Conclusions:** Our preliminary data suggest that dynamic, whole-body movement-based interventions can be used to promote gross motor skills, agility, and coordination in school-age children with ASD. Given the high prevalence of motor impairments in this population, our work calls for the inclusion of whole-body movement games and activities in the plan of care of children with ASD.

**407.170 (Poster)** Difficulties of Brazilian Families in Choosing the Best Intervention Option for Children with Autism Spectrum Disorder.

**C. S. Paula<sup>1</sup>, L. C. Silva<sup>1</sup>, E. S. Coutinho<sup>2</sup> and M. C. Teixeira<sup>1</sup>,** (1)Developmental Disorder Program, Universidade Presbiteriana Mackenzie, São Paulo, Brazil, (2)Social Medicine Institute, Universidade Estadual do Rio de Janeiro (UERJ), Rio de Janeiro, Brazil

---

**Background:**

The Autism Spectrum Disorder (ASD) is a developmental disorder that primarily affects social communication and behaviour. The impact on the family of individuals with ASD is high. Since it is a disorder that there is no single treatment, the main recommendation is to invest in interventions for a better prognosis and symptom improvement, focusing mainly on autonomy and adaptive functioning. However, there are several types of intervention and one of the difficulties of families is choosing the best option.

**Objectives:**

The objective of this study is to characterize the health service use by children with ASD in Brazil.

**Methods:**

The participants were 184 mothers of children with ASD between 6 and 12 years old; 49.50% of them had private health insurance, while 17.4% used exclusively the public health system. They answered an online questionnaire through the Google Form platform. This protocol consisted of 3 instruments: (1) Socioeconomic Questionnaire, developed by the authors, (2) Revised Illness-Perception Questionnaire modified for autism - IPQ - RA and (3) Maternal Autism Knowledge Questionnaire (MAKQ).

**Results:**

Treatment choice (defined by the therapy that the child is undergoing, and the mother is satisfied plus the therapy that the child does not do but she would like him/her to do) was predominately Behavioral Interventions (77.2%). Mothers who had the perception that ASD of their child brought negative consequences in their lives tended to choose a higher number of simultaneous treatments for their children. Also, there were a significant

correlation higher scores in the MAKQ with the use of scientific publications as the principal source of information ( $r=0.379$  e  $p<0.01$ ); in other words, mothers who knew more about ASD symptomatology preferred to look for ASD information on scientific journals. Another correlation found in the study was that mothers who felt more strongly emotional negative impacts of the ASD had higher odds to use other families with children with ASD as the main source of information ( $r=0.175$ ;  $p=0.017$ ). Finally, mothers who had the perception that their behavior could affect the trajectory of the ASD of their child tended to consider their children's therapists as a reliable source of information ( $r=0.228$  e  $p=0.002$ ).

#### Conclusions:

The results are relevant for improving the comprehension of the trajectory of Brazilian mothers of children with ASD in the search for interventions. Maternal perceptions and knowledge of ASD were associated with their sources of information to learn about the condition, as well as with the therapeutical types that they chose for their children.

#### **407.171 (Poster) Voices from the Field: Informing Research and Practice on Capacity Building Strategies in Mongolia**

**J. D. Lee<sup>1</sup>, H. Meadan<sup>2</sup> and E. Oyunbaatar<sup>3</sup>,** (1)444 Minnesota Avenue Ste 300, Juniper Gardens Children's Project, Kansas City, KS, (2)University of Illinois, Champaign, IL 61820, IL, (3)University of Western Ontario, London, ON, Canada

---

#### **Background:**

Although global prevalence of autism has grown substantially, researchers still report inequity in access to evidence-based interventions (EBI) in many low-resource setting (LRS). As a field, there is still much to be learned about the strategies stakeholders in LRS use to build capacity in response to the low level of resources. Capacity building refers to the advancement of knowledge and skills among stakeholders and the development of cohesiveness among stakeholders in the community. Although autism researchers highlight the needs in research in LRS, the field knows very little about what stakeholders of children with autism in LRS suggest as effective strategies for capacity building in their communities, which may have significant implications for novel interventions.

#### **Objectives:**

As a middle-income Asian country, Mongolia can serve as an example to other LRS because of the geographical and cultural proximity to other nations. Furthermore, there is very limited autism research in Mongolia, which has led to invisibility and limited access to EBI. To develop socially valid and sustainable interventions, it is crucial to understand what stakeholders of children with autism report as effective strategies to address the limited resources in their country. Therefore, the purpose of this study was to examine perceptions of the stakeholders related to strategies for capacity building in Mongolia.

#### **Methods:**

We conducted qualitative research including five focus groups with 30 Mongolian caregivers of children with autism and individual interviews with 15 professionals who work with children with autism and their families in Mongolia. We incorporated the principles of community partnered participatory research, in which several local community stakeholders were involved in different aspects of this study, including identifying priorities, study planning, logistics, data collection, analysis, and dissemination. A constant comparative method was used for data analysis, which formed codes, categories, and themes.

#### **Results:**

Three main themes were identified as strategies for capacity building, including (a) partnership, (b) advocacy, and (c) empowerment. Two categories formed the theme of *partnership*, including enhancing collaboration among stakeholders and collaborating with international development agencies in Mongolia. Through these categories, stakeholders emphasized the importance of close collaboration of all relevant agencies and stakeholders to create a more cohesive autism community. The theme *advocacy* consisted of two categories, including parental advocacy and legislative advocacy. Stakeholders stressed the significance of increasing autism awareness and using cascading model to disseminate information, such as using parent peer support. Legislative advocacy was another commonly mentioned category, which refers to increasing awareness of relevant legislation and caregivers' collective efforts to advocate for each other. In *empowerment*, stakeholders highlighted the value of providing more opportunities to disseminate information to caregivers and other stakeholders, such as school administrators.

#### **Conclusions:**

It is imperative that the reach of autism research expands to traditionally underserved, underrepresented populations globally. Through this qualitative inquiry with 45 stakeholders of children with autism in Mongolia, we found several strategies that empower them by increasing their capacity to respond to the low level of resources. Furthermore, the findings from this study may suggest important implications for future intervention research.

#### **407.172 (Poster) Capacity Building of Parents of Children with ASD in Mongolia, a Low-Resource Setting**

**J. D. Lee<sup>1</sup> and H. Meadan<sup>2</sup>,** (1)Juniper Gardens Children's Project, University of Kansas, Kansas City, KS, (2)University of Illinois, Champaign, IL 61820, IL

---

## Background:

Parents of children with autism have reported significant hardships in raising their children, likely due to their limited capacity to respond to their children's unique needs. These hardships are exacerbated in low-resource settings (LRS) where parents are reported to have inequitable access to evidence-based interventions (EBI) for their young children. Furthermore, although careful considerations are warranted when conducting novel, experimental applied research in a LRS with little extant research, autism research in LRS is still underrepresented. Therefore, this study was conducted with families in Mongolia, an example of LRS. A previous qualitative study with Mongolian parents provided rationale for this study, where parents expressed barriers and needs to increase their capacity to support their children.

## Objectives:

The purpose of this study was to examine the effects of the Parent Peer Coaching program with Mongolian parents of children with autism to build the capacity within the community of parents and address the inequitable service access in Mongolia.

## Methods:

This experimental single-case research using multiple probe design included three phases of baseline, intervention and maintenance. A local research assistant (RA), four parent mentors (PM) and five parent peers (PP) and their children with autism participated in this study. A cascading intervention model was used in this study to examine capacity building process in LRS, in which synchronous coaching occurred across all stakeholders in a stepwise fashion. The independent variable was the Parent Peer Coaching program comprised of online training modules and telepractice coaching. Participants received access to the training, which consisted of modules covering behavior management and social-communication teaching strategies. Coaching first occurred between the RA and each PM, then PM to each PP, and consisted of (a) preobservation (planning for the observation), (b) observation of the coachee's actions, and (c) postobservation (reflection and feedback). All interactions between participants occurred via telepractice to examine its feasibility in LRS.

## Results:

The main dependent variable in this study was the PMs' coaching fidelity with PPs, which was measured by an observational measure that quantifies coaches' adherence. Visual analysis revealed functional relation between the intervention package and increase in each PM's coaching fidelity. In addition, effect size was calculated to quantify magnitude of the functional relations between phases across each tier using the log response ratio, which revealed large percentage changes. Furthermore, we conducted semi-structured individual social validity interviews, which revealed the acceptability, effectiveness, and potential sustainability of both intervention contents and implementation.

## Conclusions:

There are several implications from this study. First, more research is warranted to explore how such cascading intervention (parent-to-parent) can help increase other non-specialists' coaching skills in different content areas (e.g., teachers, therapists). Such examination would allow us to utilize diverse stakeholders of children with autism to deliver EBI in many LRS. Also, future research should also examine how to adapt interventions to be culturally relevant in underrepresented settings with marginalized and minoritized populations to increase equity in access to EBI. The results of this study suggest feasibility, acceptability, and effectiveness of delivering interventions with and to stakeholders in LRS.

## 407.173 (Poster) Cultural Adaptation Checklist: Enhancing Implementation and Sustainment of Autism Interventions

**J. D. Lee<sup>1</sup>, H. Meadan<sup>2</sup>, M. Sands<sup>3</sup>, A. Terol<sup>4</sup>, M. Martin<sup>4</sup> and C. Yoon<sup>1</sup>,** (1)444 Minnesota Avenue Ste 300, Juniper Gardens Children's Project, Kansas City, KS, (2)University of Illinois, Champaign, IL 61820, IL, (3)University of Wisconsin at Oshkosh, Oshkosh, WI, (4)University of Illinois at Urbana-Champaign, Champaign, IL

## Background:

In implementation science, systematic uptake of evidence-based interventions (EBI) is critical to improve the quality and effectiveness. Due to the increasing global prevalence of autism, it is crucial that the field enhances service access for stakeholders of individuals with autism. Although cultural adaptation of an EBI for autism may be crucial to address the global inequity in research with populations in low-resource settings, very few systematic tools or theoretical frameworks are used by autism researchers to guide these adaptations. When these interventions are not properly adapted with sufficient considerations for the unique cultural characteristics of a group, it may result in implementation failure and exacerbate the research-to-practice gaps.

## Objectives:

With this gap in mind, we developed the Cultural Adaptation Checklist with primary purposes to (a) guide research and practice on the cultural adaptation of existing EBI with minoritized and marginalized populations, and (b) systematically appraise the quality of cultural adaptation conducted in autism literature. In this presentation, we will showcase the Checklist, its development, and an example of its use in reviewing extant research in autism literature.

## Methods:

There are seven dimensions with 33 items on this Checklist, which are largely adapted and modified from broader mental health literature, including the ecological validity model (EVM) by Bernal et al. (1995). The dimensions include *language, persons, content, goals, methods, context*, and *process*. It was developed through an iterative process with feedback from experts in autism research and implementation science. To promote more accurate evaluation, we have further divided each dimension into two pillars, adaptation planning and implementation process, which allowed us to examine both aspects of an intervention. This process also allowed us to examine the characteristics of each dimension, critically analyze the literature, and provide specific guidelines. The 33 items across the seven dimensions and a detailed rubric for each item were developed to increase accuracy in quality appraisal of the literature. A total of 12 studies from a prior literature review on parent-mediated interventions for children with autism in low-resource settings internationally were appraised using the Checklist.

## Results:

In our preliminary analysis of the literature using the Checklist, it was revealed that all studies reported some level of adaptations to an existing EBI in autism (i.e., parent-mediated intervention) to target outcomes of both child and parent levels. While many of these studies reported practices on linguistic translations (i.e., language dimension), most did not report adaptations in other dimensions or described how adapted interventions were implemented in the community.

## Conclusions:

Future research is warranted to examine the mechanisms of how interventions are culturally adapted to be delivered for minoritized and marginalized population in low resource settings internationally. Furthermore, there are limited reports of cultural adaptation in extant literature as indicated in our literature review, which indicate the needs for future research to examine how to better facilitate the process. With more systematic guidance for cultural adaptation of both research and practice, the field may enhance uptake of EBI across the world.

# Communication and Language

## PANEL — COMMUNICATION AND LANGUAGE

### 207 - Quantification of Language and Communication in Minimally Verbal Individuals

**Panel Chair:** **Kristina Johnson**, *Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital/Harvard Medical School, Boston, MA, MIT, Cambridge, MA, Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital/Harvard Medical School, Boston, MA, MIT, Cambridge, MA*

**Discussant:** **Amanda O'Brien**, *Harvard University, Cambridge, MA*

**207.001** (Panel) Phonemic Content of Nonverbal Vocalizations from Individuals with 0-10 Spoken Words

**K. T. Johnson<sup>1</sup>**, **J. Narain<sup>2</sup>**, **A. M. O'Brien<sup>3</sup>**, **A. Kershenbaum<sup>4</sup>**, **T. Quatieri<sup>4</sup>** and **R. W. Picard<sup>3</sup>**, (1)*Boston Children's Hospital, Cambridge, MA*, (2)*MIT, Cambridge, MA*, (3)*Harvard University, Cambridge, MA*, (4)*MIT Lincoln Laboratory, Lexington, MA*

**Background:** Little is known about the vocal communication of individuals with few spoken words or word approximations. Even without typical verbal speech, these individuals employ vocalizations that are rich with affective and communicative information (Johnson & Narain et al. 2020). While the developmental trajectory of speech production and language development has been well-characterized in young children, even infants, who are developing "typically" (e.g., Oller 2000), little is known about the development of communicative but non-speech vocalizations in mvASD individuals.

**Objectives:** This research aims to develop sensitive and quantitative developmental markers for the mvASD population – particularly subtle language and communication progressions for those with no or few spoken words. Here, we generate repertoires of produced sounds from minimally verbal individuals and compare that to typical acquisition of vowels and consonants. We also discuss key perceptual or acoustic differences between vocalization types, such as what sounds might more readily indicate an affective state like frustration compared to a directed communication exchange like a request.

**Methods:** Vocalizations were captured in the wild during daily activities and labeled in the moment by family members or care providers who knew the mvASD communicator well (see Narain & Johnson et al. 2020 for a detailed discussion of the data acquisition methods). These labeled vocalizations were then isolated and analyzed for their phonemic content (see Figure 1). Consonant and vowel inventories were procured for each of five participants (4 male, 1 female; ages 9-23) across two vocalization types (Frustration and Request). Three participants had zero spoken words/approximations, while two vocally produced 3-4 spoken words/approximations, per parent report. Vowel production was normalized by age and gender, and consonant production was examined following the typical order of acquisition of English consonants (Sander 1972; Crowe and McLeod 2020). Other expressive features, such as mean vocalization length, mean vowel durations, and metrics of linguistic complexity, were calculated for each participant across multiple vocalization types.

**Results:** Early consonant sounds like 'm' and 'h' were well represented (see Figure 2 for a representative example); however, other common early sounds like 'b', 'p', and 'n' were produced surprisingly rarely, if at all, in this sample. Although sample sizes were small, individuals with more spoken words were found to have occurrences of later developmental sounds, such as 'l', supporting the expansion of sound diversity with word

development. Both vocalizations and vowels associated with expressions of frustration were consistently longer than those associated with a request, suggesting quantifiable perceptual differences between different types of vocalizations. In addition, request vocalizations showed lower vowel durations combined with a lower number of vowels per consonant, suggesting greater linguistic structure.

**Conclusions:** These results suggest that individuals with few or no spoken words produce measurable repertoires of phonemes that may serve as sensitive developmental markers or intervention targets for this population. Importantly, this approach to quantifying language and development in mvASD individuals emphasizes the ways in which they **succeed** in communicating and expressing different needs and desires even without typical verbal speech.

#### **207.002 (Panel) Linguistic Analyses of Expressive Language from Minimally Verbal Children with ASD**

*H. Tager-Flusberg<sup>1</sup> and L. Butler<sup>2</sup>, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Psychological & Brain Sciences, Boston University, Boston, MA*

---

##### **Background:**

Little is known about the expressive language abilities of the almost one-third of the ASD population who remain minimally or low verbal (MLV) as until recently, they have not been the focus of scientific investigations. In typically developing children there are clear benchmarks for defining stages of language development with respect to number of sounds and words used, composition of vocabulary and how these relate to emerging grammatical abilities evident in word combination and early morphosyntax. It remains unknown whether these benchmarks apply to expressive language in children and adolescents with MLV ASD.

##### **Objectives:**

1. Identify the stages and language benchmarks in a group of MLV ASD children and adolescents.
2. Investigate the relationship between vocabulary size (number of different words; NDW) and composition of vocabulary, particularly nouns and verbs.
3. Investigate the relationship between NDW and the emergence of combinatorial language.

##### **Methods:**

Transcripts were derived using SALT conventions from the ADOS administration to 49 (11 females) English-speaking children and adolescents (age range 6-21 years) who were MV (ADOS Module 1 – N=33) or LV (ADOS Module 2 – N=16). All participants had a minimum of 1 word (and a maximum of 200). Only intelligible/partially intelligible non-stereotyped language was coded from the first 20 minutes of the transcripts. SALT provided measures of NDW, total number of words, nouns, verbs, and mean length of utterance in morphemes (MLUm). Participants were coded into language stages using Tager-Flusberg et al.'s (2009) benchmarks: preverbal (fewer than 5 NDW or 20 word tokens); first words (over 5 NDW and 20 tokens; word combinations (over 30 different words and MLUm 1.8).

##### **Results:**

1. Almost half the participants (45%) were preverbal with almost 2/3 using few different and total words; 39% were in the first words stage and 16% met criteria for word combinations.
2. Figure 1 shows the proportion of nouns verbs and other word categories used by participants in the different language stages. AS NDW grows, the proportion of nouns and verbs increase but a linear regression model did not find that NDW was a significant predictor.
3. Figure 2 shows the relationship between NDW and MLUm. In the linear regression model, NDW was a significant predictor of MLUm ( $\beta = 78.9, SE = 5.69, t = 13.87, p < .001$ ), while age and nonverbal IQ were not.

##### **Conclusions:**

The findings confirm the heterogeneity of linguistic profiles in MLV ASD, and suggest that their language falls on a continuum, although traditional definitions of developmental stages do not apply so clearly. This has important implications for clinical practice as, unlike in typical development, even individuals with fewer than 10 words are able to combine words in their spontaneous speech, which may be used to bootstrap further growth in linguistic abilities.

#### **207.003 (Panel) Quantifying the Complexity of Vocal Expression Using Articulatory Coordination**

*T. Quatieri<sup>1</sup>, T. Talker<sup>1,2</sup>, K. T. Johnson<sup>3,4</sup>, J. Narain<sup>1</sup> and R. W. Picard<sup>1</sup>, (1)MIT Lincoln Laboratory, Lexington, MA, (2)Harvard University, Cambridge, MA, (3)Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital/Harvard Medical School, Boston, MA, (4)MIT, Cambridge, MA*

---

**Background:** Autism Spectrum Disorder (ASD) is a developmental condition characterized by difficulty in communication, typically accompanied by neuromotor challenges. In this current work, we address minimally-verbal ASD individuals who have twenty or fewer spoken words or word approximations (designated by mv\*). Though limited in their expressive vocabulary, mv\* individuals exhibit a rich repertoire of vocalizations with

meaning, including grunts, yells, sighs, and sequences of phonemes and syllables. These vocalizations are used among other modalities to express needs, desires, affections, and emotions.

**Objectives:** Because mv\* individuals can exhibit limited neuromotor skills, we were motivated to explore the neurophysiological coordination associated with the clusters of vocalizations that represent various sound classes. Our data is taken from the *Commalla* study, where audio is captured using a wearable microphone in natural settings (Johnson & Narain et al., 2020). Common sound classes (request, dysregulation, delight, frustration, self-talk, social) are labeled in real-time by a parent or caregiver. Through a case study of one participant, we investigated the relative *complexity of coordination* within two motor subsystems: phonation and articulation.

**Methods:** Our metric of complexity leverages previous work in using speech motor coordination measures to detect and track a variety of neurological and stress conditions including verbal ASD, depression, Parkinson's disease, traumatic brain injury, and fatigue (Quatieri et al., 2017; Talkar et al., 2020). Although these previous studies involved verbal speech, we can use the coordination method to quantify the complexity of a vocalization even without typical speech, making it a valuable metric to tracking vocal complexity as mv\* individuals grow and develop. We first extract a set of low-level speech features: fundamental frequency (F0, pitch) during phonation and formant frequencies (F1-F3, vocal tract resonances) to characterize articulation. Cross-correlations of the acoustic low-level features were then used as a proxy for motor coordination across articulatory and laryngeal speech production systems.

**Results:** In this case study, we investigated the relative complexity of three Commalla vocalization classes: dysregulation, request, and delight for one male of age 19. With dysregulation as the reference, we found effect sizes of correlation measures in the range of ~0.2 to -0.8 for F0 and between ~0.8 to -0.8 for the first three formant frequencies (see Figure 1). Moreover, the morphology of the effect sizes indicated lower complexity of coordination in dysregulated utterances as compared to request or delighted utterances. These quantitative findings are consistent with qualitative observations of harmonic and formant structure in spectrographic analysis, which are both more constrained in the dysregulated state.

**Conclusions:** In ongoing work, this pilot case study will be expanded to all six vocalization classes and across the full (8) subject pool. Also ongoing is mapping acoustic parameters (fundamental and formant frequencies) for a more direct connection to neurophysiological coordination toward a richer understanding of the nature of coordination complexity in the mv\* ASD population. Our long-term goal is a neuromotor-based feature representation that translates to an enhanced machine-based recognition of classes – as discussed separately in the panel – and also aids in more effective intervention.

#### **207.004 (Panel) Acoustic Features and Models to Classify Affect and Communicative Intent of Nonverbal Vocalizations from Minimally Speaking Individuals with Autism**

**J. Narain<sup>1</sup>, K. T. Johnson<sup>2</sup>, A. M. O'Brien<sup>3</sup>, A. Kershenbaum<sup>3</sup>, T. Quatieri<sup>4</sup>, R. W. Picard<sup>1</sup> and P. Maes<sup>5</sup>, (1)MIT, Cambridge, MA, (2)Boston Children's Hospital, Cambridge, MA, (3)Harvard University, Cambridge, MA, (4)MIT Lincoln Laboratory, Lexington, MA, (5)MIT Media Lab, Cambridge, MA**

**Background:** Non- and minimally speaking individuals with autism convey important affective and communicative information through nonverbal vocalizations. Nonverbal vocalizations can vary in pitch, tone, and other acoustic parameters depending on their function. Prior work has included speech analyses for diagnosing developmental differences but not on characterizing the acoustics of affective and communicative nonverbal vocalizations from minimally speaking children and adults with autism.

**Objectives:** Our objective was to evaluate and develop acoustic feature sets and machine learning models that enable the classification of communicative and affective nonverbal vocalizations from individuals with autism, contributing to a deeper understanding of vocal communication by this population.

**Methods:** We collected vocalization data with seven individuals with autism who are minimally speaking and have limited expressive language through speech and writing. Data was collected in real-world environments. Communicative or affective labels for vocalizations were provided by a caregiver in real-time. Labels in the analyses included: "delighted", "dysregulated", "frustrated", "social", "request", and "self-talk". Data was collected longitudinally for 4-64 weeks, varying based on the data collection rate and availability of each participating family.

We evaluated the performance of acoustic feature sets commonly used for modeling affect in verbal speech: the extended Geneva minimalistic acoustic parameter set (eGeMAPs), mel and gammatone cepstral coefficients, and mel and ERB-based filter bank values. We also developed a custom feature set based on our observations, consultation with clinicians, and related explorations in the literature. Our custom feature set included parameters describing the pitch contour, formants, voice quality, and spectral and cepstral characteristics of the vocalization. Both speaker independent and personalized multi-class models were trained and evaluated for each participant. We evaluated random forest models, linear support vector machines with stochastic gradient descent training, and support vector machines with a nonlinear radial basis kernel function.

**Results:** With the fully personalized modeling approach, F1-scores were markedly above chance for each participant, indicating that vocalizations could be well classified using acoustic features. Speaker-dependent models generally had F1-scores below chance, indicating that nonverbal communication practices varied significantly from person-to-person in the evaluated dataset. The custom feature set was the best performing feature set for five of the seven participants. Nonlinear models outperformed linear models for six of the seven participants. Unlike the cepstral coefficients and filter bank features, the custom feature set and eGeMAPs feature sets both contained parameters related to pitch, formants, and voice quality. The custom feature was unique in that it applied functionals related to the pitch contour of the vocalization and values of sustained formants.

**Conclusions:** Acoustic characteristics were used to classify affective and communicative functions of nonverbal vocalizations from seven minimally speaking individuals with autism with F1-scores above chance. This work suggests that the function of nonverbal vocalizations from non- and minimally speaking individuals with autism can be characterized audio alone. Our custom feature set outperformed other commonly used feature sets for the classification task, highlighting the unique nature of nonverbal speech from the studied population and the need for specialized analyses methods as presented here.

## ORAL SESSION - 2B — COMMUNICATION AND LANGUAGE

### 308 - Using Parent-Child Interactions to Learn About Language

**308.001** (Oral) Describing (pre-)Linguistic Oral Productions in Young Autistic Children: A Cluster Analysis

*P. Maes, M. Weyland and M. Kissine, ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium*

**Background:** Investigation of naturalistic speech sample as an estimate of (pre-)verbal production have highlighted the fact that, very early on, autistic children produce at lower rates than typically developing (TD) peers and experience delays in the acquisition of all typical milestones of language development (e.g., preverbal vocalizations, canonical babbling, first words). Few studies have tried to describe oral production patterns of autistic children after the age of 3. However, speech emergence is very likely to happen after this age. Moreover, while language acquisition and development are marked by a great heterogeneity in autism, studies have mostly focused on between-group differences with control groups, rather than within-group differences in a group of autistic children.

**Objectives:** Using manually transcribed speech samples of 59 3- to 5-year-old autistic children, we seek to qualitatively delineate different profiles of (pre-)linguistic behaviors and to document those profiles in terms of language, psychometric and demographic measures.

**Methods:** Speech samples were retrieved during a parent-child interaction and the administration of the ADOS-2 and were then manually coded and transcribed. Each child's production was assigned one of seven "type of production" codes: vocalic preverbal, nonvocalic preverbal, syllabic, proto-word, isolated word, word combination, phrase. In order to find subgroups of oral production behaviors, hierarchical clustering was conducted on ratios of each type of production. Between-cluster differences on a series of measures of interest were then investigated using linear regression.

**Results:** The analysis yielded a clustering solution of five clusters, each corresponding to a different profile of types of oral productions. Cluster 1 and 4, identified as verbal, produced mainly phrases and isolated words, respectively. Cluster 2, 3 and 5 were identified as preverbal. Cluster 2 produced barely anything. Cluster 3 produced a fair amount of preverbal and syllabic productions. Cluster 5 produced a lot of syllabic productions, especially. Age was not related to cluster membership, suggesting that children in preverbal clusters were not younger than those of verbal clusters ( $F(54, 4) = 1.23, p = .31$ ). Scores on the ADOS-2 ( $F(53, 4) = 8.37, p < .001$ ), as well as verbal ( $F(23, 4) = 4.79, p = .006$ ) and nonverbal IQ scores ( $F(38, 4) = 9.56, p < .001$ ), however, were found to be related to cluster membership. Overall, children in verbal clusters had higher cognitive abilities and milder autistic symptomatology than children in preverbal clusters. Finally, children in cluster 4, i.e. verbal children that do not produce a lot of phrase speech, were the only ones to display a significant increase in expressive vocabulary between the time of the study and one year poststudy ( $\beta = -182.29, p = .007$ ), suggesting that those children were in the process of developing language.

**Conclusions:** There are different profiles of both verbal and minimally verbal children in a sample of autistic preschoolers. It is very likely that the causes for the success or failure to acquire language by that point differ between clusters. Predictors of different profiles of language production and development should be investigated.

**308.002** (Oral) What Role Does the Environment Play in Language Development? SES, Parent Language Input, and Language Abilities in Children with ASD

*M. Pecukonis<sup>1</sup>, L. Butler<sup>2</sup> and H. Tager-Flusberg<sup>1</sup>, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Psychological & Brain Sciences, Boston University, Boston, MA*

**Background:** Language development in children with ASD is influenced by both proximal (e.g., parent language input) and distal (e.g., socioeconomic status) environmental factors. Several studies have found that "rich and responsive" parent language input supports language development in children with ASD (Swanson, 2020), and newer work has reported a positive relation between socioeconomic status (SES) and language abilities in this population (Olson et al., 2021). While less is known about how these variables interact to shape language development, Swanson and colleagues (2019) found that parent language input mediated the relation between maternal education level, a measure of SES, and language abilities in 24-month-old infants with ASD. However, no studies have explored the relation among these variables in older children with ASD.

**Objectives:** (1) Investigate the relation between SES, parent language input, and language abilities in children with ASD. (2) Explore whether parent language input mediates the relation between SES and child language abilities.

**Methods:** Our sample included  $N=41$  (32M, 9F) children with ASD, 50- to 94-months-old, recruited from SPARK. Parent-child interactions (PCIs) were conducted at home and recording through Zoom. Parents were directed to play with their child for 15-minutes. PCIs were transcribed offline and processed using SALT (Miller & Iglesias, 2012) to obtain number of different words (NDWs) produced by the parent, number of conversational

turns (CTs) between the parent and child, and parent mean length of utterance (MLU) in morphemes. The Vineland Adaptive Behavior Scales, Third Edition Comprehensive Interview Form (Sparrow et al., 2016) was used to assess children's expressive language (EL) and receptive language (RL) abilities. Information about SES (parent education level and annual household income) was collected using an online parent-report demographics form.

**Results:** Spearman's rho correlations were conducted among variables of interest (Table1). Child EL v-scores were positively correlated with parent MLU ( $r_s=.380, p=.014$ ) and CTs ( $r_s=.469, p=.002$ ). The correlation between child EL v-scores and caregiver education level was positive but did not reach significance ( $r_s=.263, p=.097$ ). Child RL v-scores were positively correlated with CTs ( $r_s=.426, p=.005$ ). To investigate whether parent MLU mediated the relation between parent education level and child EL v-scores, path model with robust maximum likelihood estimation was explored in Mplus (Muthen & Muthen, 1998-2017; Figure1). This model showed that while parent MLU was significantly related to child EL v-scores ( $B=2.413, SE=.939, p=.010$ ), parent education level was not significantly related to parent MLU ( $B=.018, SE=.077, p=.817$ ). The indirect effect of parent education level on child EL v-scores via parent MLU was non-significant ( $B=.043, SE=.191, p=.822$ ). The direct effect of parent education level on child EL v-scores was significant ( $B=.758, SE=.328, p=.021$ ).

**Conclusions:** Findings suggest that both proximal and distal environmental factors are related to expressive language abilities in children with ASD. However, parent MLU did not explain the relation between parent education level and children's EL v-scores in the current sample. Future studies should identify which variables within the child's proximal environment significantly mediate this relation, and further explore the bidirectional relation between parent language input and child language abilities.

**308.003 (Oral)** Remote Natural Language Sampling for Children with ASD: Role of Parent-Selected Activities and Child Language Level  
**L. Butler<sup>1</sup>, H. Tager-Flusberg<sup>2</sup>, S. Shen<sup>3</sup>, C. La Valle<sup>2</sup>, J. Palana<sup>4</sup>, N. Peterman<sup>1</sup> and C. Liu<sup>1</sup>,** (1)Psychological & Brain Sciences, Boston University, Boston, MA, (2)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (3)Department of Speech, Language, and Hearing Sciences, Boston University, Boston, MA, (4)Psychological and Brain Sciences, Boston University, Boston, MA

---

#### Background:

Natural language samples (NLS) provide an optimal approach for examining expressive language in minimally verbal (MV) children with ASD (Barokova & Tager-Flusberg, 2018). Remote data collection has provided researchers the opportunity to collect an NLS at home while children interact with their parents. Using a semi-structured protocol, Barokova et al. (2020) found that children produced more speech, conversational turns, and number of different words when interacting with parents at home compared to interactions with examiners in the lab. One open question is what kinds of activities do parents select when they are given the opportunity to choose the context for a home-based language sample?

#### Objectives:

1. What activities do parents choose in a remote parent-child interaction?
2. Is the number of different activities related to the child's language level?
3. Is the type of activity associated with the child's language level?

#### Methods:

Remote NLSs of 38 parent-child dyads (child age: 3-7 years, 8 female) were collected. Families were recruited from SPARK, and an autism diagnosis was confirmed using the *Social Communication Questionnaire* (Rutter et al., 2003) (Corsello et al., 2007). Parents completed the *Vineland Adaptive Behavior Scales, Third Edition Comprehensive Interview* (Sparrow et al., 2016). The Expressive Language v-scale score from the VABS was used as a measure of the child's expressive language (EL). Parents were asked to select 2-4 activities to promote communication with their child. A 15-minute parent-child interaction was recorded over Zoom.

#### Results:

1. Parent-selected activities fell into 11 different categories: 1) coloring and art, 2) conversation only, 3) cooking and baking, 4) educational (literacy, math), 5) turn-taking games and puzzles, 6) object play (manipulatives and figures), 7) screen time, 8) sensory-motor, 9) book reading, 10) singing and reciting, and 11) snack. Sensory-motor, object play, conversation only and coloring/art activities occurred the most frequently (Figure 1).
2. Vineland EL v-scale scores significantly predicted the number of different activity types ( $B=-.13, t=-3.75, p<.001$ ), with lower child EL associated with a higher number of activity types (Figure 2).
3. Vineland EL v-scale scores did not differ significantly by type of activity.

#### Conclusions:

Our results support the feasibility of remote in-home NLS with children with ASD including those who have low language levels for whom in-home NLS with a parent (vs. lab-based with an experimenter) allows them to demonstrate higher EL skills. Parents of children with more difficulties in EL employed additional activities as a strategy to elicit more language. These results suggest that approaches exploring activities during parent-child

interactions in the home can allow for a richer and ecologically valid assessment of children's expressive language (Costanza-Smith, 2010).

### **308.004 (Oral) Play Skills As a Predictor of Sentence Diversity in Young Children with Autism Spectrum Disorder**

*G. Duncan<sup>1</sup>, B. Manning<sup>2</sup>, E. Clark-Whitney<sup>3</sup>, C. B. Klein<sup>4</sup>, A. Lemelman<sup>1</sup>, J. Winter<sup>3</sup> and S. H. Kim<sup>1</sup>, (1)Psychiatry, Center for Autism and the Developing Brain, Weill Cornell Medical College, White Plains, NY, (2)Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY, (3)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY, (4)Psychiatry, TEACCH Autism Program, UNC Chapel Hill, White Plains, NY*

**Background:** Play skills have been shown to facilitate language development in young children. Children with ASD show varying degrees of impairments in both play and language skills. However, no studies have yet examined the relation between play skills and sentence diversity, which is predictive of later grammatical outcomes (Hadley et al., 2018), as well as how play skills facilitate language development over the course of early intervention in children with ASD.

**Objectives:** (1) To determine how play skills, measured both by parent reports as well as observations, are related to sentence diversity in children with ASD; and (2) to examine whether baseline play skills predict growth in sentence diversity over Naturalistic Developmental Behavioral Interventions (NDBIs).

**Methods:** Participants included 50 children with ASD (2-4 years) who were receiving NDBIs and their caregivers. Child speech was coded for child sentence diversity, based on two 10-minute video-recorded caregiver-child play interactions, conducted six months apart during which all children received NDBIs (Baseline and 6-months after the baseline). Specifically, unique subject-verb combinations (SV) were coded using the Systematic Analysis of Language Transcripts (SALT) software. Baseline functional play skills were measured using the Play with Objects item on the Brief Observation of Social Communication Change (BOSCC), a new observational treatment outcome measure, and caregiver reports based on the Vineland Adaptive Behaviors Scale (VABS-2) Play and Leisure subdomain V-scale scores. Generalized Linear Mixed Models were used to examine the effects of baseline play skills, timepoint, and the interaction between play and timepoint, on sentence diversity while controlling for age, gender, and Non-Verbal IQ (NVIQ). Following up on the significant interaction effects, posthoc t-tests were conducted to examine whether changes in SV were significantly different between the low vs. high play level groups based on the median BOSCC and VABS-2 scores.

**Results:** The main effects of time ( $B=16.85$ ,  $p<.001$ ) and baseline BOSCC play skills ( $B=30.22$ ,  $p<.001$ ) on SV emerged. The interaction effect between BOSCC baseline play level and time also emerged ( $B=7.19$ ,  $p=.009$ ). For the VABS-2 play skills, there was a significant interaction effect of baseline play skills and time ( $B=7.808$ ,  $p=.006$ ). All of these effects were significant even after controlling for the effects of age, gender, and NVIQ. As seen in Figures 1 and 2, posthoc analyses revealed that the high play level groups showed significantly larger improvements in SV compared to the low play level groups (BOSCC  $t=-3.866$ ,  $p<.001$ ; VABS  $t=-2.036$ ,  $p=.048$ ).

**Conclusions:** More mature play skills at baseline were associated with a greater increase in sentence diversity over the course of NDBIs, suggesting that early play skills may facilitate the gains in language skills over the NDBIs. Given that early functional use of language has been shown to be a strong predictor of positive long-term outcomes in children with ASD, these results indicate that targeting both play and language skills early on can have cascading effects on long-term outcomes.

## **ORAL SESSION - 12B — COMMUNICATION AND LANGUAGE**

### **324 - Beyond Standard Scores: New Approaches for Exploring Linguistic Heterogeneity**

#### **324.001 (Oral) Multisensory Integration and Adaptive Communication in Autistic and Non-Autistic Youth**

*C. Sancimino<sup>1</sup>, M. C. Cotter<sup>2</sup>, D. J. Horsthuis<sup>3</sup>, L. A. Ross<sup>4</sup>, J. J. Foxe<sup>1</sup> and S. Molholm<sup>1</sup>, (1)Neuroscience, Pediatrics, Albert Einstein College of Medicine, Bronx, NY, (2)Albert Einstein College of Medicine, Bronx, NY, (3)Departments of Imaging Sciences and Neuroscience, University of Rochester Medical Center, Rochester, NY, (4)The Ernest J. Del Monte Institute for Neuroscience, University of Rochester Medical Center, Rochester, NY*

**Background:** Neural and behavioral data show that multisensory integration (MSI) develops later in autistic as compared to non-autistic individuals. Additionally, caregivers rate autistic individuals without co-occurring intellectual disability (ID) as having lower adaptive functioning than their non-autistic cohorts. Methods to measure these phenomena include the Audio-Visual Speech-In-Noise (AV-SIN) paradigm and the Vineland Adaptive Behavior Scales (Vineland), respectively.

The AV-SIN paradigm demonstrates the effect of MSI on speech perception. During AV-SIN, speech is presented within an increasingly noisy background, obstructing intelligibility. When mouth movements are presented, speech intelligibility improves. This “gain” score (audiovisual – audio) is the amount of improved perception allowed by visual articulation. Previous research shows autistic children express a lower gain score than non-autistic, indicating lower MSI. As they reach adolescence, autistic and non-autistic individuals demonstrate a similar gain score, thus indicating delayed MSI in autistic individuals in childhood which resolves during adolescence.

The Vineland measures independent communication, socialization, and daily living skills. The Vineland Communication domain (Communication) includes Receptive, Expressive, and Written subscales. Robust literature indicates autistic individuals without ID have lower Vineland scores than IQ scores.

**Objectives:** We predicted autistic adolescents' language perception would improve as improved MSI ability allows visual articulation to strengthen auditory perception. We hypothesized autistic adolescents would show improving Communication scores mirroring improved gain scores in the AV-SIN paradigm. Communication scores for autistic individuals were not expected to reach the same level as non-autistic individuals; however, we expected a general trend to higher Communication scores correlating with improved MSI functioning.

**Methods:** The dataset included 55 autistic participants (ASD) ages 6-19 and 60 non-autistic participants (Control) ages 6-17, who completed the AV-SIN paradigm and Vineland within a year. To assess the effects of MSI, age, and Verbal-IQ (VIQ) on Communication, a hierarchical linear regression was conducted with age, VIQ, gain, and group entered sequentially, with Communication as the dependent variable.

**Results:** When controlling for age and VIQ effects, gain scores were a significant predictor of Communication ( $B=.38$ ,  $t(113)=2.10$ ,  $p=.038$ ), and the model was significant ( $F(3,110)=10.7$ ,  $p<.001$ ), accounting for 22.7% of variance. When group was added to the model, it accounted for an additional 44.9% of variance in the model ( $F(4,109)=56.8$ ,  $p<.001$ ), ( $B=-33.2$ ,  $t(113)=-12.3$ ,  $p<.001$ ). Gain coefficient was not significant ( $B=-.11$ ,  $t(113)=-.90$ ,  $p=.37$ ), indicating when group differences are factored in, MSI gain, when considered with age and VIQ effects, does not significantly contribute to Communication.

**Conclusions:** The AV-SIN paradigm showed the ASD group's improved ability to use mouth movements to understand auditory inputs at ages 12-13 years, but there was no correlating improvement in Communication scores. Thus, autistic individuals demonstrated improved MSI ability without improved listening and language comprehension skills. We are left with important questions: if improved MSI ability in autistic individuals does not lead to improved listening and language comprehension ability, what is the practical effect of improved MSI ability? What are the everyday benefits of increased MSI functioning? Further research should identify or develop instruments that adequately measure the impact of improved MSI ability on daily functioning of autistic individuals.

**324.002 (Oral)** Discovering Novel Predictors of Minimally Verbal Outcomes in Autism through Computational Modeling  
*M. Xu<sup>1</sup>, J. M. Rehg<sup>2</sup>, A. Rozga<sup>1</sup>, J. McDaniel<sup>3</sup>, P. Yoder<sup>4</sup>, L. R. Watson<sup>4</sup> and N. Brady<sup>5</sup>, (1)Georgia Institute of Technology, Atlanta, GA, (2)Life Span Institute, University of Kansas, Lawrence, KS, (3)Department of Special Education, Vanderbilt University, Nashville, TN, (4)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (5)University of Kansas, Lawrence, KS*

---

## **Background:**

As many as a third of individuals with autism spectrum disorder (ASD) remain minimally verbal (MV), producing few if any spoken words. Significant gaps remain in our ability to predict which children will remain MV. Current approaches typically rely on measures taken at a single time point to predict language growth or outcome. In contrast, Continuous-Time Hidden Markov Models (CT-HMMs) make it possible to model early linguistic development as a series of stages corresponding to developmental milestones. Doing so allows the developmental trajectories themselves to become potential predictors of communication outcomes.

## **Objectives:**

We aim to demonstrate the feasibility for using CT-HMMs for modeling early linguistic development of children with ASD as a step in identifying novel predictors of MV outcomes. One potential clinical use for inflection point-derived risk markers would be in identifying the appropriate timing for interventions. Inadequate progress for a child with ASD would be a basis for altering the intensity and/or type of intervention.

## **Methods:**

Eight-seven children with ASD with MV skills (mean age = 35.2 months) were observed at five time points across 16 months (Yoder et al., 2015). We created CT-HMMs for total words said (MacArthur Communicative Development Inventory [MCDIPV]) and weighted raw score for words (Communication and Symbolic Behavior Scales [CSBSWDS]) for the whole group and when divided by MV status.

## **Results:**

Some children made steady simultaneous gains in word production on both measures (Figure 1; diagonal left to right paths), whereas others made gains based on the CSBSWDS but not on the MCDIPV (horizontal left to right paths). A sizeable number of children remained in the initial vocabulary state (0 words) on both measures (large purple node in the upper left-hand corner) or made minimal gains up to 10 words (upper left-hand quadrant) before plateauing on both measures.

We then divided the sample by MV status at the final time point. Except for one participant, the trajectories of children who remained MV ( $n = 45$ ;  $<5$  words in language sample; Figure 2; left panel) are entirely confined to the upper left-hand quadrant of the state space, suggesting these children either remained in an initial state of 0 words or made minimal gains up to an average of 10 words. In contrast, children who were deemed verbal by study outcome ( $n = 33$ ; Figure 2; right panel) were more heterogeneous. Some made steady simultaneous gains in word production on both measures. Others made gains based on clinician observation, but not based on caregiver report.

## **Conclusions:**

These findings support the promise of CT-HMMs for revealing developmental progressions that differentiate children by MV status. For example, we observed that the average dwell time for verbally developed children in state (1,1) was 4.69 months, whereas the average dwelling time for MV

children was 8.08 months. It follows that children who remain in this state beyond 4.69 months are exhibiting below average progress, which could be the basis for making intervention changes. With continued development, a CT-HMM could be used in clinical settings to inform intervention decisions.

**324.003 (Oral)** When Cut-Off Scores Don't Cut It: Children with ASD Who Test As Having 'Normal' Language Make Twice As Many Language Errors As NT Peers

*E. Zane<sup>1</sup>, N. Sperrazza<sup>2</sup> and R. Grossman<sup>3</sup>, (1)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA, (2)James Madison University, Harrisonburg, VA, (3)CSD, Emerson College, Boston, MA*

---

**Background:** There are reasons to suspect that standardized language tests may not effectively capture the way that individuals with ASD use language in interactional contexts (see Eigsti and Schuh, 2016, for review). For instance, the context of standardized testing is less social, less time-pressured, and more predictable than spontaneous, natural interaction. Thus, it is possible that, for children with ASD, standardized language scores within the normal range may belie subtle, but important underlying weaknesses, that can become apparent in spontaneous language.

**Objectives:** To determine whether children with and without ASD with statistically equivalent scores on standardized language tests will show significant differences in frequencies of language errors in a spontaneous language sample.

**Methods:** Eighteen older children with ASD (m=13:6) and 20 neurotypical (NT) peers (m=13:1) participated. All participants' standard scores on the CELF-5 fell above one standard deviation below the mean (ASD m=110; NT m=113,  $p=0.61$ ). Participants engaged in a semi-structured conversation, which was video-recorded and transcribed. We then coded all written transcripts for language (not pragmatic) errors. All coding was completed blind to diagnosis. Each of the three coders independently read all transcripts and marked any language error produced by the participant. We compared error codes and included only those in the final dataset that were identified by two or more coders. We then categorized agreed-upon errors as semantic (e.g., inappropriate word choice) or morphosyntactic (e.g., subject-verb disagreement). Semantic and morphosyntactic error counts were then converted to proportions of utterances, and we used hierarchical mixed linear models with Group (ASD vs. NT), Error Type (morphosyntactic vs. semantic), and CELF scores as fixed effects, and with Participant as a random effect. Significance of fixed effects was assessed by performing likelihood ratio tests in which we compared a model containing the effect to another otherwise identical model.

**Results:** ASD participants made more semantic ( $n=16.00$ ; 10.93% of utterances) and morphosyntactic errors ( $n=13.38$ ; 9.34% of utterances) than NT participants ( $n=6.70$  [5.51%];  $n=6.75$  [5.11%]). See Figure. Regressions revealed a main effect of Group ( $X^2=11.54$ ,  $p<0.001$ ), where participants with ASD made significantly more errors than NT participants ( $\beta=0.04$ ,  $SE=0.01$ ,  $p=0.001$ ). Neither the fixed effect of CELF scores ( $p=0.12$ ) nor error type ( $p=0.17$ ) was significant, nor was any interaction.

**Conclusions:** Despite statistically equivalent scores on the CELF-5, older children with ASD made twice as many language errors than their NT peers during a conversation. This result, combined with the fact that CELF scores do not significantly predict error rates, suggest that the use of standardized measures may not accurately capture functional, interactional language in ASD. Researchers and clinicians should use other measures to determine language functioning, rather than relying on standardized test scores, which may miss differences that could be revealed in analysis of spontaneous language use.

**324.004 (Oral)** Phonological and Morphosyntactic Skills in Arabic-Speaking Children with and without Autism Spectrum Disorder (ASD):

Evidence from Non-Word and Sentence Repetition Tasks

*M. Abd El-Raziq<sup>1</sup>, N. Meir<sup>2</sup> and E. Saiegh-Haddad<sup>3</sup>, (1)The department of English Literature and Linguistics, Bar-Ilan University, Ramat-Gan, Israel, (2)Department of English Literature and Linguistics, Bar-Ilan University, Ramat Gan, Israel, (3)The Department of English Literature and Linguistics, Bar-Ilan University, Ramat-Gan, Israel*

---

**Background:** Structural language deficit (e.g., phonological and morphosyntactic) is not a core phenotype of Autism Spectrum Disorder (ASD), yet some children with ASD manifest significant impairment in this domain (Kjelgaard & Tager-Flusberg, 2001). Non-word (NWR) repetition as a measure of phonological memory and Sentence repetition (SRep) as a measure of morphosyntactic skills have been consistently shown to be reliable tools for diagnosing structural language impairment (Conti-Ramsden et al., 2001; Armon-Lotem & Meir, 2016).

**Objectives:** The current study aimed to assess structural language skills of Palestinian-Arabic speaking children with and without ASD using NWR and SRep tasks. The Arabic language is the mother tongue of over 313 million people in the Middle East and North Africa and the fifth most spoken language globally (Simons & Fennig, 2018). Although there is an increasing interest in the research on language acquisition in Arabic-speaking children with ASD, research is still rather limited.

**Methods:** A total of 164 children aged 4 -11 participated in the study: 76 children with ASD and 88 children with typical language development (TLD). Children in the two groups were matched for chronological age, and they all scored within the normal range on non-verbal IQ. We used two tasks to assess structural language skills: NWR to evaluate phonological skills (Saiegh-Haddad & Ghawi-Dakwar, 2017) and SRep to evaluate morphosyntactic skills (Saiegh-Haddad, Halabi, & Armon-Lotem, 2019). Items in both tasks varied in length and linguistic complexity.

**Results:** As a group, children with ASD scored significantly lower than their peers with TLD on both tasks. However, there was a large variability in the performance within the ASD group. 26% of the children with ASD showed intact structural language skills and scored within the normal range in both tasks, while 74% of children showed an impairment in one or both domains (5% scored within the at-risk range for phonological impairment; 33% within the at-risk range for morphosyntactic impairment, and 36% scored within the at-risk in both domains). Using Mixed-Effects Binomial

Logistic Regressions, the study also examined the effects of the stimuli length and the linguistic complexity on children's performance in each task. Children with ASD who scored within the at-risk range for phonological impairment were affected by the length of the non-words regardless of the linguistic complexity (the presence of clusters). Children who scored within the at-risk range for morphosyntactic impairment showed particular difficulties when repeating sentences with *who/which* object questions and *object relative* clauses.

**Conclusions:** The results of the current study confirm the heterogeneity of profiles in children with ASD: those with intact language abilities who perform within the TLD range and those with additional structural language impairments in at least one of the domains. Beyond the theoretical contribution, shedding light on the loci of linguistic difficulties, the documentation of various profiles of children with ASD would enable clinicians and educators develop tailor-made intervention programs for these children. Finally, we conclude that NWR and SRep tasks are valuable tools for detecting structural language difficulties in Palestinian-Arabic-speaking children with ASD.

## POSTER SESSION — COMMUNICATION AND LANGUAGE

### 408 - Communication and Language

#### 408.001 (Poster) Language Measures and ASD Risk Sensitivity: Utility of the Language Use Inventory Assessment

**J. E. Blume<sup>1</sup>**, A. Mastergeorge<sup>2</sup>, S. Ozonoff<sup>3</sup>, M. Miller<sup>4</sup> and D. O'Neill<sup>5</sup>, (1)Human Development and Family Sciences, TTU HDFS, Lubbock, TX, (2)Human Development and Family Sciences, Texas Tech University, Lubbock, TX, (3)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (5)Psychology, University of Waterloo, Waterloo, ON, Canada

**Background:** Children with a variety of developmental disorders may present with language delays and benefit from targeted interventions. However, language delays in children with autism are typically a co-occurring deficit or cascade effect of joint attention delays and social motivation differences, warranting a unique assessment and intervention approach and language measures with a pragmatic focus (Rogers et al., 2020). At present, standardized measures to assess autism symptoms such as the ADOS often require intensive training and are less accessible for many families. As the prevalence of autism continues to rise, the increased use of less time-consuming and widely accessible pragmatic language measures could serve to expedite the necessity of pursuing a more rigorous autism symptom assessment protocol.

**Objectives:** This study examines how scores on language measures are associated with concurrent evaluation of ASD symptoms, as measured by the *Autism Diagnostic Observation Schedule* (ADOS-2, Lord et al., 2000). We hypothesized that a measure focusing on pragmatic communication, the *Language Use Inventory* (LUI, O'Neill, 2009), would be more strongly associated with ADOS-2 scores than the more general language/communication subscales of the *Mullen Scales of Early Learning* (MSEL, Mullen, 1995) and *Vineland Adaptive Behavior Scales* (VABS, Sparrow et al., 2005).

**Methods:** This investigation utilized a sample of participants (175 male, 106 female) from a larger longitudinal study of younger siblings of children with ASD (high-risk group, n = 164) or typical development (low-risk group, n = 99). Participants were administered an array of developmental assessments at multiple ages; this analysis focused on the 36-month data. Bivariate correlations were estimated between ADOS-2 comparison scores and LUI total scores and T-scores from the language subscales of the MSEL and VABS.

**Results:** Scores on the three language measures were strongly correlated (see Table 1). LUI scores were highly and significantly associated with ADOS-2 comparison scores ( $r = -.661, p < .001$ ). Application of Fisher's Z transformation indicated that the correlation between the LUI and ADOS-2 was significantly stronger than the correlations between ADOS-2 and VABS Communication scores ( $z = -2.95, p < .001$ ), as well as MSEL Expressive ( $z = -3.79, p < .001$ ) and Receptive ( $z = -4.72, p < .001$ ) Language scores.

**Conclusions:** Our findings indicate that the LUI, a feasible and efficient parent-report measure of pragmatic language, yields child language scores consistent with directly administered language measures (e.g., MSEL), other parent-report measures of functional communication skills (e.g., VABS), and the gold standard assessment of autism symptoms (e.g., ADOS). While previous empirical studies have already identified the LUI as relevant for use with young children with or without autism risk (Miller et al., 2015; Pesco & O'Neill, 2012; Tager-Flusberg et al., 2009), the associations identified in the present study suggest parent-report measures such as the LUI could be a practical tool to prompt administration of more comprehensive autism assessment measures. Follow-up analyses will evaluate within-group and between group-differences on the LUI (ASD v. typical development outcomes), in addition to discriminant validity between the LUI and non-language measures.

#### 408.002 (Poster) Are Real-Time Coded Measures of Verbal Communicative Competence Sensitive to Capturing Change in Minimally Verbal Children with ASD in the Context of the Jasper Intervention?

**C. La Valle<sup>1</sup>**, E. Johnston<sup>2</sup>, W. I. Shih<sup>3</sup>, C. Kasari<sup>4</sup> and H. Tager-Flusberg<sup>1</sup>, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Boston University, Boston, MA, (3)University of California - Los Angeles, Los Angeles, CA, (4)University of California, Los Angeles, Los Angeles, CA

Background:

Expressive language is one of the strongest predictors of future outcomes for children with ASD (Friedman et al., 2019). Thus, language and communication represent important targets for intervention (Tager-Flusberg & Kasari, 2013). Previous work used real-time coded natural language

samples (NLS) to derive general measures of verbal communicative competence (Barokova & Tager-Flusberg, 2018), providing an optimal approach for the assessment of children with ASD who are minimally verbal (MV; Barokova et al., 2021). These measures hold the potential to efficiently chart change in intervention research.

#### Objectives:

In a sample of MV children with ASD, we examined 1) whether our measures of verbal communicative competence, frequency of utterances (FreqU) and conversational turns per minute (CT), are sensitive to capturing change from entry to exit JASPER+EMT intervention using real-time coded NLS; and 2) how these measures validate against the Clinical Global Impression-Improvement scale (CGI-I).

#### Methods:

Twenty-eight MV children with ASD (22 males; ages 53-98mo.) completed assessments at entry (week 1) and exit (week 18) JASPER+EMT intervention. JASPER, an NDBI, focused on teaching joint attention, play skills, and promoting communication during semi-structured play sessions with trained clinicians (Kasari et al., 2021) blended with Enhanced Milieu Teaching (Kaiser et al., 2000; JASPER+EMT). A 20-minute NLS (adult-child interaction with specified toys; Kaiser et al., 2014) and CGI-I (Guy, 1976; assesses global change in social communication) were used. CGI-I scores ranged from 7 (very much worse) through 1 (very much improved). The NLS was coded in real-time in ELAN (Lausberg & Sloetjes, 2009) to derive FreqU and CT. FreqU was computed by dividing the total number of segmented utterances by NLS length in minutes. Speech utterances were defined as vocalizations with a syllable structure that consists of vowels and consonants (Barokova et al., 2021). CT was computed by exporting the ELAN file containing the start and end time of each utterance into an excel document and applying a count formula. CT was defined as one or more consecutive utterance(s) produced by the same speaker (Miller et al., 2011).

#### Results:

1) Analyses involved a paired samples t-test or non-parametric equivalent. A statistically significant improvement was found in FreqU (median difference=1.53;  $V=342, p=0.0009657$ ) and CT ( $MD=.94; t(27)=3.55, p=0.00145$ ) from entry to exit JASPER+EMT intervention (Figures 1A-1B). 2) Analyses explored associations between CGI-I ratings and change scores (exit-entry) in FreqU and FreqCT. Twenty-one participants who were rated as "improved" on the CGI-I (very much improved, much improved, or minimally improved) also had positive change scores for FreqU and CT ( $n=23$ ; Figures 2A-2B).

#### Conclusions:

Our general measures of verbal communicative competence, FreqU and CT, using real-time coded NLS were sensitive to capturing change in the context of a JASPER+EMT intervention. Findings provide preliminary support for the implementation of these measures in intervention-based studies to efficiently track changes in participant's spoken language and communication over time and to inform individualized goals and targets. A majority of participants who showed improvement on the CGI-I also showcased positive change in FreqU and CT, providing initial support for the validation of our measures against clinical global impression.

**408.003 (Poster)** Autism Subtypes and Language Ability in Males with Co-Occurring Fragile X Syndrome and Autism Spectrum Disorder  
**C. Moser<sup>1</sup>, A. Campanelli<sup>2</sup>, L. Friedman<sup>3</sup>, A. J. Thurman<sup>1</sup>, L. Abbeduto<sup>4</sup> and J. Klusek<sup>5</sup>,** (1)Communication Sciences & Disorders, University of South Carolina, Columbia, SC, (2)University of South Carolina School of Medicine, Columbia, SC, (3)University of South Carolina, Columbia, SC, (4)M.I.N.D. Institute, UC Davis, Sacramento, CA, (5)Communication Sciences and Disorders, University of South Carolina, Columbia, SC

Background: Exploring subtypes of autism spectrum disorders (ASD) based on social interaction styles<sup>1</sup> has helped elucidate targeted treatments and inform various within-syndrome profiles. For instance, language abilities and treatment response vary by ASD subtype. The two main subtypes based on work by Wing & Gould (1979) are 'aloof/passive' and 'active-but-odd.' We have chosen to update these terms to avoid potential negative perceptions of ASD features and will instead use 'passive' and 'active'. The passive subtype is characterized by a lack of social approach. The active subtype is characterized by spontaneous social approach that tends to be repetitive and one-sided<sup>1</sup>. Like non-syndromic ASD, there is considerable within-syndrome variability in fragile X syndrome (FXS; the most common known single-gene cause of ASD); however, ASD subtypes have not been explored in this population. Characterizing subtypes in males with ASD secondary to FXS could lead to a more nuanced understanding of syndromic forms of ASD. For instance, grammatical abilities are impaired relative to cognitive expectations in those with FXS, and factors such as ASD subtype may underscore individual differences in grammatical abilities.

Objectives: To examine how grammatical abilities vary across ASD subtypes in males with ASD associated with FXS.

Methods: The present study included 42 males with FXS with ASD ( $M(SD)$  age=18.19(2.03) years). Risi et al. (2006) criteria were used to determine ASD diagnosis. Social interaction style was coded from video recordings of the ADOS-2 based on subtypes identified by Wing & Gould (1979) via consensus of two raters; reliability prior to consensus was substantial (Cohen's kappa= .64). Grammatical abilities were indexed by mean length of utterance in morphemes (MLU) during two sampling contexts: conversation and narration.

Results: Twenty-one participants were classified as active and 21 as passive. The subtypes did not differ in age ( $p=.912$ ), nonverbal IQ ( $p=.778$ ), daily living skills ( $p=.838$ ), or ASD severity ( $p=.909$ ). A random intercepts linear mixed model was fit testing the effect of ASD subtype, language sampling context, and their interaction. The interaction between ASD subtype and language sampling context was significant ( $F(1,40)=9.44, p=.004$ ).

Follow-up tests indicated ASD subtypes differed on MLU in the conversation context ( $p=.037$ ), such that the passive subtype produced significantly lower MLU than the active subtype. There was no significant difference in MLU for the narration context ( $p=.773$ ).

**Conclusions:** The identification of ASD subtypes in FXS may help explain phenotypic variability in syndromic forms of ASD. Our findings align with research in non-syndromic ASD, such that the active subtype displayed more complex grammar. However, differences across subtypes were only found in the conversation context. Thus, elicitation of language abilities is likely to relate to contextual differences in language samples. For instance, reduced grammatical complexity during the conversation compared to the narration context for those classified as passive could be due to the social demands of the conversation context. These findings, along with research focused on additional factors that may differentiate ASD subtypes within FXS, could lead to the development of more personalized interventions to improve outcomes of those with syndromic forms of ASD.

#### **408.004 (Poster)** Case Studies of Non-Interactive Bilingualism in ASD

**C. Dumont<sup>1</sup>, M. Kissine<sup>2</sup>, E. Clin<sup>3</sup>, A. Biston<sup>3</sup> and A. Wintgens<sup>4</sup>,** (1)ACTE-ULB, Bruxelles, Belgium, (2)ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium, (3)ULB, Bruxelles, Belgium, (4)Cliniques universitaires de Saint-Luc, Bruxelles, Belgium

---

#### **Background:**

One of the core characteristic of Autism Spectrum Disorder (ASD) is difficulties in verbal and non-verbal communication (American Psychiatric Association, 2015). These language disabilities are often traced back to atypicalities in processing social information, because of the importance of cooperative communication in typical language development (Luyster et al., 2008; Anderson et al., 2009; Wodka et al., 2013). For instance, a landmark and since then replicated study showed that typical infants need active interaction, as opposed to passive exposure to television, to acquire novel phonological categories (Kuhl et al., 2003). However, non-interactive language acquisition has been documented in ASD, both in the literature on 'linguistic savants' (Vulchanova et al., 2012) or in children (Kissine et al., 2019).

**Objectives:** Our objective was to further attest such non-interactive language acquisition.

**Methods:** We looked for cases of non-interactive bilingualism in the French speaking part of Belgium. In this paper we report the cases of three autistic boys (9-12) who have acquired English through passive exposure. All of them were in a French speaking environment both at school and home and some of them ( $n=1$ ) developed English before French. Data were collected during a language assessment with the Clinical Evaluation of Language Fundamentals (CELF-5) in English and French. Two analysis were carried out on their speech productions to attest to the existence of the development of distinct phonological categories for both languages: the Voice Onset Time (VOT) of stops consonants and the formants (F1 and F2) analysis of tense and lax vowels. Voiced stops (/b/, /d/, /g/) exhibit a short lag VOT in English, but a lead VOT in French. Voiceless stops (/p/, /t/, /k/) have a lead VOT in English and a short lag VOT in French (Caramazza et al., 1973; Kessinger & Blumstein, 1997; Sundara, 2005). Furthermore, the vowel system of English differs greatly from the one in French with the presence of lax (/ɪ/, /ʊ/) and tense vowels (/i:/, /u:/). French speaking speakers tend to neutralise this contrast and produce the French phonemes (/i/, /u/) instead (Capliez, 2011).

**Results:** Regarding the language assessment, one participant scored higher in English (86) than in French (50) showing a better mastery of English, one of them showed the same average level in both languages (64-62) and one of them showed better mastery in French (86-99). Multiple regressions analysis were used for the VOT and formants analysis. One child showed a significant difference for voiceless ( $p=.001$ ) and voiced stops ( $p=.006$ ) in French and English, one showed only a significant difference for voiceless stops ( $p=.03$ ) in French and English and one showed no difference. The formants analysis shows a significant difference for either F1 or F2 values for the distinction between lax and tense vowels in English and between the vowels of French and the lax ones of English for all the children.

**Conclusions:** These results suggest the development and the use of different phonological categories for each language and that passive exposure to non-interactive media enabled this development in the case of these children.

#### **408.005 (Poster)** Cluster Scores on the CSBS Reveal Widespread Social Communication Deficits in 12-Month-Old Infants Who Are Later Diagnosed with Autism

---

#### **Background:**

Autistic children demonstrate deficits in social communication skills from an early age, and these deficits have a cascading effect on later language skills (Delehanty et al., 2018; Wetherby et al., 2007; Yoder et al., 2015). Increased understanding of the associations between early social communication skills and later language is needed to enhance our ability to choose high-priority early intervention goals that support receptive and expressive language development.

## Objectives:

This study aimed to examine longitudinal development of social communication between 12-to-24-months, measure group differences in social communication skills, and explore associations between social communication and later language.

## Methods:

Infant participants (N=511) were part of the Infant Brain Imaging Study (IBIS). The Communication and Symbolic Behavior Scales (CSBS; Wetherby & Prizant, 2002) was administered at 12, 15, and 24-months to measure social communication skills across three groups: low familial risk typically developing infants (LR-Neg; n=165), high familial risk infants without autism (HR-Neg; n=295), and high familial risk infants with autism (HR-ASD; n=87). HR-ASD infants met Clinical Best-Estimate criteria for autism using the DSM-IV-TR at 24-months, and HR-Neg infants did not. LR-Neg infants did not meet criteria for autism or language delay (Table 1). Individual cluster raw scores were extracted from the CSBS. Raw scores were used to avoid floor effects in standard scores. The longitudinal statistical model included the effects of group, time (chronological age), and a group by time interaction. The Mullen Scale of Early Learning (MSEL; Mullen, 1995) was used to evaluate language skills at 24-months. For the statistical model analyzing the effects of 12-month social communication scores on later language skills, MSEL receptive and expressive language age equivalent scores were dependent variables. The analyses included social communication scores, group, and social communication scores\*group. Sex of the infant, maternal education, and site were included as covariates in all models.

## Results:

Longitudinal analyses using mixed linear models indicated significant main effects for group\*time ( $p < .01$ ) for all CSBS scores (Table 1). HR-ASD infants made fewer gains on all social communication skills between 12-24 months and had significantly lower scores on all clusters except words and understanding at 12-months of age (Table 1) when compared to HR-Neg and LR-Neg infants. Results from the language analyses revealed significant main effects for all CSBS scores ( $p < .01$ ). The cluster scores \*group effect was not significant for all social communication skills. Follow-up group analyses indicated that the effect of CSBS scores on later language was not significant for the HR-ASD infants, except for understanding, which was significantly associated with receptive language (Table 2).

## Conclusions:

Results indicate that HR-ASD infants demonstrate deficits in social communication as early as 12-months of age, well before autism diagnoses are considered stable. HR-ASD infants did not demonstrate the same associations between early social communication and later language that was seen in infants who did not meet criteria for autism. This could be due to delayed acquisition of social communication skills that were associated to later language. These findings have implications for identifying early intervention treatment targets that will impact later language.

## **408.006** (Poster) Comparing Social Communication and Language Patterns between Adults with and without Autism

**D. Kan<sup>1</sup>, J. K. Kinard<sup>2</sup>, R. K. Greene<sup>1</sup> and P. Cernasov<sup>4</sup>,** (1)School of Education, University of North Carolina at Chapel Hill, Chapel Hill, NC, (2)Carolina Institute for Developmental Disabilities, University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)Oregon Health & Science University, Portland, OR, (4)Psychology and Neuroscience, University of North Carolina, Chapel Hill, NC

Background: Support needs of adults on the autism spectrum remain largely unmet (Shattuck et al., 2012; Wright et al., 2019), one of which is communication needs. Communication difficulties that autistic adults face can significantly impact their daily functioning due to difficulties accessing, sharing or contesting information. Difficulties can also lead to a lack of engagement with local surroundings, and feelings of embarrassment which may result in isolation and withdrawal from society (Cummins et al., 2020). Multiple reasons contribute to autistic adults' communication difficulties, including a lack of understanding of communication styles of both autistic and non-autistic individuals stemming from the double empathy problem (Mitchell et al., 2021; Santhanam & Hewitt, 2020). Yet these communication differences in adults have yet to be fully elucidated.

Objectives: Since identifying differences can aid understanding and improve communication and interactions, an examination of communication differences between autistic and non-autistic adults is warranted. Our research questions are: 1. How do social communication and language patterns differ between adults with and without autism during conversation with an unfamiliar peer? and 2. To what extent do social communication and language patterns contribute to self-reported impairments in social interaction across both groups?

Methods: We had 46 adult participants (mean age=26 years), where 23 were diagnosed with autism and 20 were not. For language samples, we transcribed two sections of the Autism Diagnostic Observation Schedule-2, the 'description of a picture' and 'friends, relationship and marriage' sections. Sections were chosen to get snapshots of communication across different contexts (concrete versus abstract topics). Samples were between 3-10 minutes long. These narrative transcripts were analyzed using the Systematic Analysis of Language Transcripts (SALT) software. Exploratory factor analysis was used to reduce the number of SALT outcome variables. An independent t-test or Wilcoxon test with Bonferroni correction was used to examine differences between groups based on derived factors. Regression analyses were conducted using autism group status and SALT factors to predict the participants' self-reported social interaction impairments on the Social Responsiveness Scale-2.

Results: Results are complete on the description of a picture section, and further analysis are ongoing for the 2nd language sample. We derived a 3-factor model - amount/rate of speech (f1), diversity of vocabulary & pauses (f2), and overlapping/abandoned utterances (f3). RQ1. Adults on the autism spectrum were found to produce fewer utterances and speak less quickly ( $p = 0.007$ ). They also used greater variety of vocabulary on average and had more pauses between utterances compared to non-autistic adults ( $p < 0.001$ ). No significant difference was found between groups for factor 3

( $p = 0.23$ ). RQ2. Participants in the autism group ( $p=0.01$ ) and participants who had faster and longer utterances across both groups ( $p=0.008$ ) tended to report more social interaction impairments.

**Conclusions:** Our study have begun to explore and provide information on differences in communication styles between adults with and without autism, serving as the foundation to future larger studies. Findings potentially serve as a basis for targets in social skills interventions and trainings that include both autistic and non-autistic individuals.

#### **408.007 (Poster)** Early Predictors of Toddlers' Use of Decontextualized Language and Its Associations with Symptoms of Autism

**M. Rudling<sup>1</sup>, S. Bolte<sup>2</sup> and T. Falck-Ytter<sup>3,4</sup>**, (1)Department of Psychology, Department of Psychology, Uppsala University, Uppsala, Sweden, (2)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, & Stockholm Health Care Services, Region Stockholm, Stockholm, Sweden, (3)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (4)Department of Psychology, Uppsala University, Uppsala, Sweden

---

**Background:** Pragmatics is the functional use of language in ever-changing social contexts. One early pragmatic ability is decontextualized language; to talk about events and things beyond here and now. Pragmatic difficulties are practically universal in ASD, but we don't know about impairments in early pragmatic development. Further, the roles of early socio-communication and linguistic abilities in the development of decontextualized language is of both theoretical and practical value and has not previously been studied in young toddlers.

**Objectives:** Here, we study longitudinal associations between structural language and non-verbal socio-communicative abilities at 14 months age and decontextualized language use at 24 months age. We study both children with high and low likelihood of ASD, to discern potential differences in the predictors and use of decontextualized language between these groups.

**Methods:** Toddlers from two samples were included; Babytwins Study Sweden (BATSS; a longitudinal twin study) and Early Autism and ADHD Sweden (EASE; a prospective sibling study). The BATSS sample and the children with low familial likelihood of ASD from the EASE study constituted the combined typical likelihood group ( $N = 206$ , 49.5% boys). Children in the elevated likelihood group ( $N = 97$ , 53.6% boys) had increased familial likelihood of ASD due to first-degree relatives with the diagnosis. The main measures comes from the Swedish version of the MacArthur-Bates Communicative Development Inventory (SE-CDI): Structural language and socio-communication from the CDI Words & Gestures at 14 months of age, and decontextualized language from the CDI Words & Sentences at 24 months of age.

**Results:** For the combined typical likelihood group, there was an interaction between structural language and socio-communication in predicting later decontextualized language use, controlling for age and sex. Specifically, the positive association between socio-communication and decontextualized language was significant only at low levels of structural language, whereas structural language was an independently significant predictor. Notably, this pattern was specific to decontextualized language, as for grammatical ability at 24 months, only structural language was a significant predictor. For the elevated likelihood group, structural language independently predicted decontextualized language use, but did not interact with socio-communication. However, the interaction between structural language and socio-communication was not moderated by group in the overall sample. For the elevated likelihood group, decontextualized language scores correlated with ADOS-2, and they scored significantly lower on decontextualized language use compared to children with typical likelihood.

**Conclusions:** Structural language seems to be a more important factor in predicting decontextualized language use than social communication in both children with and without elevated likelihood of ASD. Further, while decontextualized language is closely related to structural language, these two abilities are clearly dissociable even this early in development. Lastly, toddlers with elevated likelihood of ASD already show decreased pragmatic ability compared to typically developing infants, but we found no strong evidence for differences in the factors predicting this ability across the two groups. These results may have implication for early intervention targeting pragmatic abilities in infants at elevated likelihood of ASD.

---

**Background:** Gestures are a form of early nonverbal communication and considered a core deficit of young children with ASD (Manwaring et al., 2018; QiangYe et al., 2021). Previous studies have shown that infants who are later diagnosed with ASD have deficits in early gesture use as early as 12 months of age (Iverson et al., 2017; Mitchell et al., 2006, Watson et al., 2013). Other studies have found that infants with ASD with more gestures also had better verbal skills, suggesting that early gesture use is a harbinger for later development (for a review see Ramos-Cabo et al., 2019). This existing body of literature, while growing, is based on small sample sizes and/or non-standard approaches like retrospective video reports.

**Objectives:** The goal of this study is to examine gesture growth differences in a large sample size of infants at 12, 18 and 24 months of age across three groups: high familial risk with ASD (HR-ASD), high familial risk without ASD (HR-Neg) and low familial risk without ASD (LR-Neg).

**Methods:** Gesture use was measured using the MacArthur Communicative Development Inventory - Words and Gesture (MCDI-WG; Fenson, 1993) at 12, 18, and 24 months. Groups were based on clinical best estimate diagnosis (DSM-IV-TR) at 24 months. Inclusion criteria were completion of at

least one MCDI-WG and diagnostic testing at 24 months ( $N = 473$ , see  $n$  by group in Table 1). Linear mixed models were used to longitudinally characterize early and later gesture use from 12 to 24 months. Dependent variables were raw scores of early and later gestures to account for 24-month ceiling effect. The model included the fixed effects of time (chronological age), diagnosis, and time\*diagnosis. Random effects were time grouped by participants. Covariates were sex, site, and maternal education.

Results: Analysis indicated significant main effects for diagnosis ( $p < .001$ ), time ( $p < .001$ ), and time\*diagnosis ( $p < .01$ ) for early and later gesture use. The HR-ASD group showed slower growth in gestures compared to HR-Neg and LR-Neg (Figure 1). The HR-Neg group also had slower growth when compared to LR-Neg ( $p < .05$ ). Cross-sectional analysis (Table 1) indicated that the HR-ASD group had lower early and later gesture use at 12, 18 and 24 months compared to the HR-Neg and LR-Neg groups. The HR-Neg group had lower early gesture use compared to the LR-Neg group at 12 and 18 months, but not 24 months. The HR-Neg group had lower later gesture use compared to the LR-Neg group at 12, 18, and 24 months.

Conclusions: Our results indicate that the HR-ASD group had deficits in gesture use at 12 months, with deficits increasing at 24 months. This data suggest that gesture deficit is one of many possible early red flags for ASD. These findings are important in identifying treatment targets for infant interventions aimed at supporting communication skills. Future directions include investigating the neurobiology of early gesture.

#### **408.009 (Poster)** Gesture Comprehension in Individuals with and without Autism Spectrum Disorder

**R. Canale<sup>1</sup>, A. R. Canfield<sup>2</sup>, C. Larson<sup>1</sup>, B. Castelluccio<sup>1</sup> and I. M. Eigsti<sup>1</sup>,** (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)SUNY Upstate Medical University, Syracuse, NY, (3)Psychiatry and Human Behavior, Alpert Medical School of Brown University, Providence, RI

Background: Previous studies have revealed well-established differences in gesture *production* in Autism Spectrum Disorder (ASD) (Özer et al., 2020); however, little work has examined gesture *comprehension*. Our group has developed the Gesture Comprehension (GeCo) task. In this task, participants view a 35-sec video depiction of a conversation between two women discussing the experiences of “Sam” during her move to a new apartment. The conversation is lively and includes multiple co-speech gestures which convey story details, such as how Sam called for help (by texting) and the spiral shape of a staircase. Participants are asked to respond to multiple choice questions about the video; questions probe recall of events as conveyed through either gesture (5 items) or speech (3 items).

Objectives: This experiment compares performance on the GeCo questionnaire between individuals with ASD and neurotypical (NT) individuals. We predicted that individuals with ASD would display deficits in narrative comprehension, compared to individuals in the NT groups, as reflected by reduced accuracy of multiple-choice test responses for story information conveyed in speech. We also predicted a group by modality interaction, with lower accuracy in the ASD group on items probing information conveyed exclusively in gesture, relative to info conveyed in speech.

Methods: We tested for differences in accuracy on the GeCo questionnaire accuracy (full score, gestures only, and speech only) for ASD [ $n=26$  (7 females),  $M(SD)$  age= 28.9(4.4) years] and NT [ $n=42$  (17 females),  $M(SD)$  age= 21.7(4.7)] groups.

Results: Groups differed in accuracy overall,  $t = -4.25$ ,  $p = 6.94e-05$ , and on gesture items,  $t = 0.473$ ,  $p = 1.23e-05$ . There was no difference on verbal items,  $t = -1.28$ ,  $p = 0.21$ ; Figure 1. The ASD group had greater accuracy (by 9%) on speech items relative to gesture items; the NT group showed the opposite pattern (by 5%), although these differences were not significant on within-group t-tests. Repeated measures ANOVA results suggest a main effect of group (ASD vs. NT;  $F(1, 45) = 20.4$ ,  $p = 2.67e-05$ ), question type (gesture vs. verbal;  $F(1, 47) = 12.0$ ,  $p = 0.0009$ ), and interaction of group by question type ( $F(1, 47) = 8.9$ ,  $p = 0.004$ ).

Conclusions: We examined gesture comprehension in ASD using a measure that probed recall of information conveyed in discourse. The ASD group had lower accuracy overall compared to the NT group, with a specific difficulty in recalling information that had been conveyed via gesture. Given that participants had overall cognitive abilities within the average range, this pattern is unlikely to reflect difficulty in comprehending the events related during the GeCo stimulus. Rather, we propose that results show impaired ability to attend to and integrate information conveyed through gesture. Planned analyses will investigate the role of higher order cognitive processes (specifically, theory of mind and working memory) in gesture comprehension in individuals with ASD. In addition, we will examine the relationship between gesture comprehension, and gesture production, within groups.

#### **408.010 (Poster)** Identifying Homogeneous Subgroups of Autistic Youth Based on Talkativeness

**M. L. Cola<sup>1</sup>, L. D. Yankowitz<sup>2</sup>, S. Plate<sup>2</sup>, A. S. Russell<sup>1</sup>, A. Knox<sup>2</sup>, M. R. Pelella<sup>2</sup>, M. Leuzzi<sup>2</sup>, K. G. Tena<sup>2</sup>, C. J. Zampella<sup>2</sup>, L. S. Cubit<sup>2</sup>, J. Pandey<sup>2</sup>, R. T. Schultz<sup>2</sup> and J. Parish-Morris<sup>1</sup>,** (1)The Children's Hospital of Philadelphia Center for Autism Research, Philadelphia, PA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Clinical and Social Sciences in Psychology, University of Rochester, Rochester, NY

Background: Successful communication requires that speakers do more than merely produce and perceive speech; they must also read a partner's social cues and respond by dynamically adjusting their own linguistic contributions. Sensitive and socially-responsive conversational behaviors play a significant role in successful communication, and research suggests that adaptation is associated with improved rapport, empathy, and perceived connection between social partners (Manson et al., 2013). Disruptions in this phenomenon may yield significant consequences and result in social communication difficulties, which are frequently experienced by autistic individuals. Previous research on the current sample found significant diagnostic group differences (ASC vs NT) in the overall number of words (or talkativeness) produced by participants during experimentally manipulated conversations, with the ASC group producing significantly fewer words overall. However, given the substantial within-diagnosis heterogeneity of language in ASC, it is critical to explore individual differences in the ASC group.

**Objectives:** This study utilizes an exploratory data-driven, latent class approach to (1) identify homogeneous trajectories of talkativeness across two conversational contexts (Bored vs. Interested) for autistic participants, and (2) assess the relationship between latent class membership and clinical phenotype (ADOS-2 scores).

**Methods:** Verbally fluent school-aged individuals with ASC (N=48, 28 male, 20 female; Table 1) completed the Contextual Assessment of Social Skills (CASS; Ratto et al., 2011) with two novel conversation partners naïve to diagnosis. The first person acted interested in the conversation (Interested condition; talked more), while the second acted bored (Bored condition; talked less). Language was transcribed and talkativeness was calculated using word count measured via qdap (Rinker, 2018). Participant word count in both conditions was entered into a general latent class mixed model fitted using maximum likelihood. The optimal number of classes was detected using goodness-of-fit statistics (AIC and BIC). Posterior classification probabilities and class membership are reported; class was used to predict ADOS-2 calibrated severity scores (CSS) in a logistic regression.

**Results:** The optimal number of classes in this dataset is 3 (AIC =1112.1, BIC = 1128.94; Table 2). The most talkative class (10.42%) spoke slightly more in the Bored condition than in the Interested condition (Figure). The moderately talkative class (52.08%) also spoke more in the Bored condition than the Interested condition, but spoke less overall than the most talkative class. The least talkative class (37.5%) spoke less in the Bored condition than in the Interested condition. Class membership significantly predicted ADOS-2 Total CSS ( $F=5.17, p<.001$ ) and ADOS-2 SA CSS ( $F=6.96, p=.002$ ) but not ADOS-2 RRB CSS ( $F=.58, p=.56$ ).

**Conclusions:** Subtle features of a conversation can influence whether social communication is successful, and this study highlighted the within-diagnosis heterogeneity of one potential driver of communication challenges in ASC: variable levels of talkativeness. This study utilized an exploratory data-driven approach to identify three latent classes of talkativeness across two conversational contexts that significantly predicted social phenotype, but not repetitive behaviors. Our findings have implications for understanding individual differences in one aspect of social communication (talkativeness) and may be valuable for clinicians interested in improving conversational competence in verbally fluent autistic individuals.

**408.011 (Poster)** Internal State Language Production in Storybook Versus Personal Narratives in TD Children and Children with ASD  
**J. Carmona, C. Boo and L. R. Naigles, Psychological Sciences, University of Connecticut, Storrs, CT**

---

**Background:** Studies have found that the narratives of children with autism spectrum disorder (ASD) are less likely to include terms that refer to emotional states (e.g., “happy”; Tager-Flusberg, 1992) or cognitive states (e.g., “think”; Siller et al., 2014), as compared to their typically developing (TD) peers. These studies have linked this to the social communication challenges routinely experienced by those with ASD (Capps et al., 2000; Rumpf et al., 2012). However, most of these studies have been conducted solely in the context of storybook narratives, which may not be appropriate for adolescents with ASD. Additionally, Losh & Capps (2003) found significant differences in narrative volume and complexity between storybook and personal narratives, suggesting that different prompts may reveal different strengths and challenges.

**Objectives:** 1) To determine if challenges with producing stative language persist in teenagers with ASD, and 2) to assess whether different narrative contexts (i.e., storybook versus personal) affect stative language production.

**Methods:** Participants included 11 teenagers with ASD and 10 TD children. The ASD group had significantly lower age equivalent scores on the CELF-Word Classes subscale than the TD group (Table 1). Storybook narratives were elicited using the *Tuesday* wordless picture book. Personal narratives were elicited with the investigator prompting the participant to narrate specific events (e.g., “Can you tell me about a time you got jabbed by something?” “Can you tell me about a time you felt proud of yourself?”). Participant speech was transcribed, and CLAN algorithms were used to extract number of word tokens. Manual coding was used to determine the total number of stative language tokens, and proportions were calculated out of total number of word tokens.

**Results:** After statistically controlling for participants’ Word Class scores, no significant group differences emerged for any of the stative language measures ( $ps > 0.05$ ). However, a mixed-design ANOVA, with a between-factor of group and within-factor of narrative context, revealed a significant effect of narrative context on stative language tokens for both groups,  $F(3, 36) = 2.764, p = 0.034, \eta^2 = 0.133$ . Post hoc analyses revealed that both groups produced significantly more stative tokens in the personal narrative contexts than the Tuesday storybook narrative context,  $p = 0.021$  (Figure 1).

**Conclusions:** These preliminary findings support the idea that language production varies by context. Overall, children from both groups produced fewer stative language terms in the context of storybook narratives than personal narratives. For example, a child with ASD produced two stative tokens (“guess” & “want”) in the storybook narrative context, but produced four stative tokens (“guess”, “know”, “remember”, & “think”) in one of their personal narratives. Similarly, a TD child matched on language produced only one stative token in their storybook narrative but produced five stative tokens in one of their personal narratives. In sum, tapping into personal experiences, especially those with emotional associations, elicited more stative language from both groups. Thus, when assessing stative language production, researchers should consider the ability of the narrative prompt to elicit these terms.

**408.012 (Poster)** Investigating Differences in Pronoun Comprehension and Language Abilities in Autistic and Typically-Developing Adults  
**O. Abubakare<sup>1</sup> and J. Snedeker<sup>2</sup>, (1)Psychological and Brain Sciences, Indiana University - Bloomington, Bloomington, IN, (2)Psychology, Harvard University, Cambridge, MA**

---

**Background:** Personal pronouns, such as *her*, *she*, and *his*, stitch together discourse by linking referents within and across sentences. Pronouns allow us to refer to prior content in a more efficient manner and thus are critical in understanding and continuing conversations. Previous research has shown that over development, individuals rely on two strategies to comprehend and keep track of pronouns within discourse: 1) the subject bias (i.e., the bias to interpret the pronoun as referring to the subject of the previous sentence) and 2) the repeated mention bias (i.e., the bias to interpret a pronoun as referring to the person mentioned most frequently in the prior discourse) (Hartshorne, Nappa, & Snedeker, 2015). Autistic individuals are a population that is known to have some social communication challenges. Prior work has shown that people with autism use fewer pronouns than controls (Colle et. al., 2008; Arnold, Bennetto, & Diehl, 2009). However, little is known about the possible difficulties these individuals may have in interpreting pronouns.

**Objectives:** This research is motivated by two questions: 1) Do autistic adults, with average language abilities, make use of these two pronoun comprehension strategies to the same degree as typical adults? 2) Is variation in use of these strategies linked to overall language ability?

**Methods:** Participants were adults (18-45) with native English backgrounds. The ASD (Autism Spectrum Disorder) participants were recruited from the SPARK database and self-identified as having average to above average language abilities. The TD (Typically Developing) participants were recruited from Amazon Mechanical Turk. In the subject bias task and the repeated mention task, participants read short passages containing a potentially ambiguous pronoun that could be resolved using the relevant bias (i.e., *Justin went to history class with Ethan. He brought a notepad*) and were asked to identify who the pronoun referred to (i.e., *Who brought a notepad? Justin, Ethan, or Someone else?*). In addition, we collected a vocabulary measure, the Vocabulary Size Test (VST) and the Autism Quotient (AQ).

**Results:** We calculated the percentage of bias responses in each condition. Both the ASD and TD groups showed a strong subject bias (both  $p$ 's < .05, see Figure 1), with no reliable difference between them ( $p = .4237$ ). Similarly, both groups showed a strong repeated mention bias (both  $p$ 's < .05) with no significant difference between them ( $p = .12852$ ). VST confirmed average language abilities in both groups.

**Conclusions:** Autistic individuals with strong language ability demonstrated the same pronoun interpretation biases as neurotypical adults. We plan to engage in further analysis of this data, using a theory of mind task, to ascertain whether performance on pronoun comprehension and theory of mind measures show any correlation since both measures share referential properties.

**408.013 (Poster)** Investigating the Relationship between Early Joint Attention and Later Usage of Verb Subcategories in Children with Autism Spectrum Disorder

**K. J. LeGrand<sup>1</sup>, J. Parish-Morris<sup>2</sup> and L. R. Naigles<sup>3</sup>, (1)Communication Sciences and Disorders, Emerson College, Boston, MA, (2)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (3)Psychological Sciences, University of Connecticut, Storrs, CT**

**Background:** Children with autism spectrum disorders (ASD) demonstrate deficits in joint attention (JA; Mundy et al., 1990), specifically engaging in less initiation of JA (IJA) than their neurotypical peers (Mundy & Newell, 2007). Variation in IJA predicts variation in later language skills, such as production of verb tokens/types (Abdelaziz et al., 2018). Moreover, early overall verb diversity predicts later language outcomes (LeGrand et al., 2021), and children with ASD particularly struggle with production of internal state verbs (e.g., *feel*, *learn*; Tager-Flusberg, 1992). This project explores the degree to which variation in early IJA relates to later verb use in three semantic categories: action verbs (e.g., *eat*, *run*), internal state verbs, and general all-purpose verbs (GAP; e.g., *have*, *make*).

**Objectives:** To investigate whether production of action, internal state, and GAP verb tokens/types varies based on the presence or amount of early IJA in children with ASD.

**Methods:** 31 children with ASD participated in a longitudinal project (Naigles & Fein, 2017). Across six visits between ages two and four, language samples were collected during parent-child play. IJA was coded at Visits 1-3 (Time 1 [T1],  $M_{age} = 36.96$  months), and verbs produced during Visits 4-6 (Time 2 [T2],  $M_{age} = 49.33$  months) were coded based on semantic category.

**Results:**

Children who engaged in IJA (IJA+) at T1 produced significantly more verb tokens/types in each semantic category (action, internal state, and GAP) at T2 than children who did not engage in IJA (IJA-) at T1 ( $ps < 0.001$ ). As a proportion of the total number of verbs, the IJA+ group produced a significantly higher proportion of action tokens/types and internal state tokens/types at T1 than the IJA- group ( $ps < 0.03$ ). Conversely, the IJA+ group produced a *lower* proportion of GAP tokens/types than the IJA- group, though this difference was not significant ( $ps 0.339-0.640$ ).

Variability in the *amount* of T1 IJA (i.e., IJA count and duration) was positively correlated with T2 verb tokens/types in each semantic category ( $ps < 0.001$ ). Moreover, T1 IJA count and duration were significantly positively correlated with T2 *proportion* of action tokens/types ( $ps < 0.05$ ) and internal state tokens/types ( $ps < 0.004$ ). T1 IJA count and duration were negatively (but not significantly) correlated with T2 *proportion* of GAP tokens/types ( $ps 0.134-0.812$ ).

**Conclusions:** For young children with ASD, the presence and amount of early IJA both relate to later verb quantity and diversity in all semantic categories (action, internal state, and GAP). However, the presence and amount of early IJA relate differentially to the later *proportional* breakdown of verbs that toddlers use: children whose action and internal state verb uses encompassed high proportions of total verb use engaged in more IJA 1-2 years earlier, whereas those whose use of GAP verbs was proportionately high tended to engage in less IJA earlier. Figures 1 and 2 also highlight the variability of verb use within both IJA groups. Overall, these findings have implications for the focus of early JA and language interventions,

including parent talk during episodes of IJA.

**408.014 (Poster)** Let's Talk about Trains: Personalized Stories about Special Interests Increase Language Network Activation in Children with and without ASD

**A. M. D'Mello<sup>1</sup>, H. A. Olson<sup>1</sup>, K. T. Johnson<sup>2,3</sup> and J. D. E. Gabrieli<sup>1</sup>,** (1)*Brain and Cognitive Sciences, Massachusetts Institute of Technology, Cambridge, MA*, (2)*Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital/Harvard Medical School, Boston, MA*, (3)*MIT, Cambridge, MA*

---

(\*First 3 authors are co-first authors)

**Background:** Multiple neuroimaging studies of language in individuals with autism spectrum disorder (ASD) have shown atypical activation, organization, and connectivity within the language network (e.g., Lindell and Hudry 2013; Eyler et al. 2012; Kleinhaus et al. 2008; Herringshaw et al. 2016). However, these studies have relied on standardized task designs and non-motivating language stimuli. Importantly, individuals vary greatly in what they find intrinsically motivating or rewarding, and individuals with autism often have exaggerated specificity in what they find motivating and rewarding (i.e., special interests - highly specific, interests or passions that are intense, focused, and present in up to 88% of children with ASD; Klin et al. 2007). Therefore, using special interests as stimuli in neuroimaging experiments in ASD may provide a unique opportunity to achieve high levels of motivation and affect brain activation. Past studies using personally-relevant stimuli, such as familiar faces, have revealed greater brain activation in relevant brain regions than canonical neuroimaging designs (e.g., Pierce and Redcay 2008).

**Objectives:** Despite the prevalence of special interests in ASD and their ability to modulate behavior, there is no evidence as to whether or how special interests modulate activity in the brain's language network. Here, we create a personalized neuroimaging experiment, using individualized stimuli based on each child's specific special interest, to assess language network activation in children with and without ASD.

**Methods:** We measured language network activation with functional magnetic resonance imaging (fMRI) in n=16 neurotypical (NT) and n=8 ASD children ages 7-12 years. For each child, we assessed the intensity, duration, and scope of their special interest using questionnaires, semi-structured interviews, and links to video clips of their special interest. We then wrote and recorded unique, short stories related to the precise special interest for every child. Next, we collected fMRI data while children listened to (1) personalized special interest stories, (2) "neutral," non-personalized stories about nature, and (3) backward speech as a low-level auditory control (see Figure 1). Finally, we identified brain regions that showed increased activation for special interests versus neutral stories (special interest > neutral stories) using a whole-brain approach.

**Results:** Across both children with and without ASD, activation in the language network was higher for personalized special interest stories than neutral stories (t-value > 3.1; see Figure 2). Importantly, these activation patterns were robust at the level of a single child (t-value > 3.1 at single subject level), and within each group (ASD and NT separately).

**Conclusions:** Our results suggest that neuroimaging studies of language that rely on stimuli of low personal interest may underestimate the language capacity of children with and without ASD. Approaches that take advantage of heterogeneity and highly motivating material (i.e., special interests) may provide a more accurate understanding of both strengths and challenges in language processing in ASD.

**408.015 (Poster)** Longitudinal Perspectives on Language Impairment in Minority Autistic Young Adults

**T. Girolamo<sup>1</sup> and M. L. Rice<sup>2</sup>,** (1)*Cognitive Neuroscience of Communication, University of Connecticut, Storrs, CT*, (2)*Child Language Doctoral Program, University of Kansas, Lawrence, KS*

---

**Background:** Little is known about language development in racial/ethnic minorities (hereafter, minority) with language impairment (LI) despite evidence of selection bias in research against autistic individuals with multiply marginalized identities (Durkin et al., 2015; Russell et al., 2019). Further, there is a need for longitudinal knowledge and replication of language development in older autistic individuals (Shattuck et al., 2018). To address these gaps, this study investigated the diagnostic stability of language impairment in minority autistic adolescents and young adults in a longitudinal design over three years.

**Objectives:** Research questions were: 1) Do participants change over time in their performance levels on a measure of overall language and a measure of morphosyntactic abilities? 2) Which language domains relevant to identifying LI (nonword repetition, receptive and expressive overall language, receptive and expressive vocabulary, morphosyntax) show interindividual variation and categorize individuals as having LI? 3) Do abilities in morphosyntactic marking and grammaticality judgments show more within-person variability relative to other language domains?

**Methods:** This study received institutional board approval. Thirteen minority autistic adolescents and young adults completed age-referenced assessments once per year for three years. Two timepoints took place in-person, and the third timepoint took place online. All timepoints included the Clinical Evaluation of Language Fundamentals (CELF) and the Test for Early Grammatical Impairment (TEGI). The third timepoint also included the Expressive Vocabulary Test, Peabody Picture Vocabulary Test, Syllable Repetition Task, Raven's Progressive Matrices, and the Social Responsiveness Scale. Data were analyzed with respect to age-based norms to determine the nature of abilities and how abilities in each domain changed over development. LI was defined as  $-1.25$  SD on 2 or more measures, following an epidemiological study of language impairment (Tomblin et al., 1996).

**Results:** CELF and TEGI scores did not change significantly over time (RQ1); thus, we report Time 3 scores only. CELF scores suggested broad and persistent LI across participants, who all qualified for LI (i.e., qualified on 2 or more measures; RQ2). Other outcomes were more variable; some participants did not qualify for LI on the SRT, PPVT, EVT, or TEGI; see Figure 1. Abilities in morphosyntactic marking and grammaticality judgments differentiated participants (RQ3; see Figure 2). Error analysis revealed that unlike the “TEGI-No LI” group, who showed near-100% accuracy on tense-marking probes (consistent with the adult grammar), the accuracy of the “TEGI-LI” group was <50%. Common error types on the third-person singular and past-tense probes were production of nonfinite forms (18.6% and 17.4%), present progressive *-ing* (14.7% and 10.6%), and “done” on the past-tense probe (13.7%). Common error types on the Be/Do probe were double-marking (10.2%), agreement error (9.8%), and wrong subject (e.g., second-person “you”; 14%). Omission errors were low (5.1%). NVIQ and demographic variables did not associate with language outcomes.

**Conclusions:** Even though the diagnostic stability of LI may be persistent across adolescence and young adulthood, LI may be inconsistent across dimensions of speech and language. Autistic individuals should continue to get comprehensive language assessment into adolescence to inform supports.

#### **408.016** (Poster) Pronominal Ambiguity in ASD Suggest Struggles with Social (and not linguistic) Pragmatics

**E. Zane<sup>1</sup>, K. Clark<sup>1</sup>, L. Filbey<sup>1</sup>, R. Myhaver<sup>2</sup>, A. Privett<sup>1</sup> and R. Grossman<sup>3</sup>,** (1)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA, (2)Connecticut College, New London, CT, (3)CSD, Emerson College, Boston, MA

---

Background: Autistic individuals have been shown to use more ambiguous pronouns than neurotypical (NT) peers when telling narratives (Colle et al. 2008; Novogrodsky, 2013; Novogrodsky & Edelson, 2016). Some authors have related these patterns to differences in mentalizing (e.g., Novogrodsky & Edelson, 2016), while others point to challenges with executive functioning (EF) (e.g., Arnold et al., 2009).

Most studies define pronominal ambiguity as times when a pronoun’s antecedent is missing altogether (e.g., “Once upon a time, **she**...”), but some also include pronouns that are ambiguous due to competing antecedents (e.g., “Two girls lived in a castle. **She**...”). For this study, we refer to these two distinct patterns as “never-introduced-referent” and “competing-referents ambiguity,” respectively.

No previous work has directly compared frequencies of never-introduced-referent and competing-referents ambiguity within and between groups, despite the fact that such a comparison could help disentangle the two proposed explanations for increased ambiguity in ASD: Never-introduced-referent ambiguity signals challenges recognizing that the listener must be introduced to the referent before a pronoun can be used (i.e., perspective-taking or mentalizing); whereas competing-referents ambiguity may entail difficulty tracking the presence, recency, and salience of referents in previous discourse (i.e. executive functioning).

Objectives: This is the first study to compare the frequency of never-introduced-referent vs.competing-referents ambiguity in narratives of older children with and without ASD.

Methods: Thirty-three 10-to-17-year-old participants with ASD (n=17) and Neurotypical peers (n=16), statistically on age, standardized language, and IQ scores ( $p>0.1$  for all), watched two short animated videos alone and then described the videos’ events to two listeners who were openly unfamiliar with the videos. Resulting narratives were video-recorded, and all referential terms were coded as clear or ambiguous. Ambiguous terms were classified as: 1) never-introduced-referent (e.g., “Once upon a time, **she/the girl**”); 2) competing-referents (e.g., “Two girls lived in a castle. **She/the girl**...”). We calculated the proportion of each type of ambiguity out of the total referential terms for each participant, and used a 2x2 (Group x Ambiguity-subtype) repeated-measures ANOVA to compare proportions between groups.

Results: No main effects are significant, but the interaction between group and subtype is ( $F(1,31)=6.165, p=0.019$ ), reflecting (confirmed by a Tukey HSD test) a significantly higher proportion of never-introduced ambiguity in the ASD group than the NT group.

Conclusions: Findings show that narratives of children with ASD are not more referentially ambiguous, overall. Instead, their stories contain a relatively higher frequency of never-introduced-referent ambiguity, suggesting that narrators insufficiently take the listener’s lack of knowledge into account.. This pattern of ambiguity suggests that challenges with perspective taking or mentalizing -- and not executive functioning-- underlie ambiguous referencing in ASD. This is in line with recent findings that children with ASD show greater challenges with social pragmatics (listener/context-specific pragmatic rules) than linguistic pragmatics (e.g., Gricean maxims) as compared to NT children and children with developmental language disorder (Andrés-Roqueta & Katsos, 2020).

#### **408.017** (Poster) The Use of Discourse-Marker ‘like’ By Older Children with ASD

**E. Zane<sup>1</sup>, R. Jones<sup>1</sup>, G. R. Timler<sup>2</sup> and R. Grossman<sup>3</sup>,** (1)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA, (2)Miami University, Glendale, OH, (3)CSD, Emerson College, Boston, MA

---

Background: Discourse markers, such as *well*, or *I mean*, or *like*, are important to conversational reciprocity: they fill pauses, aid in word-finding, convey uncertainty, hold conversational turns, and provide information about pause length. There is substantial evidence that individuals with ASD use discourse markers less frequently than neurotypical (NT) peers (e.g., Lake et al., 2011), especially those that are “listener-oriented” (e.g., Gorman et al., 2016). One listener-oriented discourse marker that has not yet been studied in ASD is *like*, which serves important pragmatic functions that are

not encoded by other discourse markers (Underhill, 1988; Fuller, 2003). Specifically, *like* serves four distinct functions, signalling to the listener that the content of upcoming speech is: 1) Important/new; 2) Loose/approximate; 3) Reformulative; or 4) Quotative. Because of the ubiquity of this discourse marker in typical adolescent speech and the multiple important listener-directed functions it serves, understanding how adolescents with ASD employ this discourse marker can advance our knowledge of communicative reciprocity in this population.

**Objectives:** The current study compares the frequency of discourse-marker-*like* use between older children with and without ASD. We also explore patterns of usage, by comparing relative proportions of the four *like* functions.

**Methods:**

Twenty-one older children with ASD and 20 NT peers participated, aged 10-17 years. Groups were not statistically different in age, sex, nonverbal and verbal IQ scores, and standardized language scores ( $p>0.1$ ). Participants engaged in a semi-structured *Double Interview* (Garcia Winner, 2008) with a researcher, wherein the researcher asked participants questions about hobbies, vacations, and school, and then reversed roles, so that participants were responsible for asking questions of researchers. We video-recorded and transcribed all interviews. In each transcript, we categorized the use of discourse-marker *like* as marking subsequent speech as one of the following:

1. important/new: For a hobby I, like, collect hats
2. loose/approximate: I own, like, 500 hats
3. revised/reformulated: I own 500... like, so many hats
4. quotative: When I see a new hat, I'm like, "OMG!"

We used a t-test to compare overall *like* frequencies between groups and a Fisher exact test to compare relative proportions of *like* subtypes between groups.

**Results:** There were no significant differences in *like* frequencies between groups (ASD  $m=16.86$ ; NT  $m=20.15$ ;  $t=0.438$ ,  $p=0.661$ ), nor were there differences in relative proportions of functions ( $p=0.33$ ). See Figure.

**Conclusions:** Research consistently indicates that individuals with ASD use some listener-directed discourse markers significantly less often than their NT counterparts, but the findings from our study suggest that this pattern does not persist to all such markers. This group of older children with ASD use *like* as often as their peers, and they use it to signify similar information about upcoming speech to their listener. We interpret findings as showing that older children with ASD are adept at using *like* to signal complex and nuanced pragmatic information; we argue this represents a pragmatic strength in ASD that has henceforth gone unnoticed.

#### **408.018 (Poster)** Sex Differences in Social Communication between Males and Females with Autism

**E. Dhawan<sup>1</sup>, J. P. Hegarty<sup>1</sup>, M. Uljarevic<sup>2</sup>, R. Libove<sup>1</sup> and A. Y. Hardan<sup>1</sup>, (1)Psychiatry & Behavioral Sciences, Stanford University, Stanford, CA, (2)School of Psychological Sciences, University of Melbourne, Melbourne, VIC, Australia**

**Background:** There is a male bias in autism prevalence, with a ratio of approximately 4:1 diagnosed males to females. Existing research regarding sex differences suggests that core social communication challenges may differ between males and females. Social processing domains defined by the National Institute of Mental Health (NIMH)'s Research Domain Criteria include attachment and affiliation, or the desire to engage in positive social interactions, and social communication, or the ability to communicate information through facial and non-facial expressions.

**Objectives:** The primary objective of this investigation was to use a newly developed measure of social processing subdomains to examine sex differences in social communication in a large population sample of children with and without autism. These subdomains – facial communication production, non-facial communication production, and attachment and affiliation – can address existing limitations regarding which aspects of social communication are different between males and females with autism.

**Methods:** The Social Communication Questionnaire-Lifetime (SCQ) was collected from 42,315 individuals with autism and 18,751 control siblings without autism who participated in the Simons Powering Autism Research (SPARK) study, a nationwide research project collecting medical and genetic information from families affected by autism. Facial communication production, attachment and affiliation, and non-facial communication production were measured using our novel method that combines items from the SCQ to calculate new subdomains (Uljarevic et al., 2020), for which higher scores reflect more challenges in each domain. Non-parametric Mann-Whitney tests were performed to compare the subscores of males and females in each group. Z-scores are reported from the sum of ranks.

**Results:** We found that males and females with autism only differed in their levels of attachment and affiliation ( $z = -11.05$ ,  $p < .001$ ). The 33,050 males with autism exhibited more difficulty with attachment and affiliation compared to 9,265 females with autism (Figure 1). In the non-autism sibling group, there were differences between males and females in attachment and affiliation ( $z = -12.15$ ,  $p < .001$ ), and facial ( $z = -5.11$ ,  $p < .001$ ), and non-facial communication production ( $z = -7.04$ ,  $p < .001$ ), such that the 9,157 males exhibited more difficulties in each of these domains compared to 9,594 females (Figure 2).

**Conclusions:** Our results indicate that sex differences in social communication were only found for attachment and affiliation in children with autism whereas males and females exhibited similar challenges in facial and non-facial communication. However, female siblings without autism exhibited more general differences in social communication compared to male siblings without autism, with sex differences in all domains of social

communication that were assessed. These findings suggest that there may be fewer sex differences in social communication in children with autism, consistent with previous research. Our novel subdomains also indicated that attachment and affiliation may differ in females with autism compared to males, which suggests that males may show greater social challenges in specific subdomains rather than in all subdomains of social communication. Exploring sex differences in additional areas of interest will provide additional insights regarding important differences between males and females with autism.

**408.019 (Poster)** The Effect of Word-Learning Biases on Early Vocabulary Acquisition in Children with Autism Spectrum Disorder

**C. Bourgeois<sup>1</sup>, E. Haebig<sup>1</sup>, S. West<sup>2</sup> and C. Cox<sup>2</sup>, (1)Communication Sciences and Disorders, Louisiana State University, Baton Rouge, LA, (2)Louisiana State University, Baton Rouge, LA**

---

**Background:** Vocabulary composition and word-learning biases are closely interrelated in typical development<sup>1</sup>. Learning new words involves attending to certain properties to facilitate word learning<sup>2</sup>. Such word-learning biases are influenced by perceptually and conceptually salient words that are highly imageable, concrete, and iconic. Imageability quantifies the perceptual salience of a word by rating how easily it evokes a mental image<sup>3</sup>. Iconicity refers to the perceptual similarity between a symbol and its referent<sup>4</sup>. Concrete words refer to easily perceptible items<sup>5</sup>. Children with ASD often have delayed language acquisition. Although previous studies have documented that children with ASD use many of the same word-learning strategies as typically developing children, differences in language processing have been reported<sup>6</sup>. Individuals with ASD have difficulties comprehending words with several, vague conceptual units and have an abnormally increased reliance on perceptually-based processing for words<sup>7-9</sup>.

**Objectives:** The current study aims to examine the relationship between early vocabulary composition in children with ASD and lexical features such as imageability, iconicity, and concreteness.

**Methods:** Secondary data analyses were conducted using data obtained from the NIH-supported National Database for Autism Research (NDAR). The productive vocabularies of 264 children with ASD ( $M = 53.06$  months) were measured using the MacArthur-Bates Communicative Development Inventory (MB-CDI; Fenson et al., 2007). Vocabularies ranged from 5 to 680 words, with an average of 446.1 words produced. We gathered concreteness scores for 625 words (Brysbaert et al., 2014), iconicity scores for 578 words (Perry et al., 2015), and imageability scores for 126 words (Masterson & Druks, 1998). Polynomial regression analyses were conducted to examine the association between each child's total vocabulary size and average word feature score (concreteness, iconicity, and imageability). The dependent variable was the average word feature score. Independent variables included linear, quadratic, and cubic growth across vocabulary size. Total vocabulary scores were taken from the number of words that overlapped between the MB-CDI and the respective word-feature databases.

**Results:** Preliminary results indicate that word features are associated with vocabulary size. Although results varied slightly across the word features, the earliest words learned, on average, are highly imageable, iconic, and concrete. The average imageability of words produced displayed a negative linear change as vocabulary size increased. In contrast, nonlinear change was observed for iconicity and concreteness. See Figure 1 and Table 1 for exact results.

**Conclusions:** The results for imageability, iconicity, and concreteness broadly align with the pattern observed in typically developing (TD) toddlers reported in the literature. Children with ASD initially learn words that are highly imageable and iconic. Although this is generally true for concreteness, the very first words are variable. Then, average concreteness increases as children typically experience a burst in vocabulary growth (10-100 words) and as vocabulary size reaches 200 words, concreteness declines. This work contributes novel insights into early word learning patterns in children with ASD and demonstrates an overlap with TD toddlers in word-learning strategies. Furthermore, we report unique information about the nonlinear growth patterns associated with each word feature. Future work will make direct comparisons to TD toddlers.

**408.020 (Poster)** Recognition of Gradable Adjectives in Children with ASD

**D. R. M. Murphy<sup>1</sup>, L. Tecoulesco<sup>1</sup>, J. Carmona<sup>1</sup>, P. de Villiers<sup>2</sup> and L. R. Naigles<sup>1</sup>, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)Smith College, Northampton, MA**

---

**Background:**

Concepts such as height and length, and intensity of emotion, show an ordered, scalable relation to the objects they describe. These are gradable adjectives (GAs) and include two types: Relative, which change based on the context (e.g., which sticks are *short* depends on the lengths of the other sticks in the set) and Absolute, which do not (e.g., which umbrellas are *spotted* does not vary by the 'spotted-ness' of the other umbrellas in the set)<sup>1</sup>. Typically-developing (TD) children as young as four show sensitivity to the relative/absolute distinction with gradable adjectives, including emotions<sup>1,2</sup>. Because children with ASD, despite intact syntactic and vocabulary skills, often show differences in semantic and pragmatic processes in relation to the mental states of others<sup>3</sup>, they may show challenges in processing gradable adjectives, especially those related to emotion.

**Objectives:**

To examine whether children with ASD and TD children differentially process gradable adjectives (GAs) across contexts.

**Methods:**

Participants were thirty-three individuals (ASD:  $n = 15$ , TD:  $n = 18$ ) ranging in age from 6-20 years old, all part of a longitudinal study on language acquisition and originally matched on language ability<sup>4</sup>. Testing occurred at two time points separated by four years.

Processing of GAs was tested via a sorting task. Participants sorted 9 sets of pictures or objects on the basis of an emotion (happy, sad, angry; see Figure 1) or a physical property (gradable-long; absolute-spotted and striped), selecting "all the sad faces", "all the striped umbrellas", or "all the long pencils". Picture sets were presented twice: a baseline was established using 9 pictures in each set; for the 2<sup>nd</sup> presentation, four more pictures of the most extreme dimension of interest were added. Pictures were coded 1-13 in order of intensity. Of the pictures selected, the lowest number was recorded as the cutoff.

#### Results:

For absolute adjectives, no change with different sized sets at either Time1 or Time2 was seen for either group. For relative adjectives, children were sensitive to the relative adjective *long*, in that with the addition of more pencils the cutoff for "long" shifted upward. The upward shift was present in the ASD group ( $T1 = +.7$ ;  $T2 = +.6$ ) but statistically significant at both time points only for the TD group ( $T1 = +.9$ ;  $t2 = +1.1$ ;  $ps < .05$ ). For emotion GAs, both groups at both time points sorted such that cutoffs shifted upwards with the addition of more extreme expressions. The shift was only statistically significant for the ASD group at Time2 ( $= .7$ ;  $p = .017$ ). The groups did not differ in performance from Time1 to Time2 except that the ASD group showed a significant increase from baseline and test from Time 1 to Time 2 for the relative adjective "long" (Time1a-2a  $+1.8$ ;  $t = -2.3$ ;  $p = .038$ ; Time1b-2b  $1.7$ ;  $t = -2.6$ ;  $p = .019$ ).

#### Conclusions:

School-age and adolescent children with ASD performed similarly to their TD peers in the processing of GAs, including both absolute and relative adjectives with both physical and emotional dimensions. Interestingly, at the second time point, the ASD group were more impacted by the extremes with the emotion stimuli, indicating that age—or possibly explicit interventions—may have enhanced their sensitivity to social stimuli.

#### 408.021 (Poster) Vocalization and Word Usage from Minimally Verbal Individuals

**K. T. Johnson<sup>1,2</sup>, J. Narain<sup>3,4</sup>, A. M. O'Brien<sup>5,6</sup>, R. W. Picard<sup>3</sup> and T. Quatieri<sup>7</sup>**, (1)Boston Children's Hospital, Cambridge, MA, (2)Rosamund Stone Zander Translational Neuroscience Center, Boston Children's Hospital/Harvard Medical School, Boston, MA, (3)MIT, Cambridge, MA, (4)MIT Media Lab, Cambridge, MA, (5)Harvard University, Cambridge, MA, (6)McGovern Institute, Massachusetts Institute of Technology, Cambridge, MA, (7)MIT Lincoln Laboratory, Lexington, MA

**Background:** Minimally verbal (MV) individuals have been inconsistently defined, making it difficult to obtain reliable measures within and across studies (Koegel et al. 2020; Bal et al. 2016). In addition, particularly little is known about individuals who have zero to few spoken words or word approximations (Tager-Flusberg et al. 2009). These individuals use a variety of means of expression, including gestures, hand leading, sign language, augmentative and assistive communication (AAC) devices, and non-speech vocalizations. Standardized assessments often fail to capture the diversity and nuances of minimally verbal communication (Tager-Flusberg and Kasari 2013). Both quantitative and qualitative methods are required to better understand the language and communication development of this underserved population.

**Objectives:** This research aims to examine in-depth communication profiles from a spectrum of individuals identifying as minimally verbal and to ascertain viable metrics of communication for those with few spoken words.

**Methods:** Family members of individuals identifying as minimally verbal filled out a communication profile questionnaire ( $n = 22$ ). In one section, participants were asked to indicate whether the MV individual used a word/word approximation, a non-speech vocalization, or no sound for various communicative and affective states such as delight, anger, pain, and requests for various items and activities. Detailed communication profiles were also collected, including parent-reported lists of spoken words/word approximations, all communication modalities (gestures, hand leading, vocalizations, sign language, AAC, etc.), and AAC programs used. Demographic information including age, gender, diagnoses, sibling and parent ages, languages spoken in the home, race, therapy service history, parent education, and household income, was also acquired.

**Results:** Figure 1 presents a matrix of vocalization and word usage from survey respondents. Individuals produced 0-500+ words, per parent report, highlighting the breadth of the term "minimally verbal." Individuals with greater than 20 parent-reported spoken words were the first to produce more words than vocalizations, suggesting a possible sub-category of minimally verbal individuals for those producing 0-20 spoken words/approximations. Across all participants, specific communicative expressions like requesting a person, requesting help, or a greeting were likely to emerge as words earlier than affective expressions. Hunger and thirst were also unlikely to be expressed as vocalizations until produced as a word. "Yes" seemed to emerge as a spoken word more commonly than "no," possibly indicating that it may be easier to more clearly reject something with a vocalization than it is to affirm it. This would suggest that the motivation to be understood is a driving factor in the development of words in early MV individuals; however, more precise questioning and a larger sample across contexts and language levels is necessary to further support this observation.

**Conclusions:** Our results suggest a natural delineation for minimally verbal individuals, with a special sub-category for those producing 0-20 spoken words or word approximations. We refer to this 0-20 word population as *mv\** and suggest that looking across this population of individuals, regardless of diagnosis, could provide greater insight into the origin of vocal expression within and across autism and other neurodevelopmental disorders.

#### **408.022 (Poster) Vowel Distinctiveness and Expressive Language in Children with ASD**

**K. V. Chenausky<sup>1,2,3</sup>, L. Butler<sup>4</sup>, J. Palana<sup>5</sup>, S. Shen<sup>5</sup>, J. R. Green<sup>6</sup> and H. Tager-Flusberg<sup>7</sup>,** (1)Communication Sciences and Disorders, MGH Institute of Health Professions, Boston, MA, (2)Department of Neurology, Harvard Medical School, Boston, MA, (3)Psychological and Brain Sciences, Boston University, Boston, MA, (4)Psychological & Brain Sciences, Boston University, Boston, MA, (5)Department of Speech, Language, and Hearing Sciences, Boston University, Boston, MA, (6)Speech and Feeding Disorders Lab, MGH Institute of Health Professions, Boston, MA, (7)Department of Psychological and Brain Sciences, Boston University, Boston, MA

#### **Background:**

A significant portion of children with autism (ASD) experience comorbid motor speech impairment – this is true for up to ¼ of minimally and low-verbal (MLV) children with ASD, for example. Speech production ability has been shown to predict concurrent expressive language (EL) ability in MLV ASD. Because vowels emerge earlier than consonants, identifying vowel development delays may be a particularly useful predictor of EL impairment.

#### **Objectives:**

We investigated the relationship of an acoustic measure of speech production, Vowel Distinctiveness, to a standardized measure of EL. Vowel Distinctiveness is normalized for different vocal tract sizes and can be used with children of any age. EL was indexed by the EL v-score from the Vineland, a parent questionnaire measure that is useful for children with a range of verbal abilities.

#### **Methods:**

41 participants with ASD were prompted to repeat the syllables /bi/, /ba/, /bu/, /bæ/, and /bʌ/ four times each. Fundamental frequency (F0) and the first three vowel formants (F1-F3) were measured in the middle third of each vowel. Mean values for F0 and F1-F3 for each vowel target were calculated. The acoustic distance from each of the first four vowels to /ʌ/ was then averaged to produce a Vowel Distinctiveness score for each child. Pearson's correlations compared Vowel Distinctiveness to five descriptive variables: Chronological age, Vineland Adaptive SS (a proxy for IQ that correlates at  $r = 0.86$  with Leiter NVIQ standard score), Vineland Receptive Language (RL) v-score, Vineland EL v-score, and Total Score from the Social Communication Questionnaire (SCQ; a measure of ASD severity). Vowel Distinctiveness was then regressed on EL v-score. For reference, v-scores have a mean of 15 and SD of 3.

#### **Results:**

We report initial results from 13 children (6 F) aged 5;0-7;11 (mean 6;11, SD 0.10); data analysis for the remaining 28 is ongoing. Mean EL v-score for the initial cohort was 5.9 (SD 5.5); mean RL v-score was 6.7 (SD 3.1). Vowel Distinctiveness (mean 0.29, SD 0.08) was lower than for typically-developing 7-year-olds (0.34) and was significantly correlated with EL v-score ( $r = 0.715$ ,  $p = 0.006$ ) but not with age, Adaptive Score, RL v-score, or SCQ Total Score. Vowel Distinctiveness significantly predicted concurrent EL v-score ( $F(1,11) = 11.529$ ,  $p = 0.006$ ) and accounted for 46.7% of the variance in EL v-score (adjusted  $R^2$ ). Figure 1 shows mean Vowel Distinctiveness vs. EL v-score.

#### **Conclusions:**

Mean RL v-scores, EL v-scores, and Vowel Distinctiveness were lower for our initial cohort of 13 than for typical children; however, there was significant heterogeneity in the group. This is a common finding in ASD that warrants further investigation, especially since Figure 1 and previous work suggest the presence of distinct subgroups with regard to Vowel Distinctiveness. Vowel Distinctiveness was significantly correlated with and accounted for almost half of the variance in concurrent EL v-score, consistent with previous work showing that motor speech ability contributes to expressive language ability in at least some children with ASD.

### **VIRTUAL POSTER SESSION — COMMUNICATION AND LANGUAGE**

#### **508 - Communication and Language --- (V)**

#### **508.001 (Virtual Poster) A Game of Telephone: Longitudinal, Telephone-Based Natural Language Sampling Among Neurodiverse, School-Aged Children**

**K. G. Tena<sup>1</sup>, A. Knox<sup>1</sup>, M. R. Pelella<sup>1</sup>, M. Leuzzi<sup>1</sup>, A. S. Russell<sup>1</sup>, M. L. Cola<sup>2</sup>, S. Cho<sup>3</sup>, M. Liberman<sup>4</sup>, R. Fusaroli<sup>5</sup>, C. Cieri<sup>6</sup>, A. Hulick<sup>7</sup>, J. Fiumara<sup>8</sup>, K. Walker<sup>8</sup>, A. Nenkova<sup>6</sup>, J. Uzokwe<sup>7</sup>, C. H. Chatham<sup>8</sup>, J. S. Miller<sup>8</sup>, J. Pandey<sup>8</sup>, R. T. Schultz<sup>8</sup> and J. Parish-Morris<sup>1</sup>,** (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)The Children's Hospital of Philadelphia Center for Autism Research, Philadelphia, PA, (3)University of Pennsylvania, Philadelphia, PA, (4)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (5)Aarhus University, Aarhus, Denmark, (6)Computer and Information Science, University of Pennsylvania, Philadelphia, PA, (7)Children Hospital of Philadelphia, Philadelphia, PA, (8)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, New York, CA

Background: School-based support is a primary service modality for autistic youth (Rosen et al., 2019). Since the onset of the COVID-19 pandemic, video conferencing (VC) has been the preferred modality for interventions (e.g. speech therapy and social groups) that would otherwise occur in

schools (Ellison et al., 2021). Researchers have similarly made progress on the development of protocols for VC-based autism assessments (Talbot et al., 2021). However, technical issues and lack of familiarity with novel VC platforms have rendered it challenging to deliver on the promise of telehealth (Auchus et al., 2021). Naturalistic language samples (NLS) are critical for assessing language outcomes, but for autistic children, the presence of an unfamiliar adult (i.e., clinician/staff) during both in-person and VC monitoring sessions could adversely impact their behavior and reduce the accuracy of language ability estimates (Barokova & Tager-Flusberg, 2020). Developing a telephony protocol to capture naturalistic language samples from children and parents, in their homes, could shed light on the real-life efficacy of support services and ultimately inform the development of scalable, cost-effective intervention progress monitoring systems.

**Objectives:** Develop and assess the implementation of a telephony protocol for collecting home-based naturalistic language samples (NLS) from autistic and neurotypical school-aged children – with the support of their parents – once per week for seven weeks.

**Methods:** A telephony platform, created by the Linguistic Data Consortium at the University of Pennsylvania, was adapted for this project in collaboration with the Center for Autism Research at the Children's Hospital of Philadelphia. The research team included experts in clinical language sampling, remote data collection, and lexical/acoustic feature extraction from elicited and spontaneous vocalization samples. The final battery consisted of eight different, engaging, and age-appropriate tasks that a parent or legal guardian could independently facilitate (Table).

**Results:** The final developed platform supports single and dual speaker modes and can record 24 phone sessions concurrently. School-aged children with Autism Spectrum Condition (ASC) and neurotypical development (NT) (N= 15; 5 ASC, 10 NT) and a participating parent complete seven, 30-minute-long sessions utilizing the telephony platform (N= 105; 44 single-speaker, 61 dual-speaker; data collection is ongoing). Prior to the first session, study staff engaged with the participating parent over VC to review the standard elicitation protocol utilized across sessions. Sessions completed without platform-related technical issues were considered successful. Single-speaker sessions yielded a 100% success rate, whereas dual-speaker sessions yielded 71% success across all participants (technological issues included muting and spontaneous system disconnections).

**Conclusions:** Telephony carries great potential as a low-cost and scalable platform for monitoring intervention responses from afar, as well as for measuring longitudinal, ecologically valid developmental changes in individual children. The demonstrated ability of parents to facilitate NLS independently and successfully with their child over the telephone marks telephony as a particularly impactful tool for use among school-aged, autistic children receiving telehealth services or participating in remote research studies. In the long term, telephony has particular potential to address service and monitoring gaps for neurodiverse children from minoritized or low-resource communities.

**508.002 (Virtual Poster)** A Preliminary Study on the Emotional Valences of Passive Sentences in Japanese Perceived By People with ASD  
**K. Yorozyua<sup>1</sup>, J. Adachi<sup>2</sup>, M. Saito<sup>3</sup> and R. Yorozyua<sup>4</sup>,** (1)Education, Hokkaido University, Sapporo, Japan, (2)Graduate School of Education, Hokkaido University, Sapporo, Japan, (3)Department of Special Education, Hokkaido University of Education, Sapporo, Sapporo, Japan, (4)Department of English Language Education, Hokkaido University of Education, Sapporo, Sapporo, Japan

---

**Background:** Lartseva, Dijkstra, and Buitelaar (2015) point out that "...individuals with ASD are able to correctly identify words, sentences or stories as emotionally positive or negative". However, it is not yet clear whether ASD individuals can accurately classify them into positive or negative in a Japanese cultural context. Direct passive sentences in Japanese almost always convey either a positive or negative meaning, with the exception of passive sentences with inanimate subjects which are usually interpreted as having no benefit or damage connotations. In addition, Japanese has the unique indirect passive sentences which require inference as to whether the sentence denote benefits or damages for the speaker. Their interpretation is further complicated since the subject is usually omitted.

**Objectives:** The purpose of this study is to clarify how individuals with ASD experience linguistic difficulties in daily life. This study investigates the difficulties that they experience by comparing them with the control group in their perception of Japanese passive sentences. Also interview data were collected. Due to the paucity of available subjects, this is a preliminary report.

**Methods:** We measured the emotional values of 5 people (17 to 28 years old) diagnosed with ASD without intellectual disabilities on three types of direct passive sentences (16 sentences respectively for damage, benefit, and neutral meanings) with the visual analog scale (VAS). The scale indicates emotional values measured by the distance in millimeters from the center point (neutral) of the straight line to the mark the participants had drawn. We compared their values with the values we had measured on the control group consisting of 106 university students with the same method (Yorozyua et al., 2020).

**Results:**

All the five ASD participants judged an emotional valence for one indirect passive sentence as positive or neutral ("*Taro ni Mado wo akerareta.*", meaning "(I was unhappy because) the window was opened by Taro."). In this sentence, the speaker's unhappy feeling is not explicitly stated. On the other hand, the control group consistently judged the sentence as negative ( $M = -8$ ,  $SD = 13.8$ ).

All the 5 participants with ASD reported that the task was difficult. They said "I could not judge well since the sentences were too short." and "I don't know Taro's feelings because *I am not Taro*". Furthermore, one participant rated all the 16 sentences as neutral, and another one often assigned the completely opposite emotional valences to the control group.

**Conclusions:** This preliminary study suggests that it was difficult for the five ASD participants to judge the emotional valences of Japanese passive sentences. For some sentences, they even showed opposite interpretations to the control group. The study also showed that some ASD subjects were

confused or gave up the task when they tried to interpret short sentences lacking background information. Contrary to the contention by Lartseva, et al. (2015) that ASD individuals are able to correctly judge the emotional values of words, sentences or stories, this study suggests the need to reevaluate the issue from the perspective of the Japanese language.

**508.003 (Virtual Poster)** Contextual Differences in Prosodic Language Profiles in Autism Spectrum Disorder

**M. Waxman<sup>1</sup>**, J. Guilfoyle<sup>2</sup>, E. Landau<sup>2</sup>, S. Crawford<sup>1</sup> and M. Losh<sup>1</sup>, (1)Communication Sciences and Disorders, Northwestern University, Evanston, IL, (2)Feinberg School of Medicine, Department of Psychiatry and Behavioral Sciences, Northwestern University, Evanston, IL

---

**Background:** Prosody (e.g. intonation, rhythm, rate of speech) is importantly used for conveying meaning during conversation. Prosody may be markedly different in autism spectrum disorder (ASD), and this can contribute to broader social communication challenges, making prosody an important focus of study. Prior studies have often relied on perceptual judgements and acoustic measurement of speech to characterize prosody, but have tended to examine prosody within a single context and often in highly structured tasks that may limit the generalization of findings to more naturalistic interactions. Characterization of prosody in both structured and semi-naturalistic tasks is an important step in understanding the exact nature and implications of prosodic differences in ASD.

**Objectives:** This study aimed to examine prosody in ASD across structured and semi-naturalistic contexts and across different linguistic functions to more comprehensively characterize prosodic atypicalities in ASD.

**Methods:** Participants included individuals with ASD (N = 24) and typically developing controls (N = 21). Language samples were recorded using high quality microphones during a structured task designed to test expressive prosody (Profiling Elements of Speech-Prosody in Communication task (PEPS-C; McCann & Peppé, 2003)), and a semi-structured conversation derived from the ADOS-2. (Lord et al., 2012). Questions and statements from the ADOS-2 were manually coded in Praat (Boersma, 2001), and elicited during PEPS-C. Using Praat, intensity and pitch (Fundamental Frequency, F0) were extracted in .01 ms intervals within each force-aligned utterance. Standard deviation (SD) of F0 was calculated as a measure of pitch variability and mean intensity was calculated as a measure of loudness.

**Results:** For questions, a context by group interaction was observed for intensity, such that the ASD group demonstrated significantly greater volume relative to the TD group during the structured task relative to the unstructured ( $F(1,37)=6.71, p<.01$ ). A context effect was observed for SDF0 where all participants demonstrated greater variability in the structured context ( $F(1,38)=32.18, p<.001$ ). For statements, context by group interactions were not observed. For intensity, a group effect emerged such that the ASD group demonstrated greater volume during both contexts relative to the TD group ( $F(1,43)=9.89, p<.01$ ). Context and group effects were observed for SDF0, where all participants demonstrated greater pitch variability in the structured task ( $F(1,43)=10.46, p<.01$ ), and the ASD group demonstrated greater pitch variability relative to controls during both tasks ( $F(1,43)=8.85, p<.01$ ).

**Conclusions:** Across contexts, findings support clinical observations of increased pitch variability and loudness in ASD. Whereas group differences were observed across tasks, they were surprisingly more robust in the structured task. It is possible that individuals with ASD may have over-corrected their speech during PEPS-C in order to produce the correct pitch contour (e.g. question or statement), evoking greater prosodic differences than in more natural interactive speech. Results suggest that the PEPS-C is sensitive in capturing acoustic differences in ASD, however, it may not reflect the true nature of prosody in naturalistic settings. Together, results highlight the importance of evaluating prosody across contexts to inform the prosodic differences in everyday life for individuals with ASD.

**508.004 (Virtual Poster)** Evaluation of Linguistic Abilities and Emerging Literacy Skills of Children with ASD

**N. Sukenik<sup>1</sup>** and S. Oren<sup>2</sup>, (1)School of education, Bar Ilan University, Ramat Gan, Israel, (2)Bar Ilan University, Ramat Gan, Israel

---

**Background:**

Many studies have been conducted regarding the optimal ways in which Typically Developing (TD) children should be exposed to reading. We know that for TD children there is a monumental connection between reading abilities and linguistic abilities and we know that this connection is already found in the earliest stages of reading, hence the stage called 'emerging literacy skills' which includes letter recognition, phonological awareness and awareness to printed materials (Catts et al., 2002; Stothard et al., 1998; Cabell, 2008). Accumulative research is now available showing that many subgroups of children with ASD show different profiles of linguistic deficits (Battaglia, 2013; Sukenik and Friedmann, 2018; Tager-Flusberg and Kjelgaard, 2001). We also know that social skills and social communication have been found as influencing factors affecting reading comprehension (Skibbe et al., 2008). Since both social skills and social communications are part of the core deficits in ASD, children with ASD are at a higher risk for developing reading deficits (Lucas and Norbury, 2015).

**Objectives:**

The aim of the current study is to test the linguistic profiles and the emerging literacy skills of pre-schoolers with ASD and examine the connection between the two abilities.

**Methods:**

Participants included 20 children with ASD aged 4-7 years old and 20 chronological age matched children with typical development. All children with ASD were studying in special education preschools. No known disabilities or delays were reported for the children in the TD group.

Background characteristics included NVIQ (RPM) social skills (SCQ) and adaptive behavior (Vineland). Linguistic skills were assessed using the Katzenberger linguistic assessment battery (Katzenberger, 2016). Emerging literacy skills were assessed using an awareness to print battery build for this study and the 'Shmone msimot' assessment battery (Ministry of education, Israel). Group scores were compared for each task and individual profiles examined the abilities and deficits in each area tested compared to the performance of TD children.

#### Results:

Group scores found a significant correlation between linguistic scores and print awareness scores in both the ASD group and the TD group although as a group, the TD group had higher scores in all variables tested.

Individual profiles showed subgroups of children with ASD: (1) children with very low scores on linguistic tasks hence indicating an overall linguistic deficit and low scores on emerging literacy skills (2) children with age-matched linguistic scores but very low scores on emerging literacy skills (3) children with higher scores than those of age-matched TD children both on linguistic scores and emerging literacy tasks.

#### Conclusions:

For children with typical development, it seems that the connection between linguistic abilities and emerging literacy skills (which will later become reading skills) is very clear. Our results demonstrate the wide variability found in the ASD population and the fact that for some children language does not predict literacy skills. This finding has implications for future intervention strategies and the fact that for some children with ASD emerging literacy skills and especially an interest in print and letters does not come naturally.

#### **508.005** (Virtual Poster) Girls with Autism Speed up More in a Tongue Twister Task

**W. Lai<sup>1</sup>, S. Cho<sup>2</sup>, M. Liberman<sup>1</sup>, A. Knox<sup>3</sup>, A. S. Russell<sup>1</sup>, M. R. Pelella<sup>4</sup>, M. L. Cola<sup>4</sup>, K. G. Tena<sup>3</sup>, J. Pandey<sup>3</sup>, R. T. Schultz<sup>3</sup> and J. Parish-Morris<sup>3</sup>,** (1)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (2)University of Pennsylvania, Philadelphia, PA, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)The Children's Hospital of Philadelphia Center for Autism Research, Philadelphia, PA

---

Background: Autism spectrum disorder (ASD) is diagnosed more frequently in boys than girls, with an estimated male-to-female ratio of 4:1 (Baio et al., 2018). However, some autistic girls may be missed, or misdiagnosed, due to behavioral characteristics that differ qualitatively or quantitatively from autistic boys (Julia Parish-Morris et al., 2017). The current study investigates potential sex differences and diagnostic group differences in autistic speech by comparing speech rates when pronouncing tongue twisters. Previous acoustic-focused studies found that ASD children either articulated more slowly (Fosnot & Jun 1999; Patel et al., 2020) or quickly (e.g., Shriberg et al., 2001) than typically developing (TD) peers. However, due to the predominance of ASD in boys, few studies have evaluated sex differences in the speech rates of autistic children, or compared autistic girls' speech rates to TD girls' speech rates in tongue twister tasks.

Objectives: Investigate speech rate in autistic and TD children, asking (a) whether speech rate is associated with ASD diagnosis and covaries with autism symptom severity, and (b) how speech rate in ASD girls may or may not differ from speech rate in ASD boys, TD boys, and TD girls.

Methods: Sixty-five ASD (n=32; 15 females; mean age=11.7±2.8 years; mean IQ=108±10.2) and TD children (n=33; 20 females; mean age=10.9±2.8 years; mean IQ=109±12.0), matched on age (p=0.68) and IQ (p=0.96), were recorded reading the same two sentences out aloud (*read\_sentence*) and reading the same two tongue twisters as fast as they can (*speeded\_tongue\_twister*). Speech rate was calculated by dividing the total number of syllables in each sentence by its duration in seconds. Then, two aggregate speech rates, one for read sentences and one for tongue twisters, were calculated for each speaker. The mean speech rate difference between tasks (*task\_difference*) was calculated by subtracting the speech rate of *read\_sentence* from *speeded\_tongue\_twister*. T-tests measured diagnostic group differences and sex differences in speech rates (Figure); speech rate was correlated with clinical phenotype using Pearson's correlation (Table).

Results: No significant diagnostic group differences or sex differences in speech rate were found for *read\_sentence* or *speeded\_tongue\_twister*. However, the *task\_difference* of speech rate differed by diagnostic group (p = 0.040), such that autistic children increased their speech rate to a larger extent than TD children in tongue twister pronunciation compared to sentence reading. This difference was driven by autistic females (p=0.015), who exhibited a significantly larger *task\_difference* compared to autistic boys (p=0.044). Negative correlations between the speech rate of *speeded\_tongue\_twister* and three SRS scores were significant for ASD boys (total: p=0.026; communication: p=0.045, RRB: p=0.008), and a negative correlation between *task\_difference* and SRS communication scores emerged in ASD girls (p=0.035). Thus, autistic children with more severe ASD symptoms, including girls, produced slower tongue twisters.

Conclusions: Compared to autistic boys and TD girls, autistic girls sped up their tongue twister pronunciations to a greater extent when instructed. This may be due to elements of behavioral inflexibility, enhanced rule-following, or social motivation which could lead to greater effort in social contexts; future research will examine these possible explanations.

#### **508.006** (Virtual Poster) Measuring Referential Communication Dynamically in Older Children with ASD

**C. Lee<sup>1</sup>, M. Schreuders<sup>1</sup>, E. Zane<sup>1</sup> and R. Grossman<sup>2</sup>,** (1)Communication Sciences and Disorders, James Madison University, Harrisonburg, VA, (2)CSD, Emerson College, Boston, MA

---

#### Background:

Successful referential communication entails efficacy and efficiency (Yule, 1996). Efficacy reflects how well speaker intentions transmit to listeners; efficiency reflects how quickly intentions are transmitted. These features are dynamic: speakers must adjust the quality/quantity of subsequent messages based on whether previous messages were understood.

Research finds individuals with autism spectrum disorder (ASD) are relatively ineffective and/or inefficient at referential communication (Review in Malkin et al., 2018). However, this research typically uses static metrics of efficacy (how accurately messages were relayed) and efficiency (overall word count), rather than dynamic ones (e.g., Does the speaker alter subsequent descriptions when the listener previously misunderstood them?).

Objectives:

To use dynamic measures of efficacy and efficiency to examine how speakers with and without ASD adjust their message to meet listener needs across time.

Methods:

Fifteen older children with (n=8) and without (n=7) ASD were included in this analysis. Groups were not statistically different in age, sex ratios, standardized language, and nonverbal/verbal IQ ( $p>0.1$ ).

Participants interacted with two research assistants (RA1 and RA2). RA1 sat beside the participant. RA2 sat across from them, behind an opaque barrier. A board was positioned before the participant with a doll in its center and four black, ten-sided shapes surrounding the doll. RA1 explained that shapes were configured around RA2 the same way they were the doll. It was the participant's task to use language to guide RA2 to select targeted shapes (displayed individually on a laptop). There were 64 trials. Sessions were video-recorded. Each trial was coded for strategy:

1. Spatial ("...is behind you")
2. Geometric ("...has a triangle on top")
3. Resemblance ("...looks like Pac-Man")
4. Nondiscriminatory ("...is black")

*Efficacy*

We created an "efficacy quotient" (EQ), which assigned a 1 for trials when participants: 1) changed strategies when the previous trial was unsuccessful; 2) maintained strategies when it was successful. Remaining trials earned a 0. We summed 1s and divided this value by 63 (participants had opportunities to switch/maintain strategies from the second trial on). We used *t*-tests to compare EQs between groups.

*Efficiency*

We measured the number of words within trials, where shorter utterances in later trials suggest referential shortening (de Marchena and Eigsti, 2016). We used linear modeling to compare slopes between groups.

Results:

*Efficacy*

There was no significant difference in EQ between groups (ASD=69.2%; NT=61.5%,  $p=0.432$ ).

*Efficiency*

There was a significant effect of trial ( $p<0.0001$ ), reflecting fewer words used in later trials. There was a marginal interaction between trial and group: Individuals with ASD showed a steeper negative slope in word count across time as compared to NT participants ( $p=0.061$ )

Conclusions:

Both groups were equally *effective* at adjusting communication strategies based on previous success. However, participants with ASD were marginally more *efficient*: they were quicker to abbreviate utterances to reflect increased listener understanding. Findings emphasize the importance of examining interactions dynamically; such measures capture the realities of turn-taking and may identify strengths in autism that have heretofore gone unnoticed.

**508.007 (Virtual Poster)** Associations between Language Use and Classroom Engagement in Inclusive Classrooms for Preschoolers with and without ASD

**R. M. Fasano<sup>1</sup>, S. G. Mitsven<sup>1</sup>, S. Custode<sup>1</sup>, D. S. Messinger<sup>2</sup> and L. K. Perry<sup>1</sup>, (1)Psychology, University of Miami, Coral Gables, FL, (2)University of Miami, Coral Gables, FL**

**Background:** Classroom engagement plays a crucial role in preschoolers' development. One possible determinant of classroom engagement is children's vocal interactions with peers and teachers, but it remains unclear if classroom vocal input and output are associated with classroom engagement. Additionally, it remains unknown whether children with autism spectrum disorder (ASD), who often have delayed social communication, have lower classroom engagement than their peers with general developmental delay (DD) or typically developing (TD) peers.

**Objectives:** We used objective measures of vocal interaction, and expert observations of classroom engagement in inclusion classrooms to examine how vocal interactions support preschoolers' classroom engagement, and how this varies across children with and without ASD.

**Methods:** Participants included 72 preschoolers (32 girls,  $M_{age}=48.57$  months) enrolled in eight inclusive classrooms. Twenty-one of the children had ASD, 22 DD, and 29 TD. During monthly observations, children wore lightweight vests equipped with Language ENvironment Analysis (LENA) to measure real-time dyadic vocalizations. They also wore two RFID tags to measure location and orientation and synchronize to LENA vocalization measures to determine instances of vocalization during social contact with peers and teachers (both child output and peer and teacher input).

Researchers observed each child using the Individualized Classroom Assessment Scoring System (inCLASS), which consists of four domains relating to children's social engagement with teachers and peers (e.g. eye contact), task engagement (e.g. staying focused on an assigned task), and negative engagement (e.g. yelling). During each inCLASS assessment, a trained researcher observed one child at a time, scoring the child on each of the four domains. Each child was observed for four 10-minute periods over the course of one day. These scores were averaged across all four periods to create a composite score for each child in each domain.

**Results:** Findings reveal that children with ASD had lower engagement with peers than their TD peers ( $p<.001$ ) and peers with DD ( $p=.035$ ). For the teacher, task, and negative domains, children with ASD had lower engagement than their TD peers ( $ps<.05$ ), but did not differ from peers with DD ( $ps>.05$ ; Table 1). Mixed effects regressions revealed that children's own vocalizations to peers and teachers were significantly positively associated with higher scores in the peer ( $p=.005$ ) and teacher ( $p=.030$ ) domains, respectively. However, peer input was negatively associated with peer domain scores ( $p<.001$ ). Teacher input was not significantly associated with the teacher domain ( $p>.05$ ). Neither children's own vocalizations nor peer/teacher input were significantly associated with the task or negative domains ( $ps>.05$ ; Table 2).

**Conclusions:** Overall, we found that children with ASD have lower classroom engagement than their TD peers, but mostly do not differ from peers with DD, suggesting engagement is affected by general language, social, or cognitive delays rather than ASD specific factors. Vocal interactions in the classroom support children's classroom engagement, but children's own vocalizations to social partners supports engagement more than the input they receive. Thus, although children with ASD tend to have lower engagement, their developing language skills can support positive classroom engagement.

#### **508.008 (Virtual Poster)** Automated Recognition of Nouns and Verbs As a Tool for Assessing Language Ability and Response to Intervention in Children with ASD

**B. Manning<sup>1</sup>, M. Kumar<sup>2</sup>, D. Swain<sup>3</sup>, S. Narayanan<sup>2</sup> and S. H. Kim<sup>4</sup>, (1)Center for Autism and the Developing Brain, Weill Cornell Medicine, White Plains, NY, (2)University of Southern California, Los Angeles, CA, (3)Virginia Polytechnic Institute and State University, Blacksburg, VA, (4)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY**

**Background:** Automated language recognition based on behavioral signal processing and machine learning may be a useful tool for assessing language and measuring response to intervention in children with ASD. Automated methods have the potential to increase objectivity and scalability, which can complement traditional human coding of language production.

**Objectives:** We aimed to: (1) examine the relation between automatized language measures and other standardized measures of language and to (2) examine the utility of automated language measures to gauge intervention response in children with ASD.

**Methods:** Fifty-two children with ASD (30 treatment, 22 active control) participated in larger randomized control trials of Naturalistic Developmental Behavioral Interventions. Using an automated speech processing pipeline, children's use of nouns and verbs were quantified from 12-minute, natural caregiver-child interactions from the Brief Observation of Social Communication Change (BOSCC) at intervention entry and 3 months after (Grzadzinski et al., 2016). We first examined correlations between automated language measures and age, communication domain age equivalents from the Vineland Adaptive Behavior Scales (VABS), and a standardized metric based on the ADOS overall level of language item (Mazurek et al., 2019). Then, we conducted Generalized Linear Mixed Models (GLMM), including time, treatment condition, and time\*treatment condition as fixed effects, to examine whether automated language measures of nouns and verbs improved over the course of intervention and whether improvement differed by the treatment groups; a zero-inflated model was used to assess verb change as more than half of the sample had 0 verbs at intervention-entry.

**Results:** At baseline, the total number of nouns was significantly correlated with age ( $r=.44$ ;  $p=.001$ ), ADOS language level ( $r=-.38$ ;  $p<.01$ ), and VABS Communication ( $r=.44$ ;  $p<.01$ ). Total number of verbs was significantly related to age ( $r=.34$ ;  $p<.05$ ), ADOS language level ( $r=-.32$ ;  $p<.05$ ), and VABS Communication ( $r=.60$ ;  $p<.001$ ). The GLMM predicting total nouns revealed a nonsignificant main effect of timepoint ( $p=.86$ ) but marginally significant interaction (timepoint\*condition), controlling for age and NVIQ ( $p=.08$ ). The model predicting total number of verbs revealed a significant main effect of timepoint ( $p<.05$ ) and interaction between condition and timepoint ( $p<.05$ ), controlling for age and NVIQ, indicating that the number of verbs increased during the 3-month intervention and that this improvement was larger for the treatment group than the control.

Conclusions: Automated language recognition may increase scalability and objectivity of assessment of simple child language features, like number of nouns and verbs produced, for children with ASD. In the future, automatized language measures may complement traditional measures of language ability as one of the markers of intervention response.

**508.009** (Virtual Poster) Children with ASD Describe Pictures Differently Than Matched Non-Autistic Peers

S. Cho<sup>1</sup>, R. Fusaroli<sup>2</sup>, K. G. Tena<sup>3</sup>, A. Knox<sup>4</sup>, M. R. Pelella<sup>5</sup>, J. S. Miller<sup>6</sup>, A. S. Russell<sup>7</sup>, A. Hulick<sup>1</sup>, M. Leuzzi<sup>1</sup>, A. Nenkova<sup>1</sup>, W. Lai<sup>1</sup>, J. Uzokwe<sup>6</sup>, K. Walker<sup>1</sup>, C. Cieri<sup>1</sup>, J. Fiumara<sup>1</sup>, J. Pandey<sup>3</sup>, C. H. Chatham<sup>7</sup>, R. T. Schultz<sup>1</sup>, M. Liberman<sup>5</sup> and J. Parish-Morris<sup>3</sup>, (1)University of Pennsylvania, Philadelphia, PA, (2)Aarhus University, Aarhus, Denmark, (3)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (4)Computer and Information Science, University of Pennsylvania, Philadelphia, PA, (5)Linguistic Data Consortium, University of Pennsylvania, Philadelphia, PA, (6)Children Hospital of Philadelphia, Philadelphia, PA, (7)Neuroscience and Rare Diseases (NRD), Roche Pharma Research and Early Development, Roche Innovation Center, New York, CA

Background: Semi-structured speech samples, such as descriptions of a single picture, may prove valuable for investigating word choice and prosodic variability in autistic children compared to typically developing (TD) controls, and could shed light on phenotypic heterogeneity within the autistic population. In this preliminary report from an on-going longitudinal study (data collection anticipated complete by May 2022), we used a telephony-based platform to collect picture descriptions from children with autism spectrum disorder (ASD) and TD peers, and compared various speech-based features by diagnostic group.

Objectives: Quantitatively characterize lexical and acoustic features of picture descriptions produced by autistic children and TD peers.

Methods: Sixteen participants with ASD (n=5; 2 females; mean age=8±0.7 years; mean IQ=113.9±16.9) or TD (n=11; 6 females; mean age=9.5±2 years; mean IQ=119.8±15.7), matched on age ( $p=0.12$ ), sex ratio ( $p=0.59$ ), and IQ ( $p=0.53$ ), described the same picture (ASD: 146.5±37.3 seconds with 287.2±80 words, TD: 172.2±31.4 seconds with 295.6±74 words; duration:  $p=0.2$ ; word count:  $p=0.84$ ) over a telephone platform. Recordings were automatically segmented using a speech activity detector and transcribed by trained annotators. Words were automatically tagged for part-of-speech (POS) categories using spaCy (Honnibal & Johnson, 2015). POS categories, fillers, partial words, repetitions, and “hm” were counted separately and converted to counts per 100 words. Content words were rated for word frequency (Brysbaert & New, 2009), concreteness (Brysbaert et al., 2014), ambiguity (Hoffman et al., 2013), age of acquisition (Brysbaert et al., 2018), and familiarity (Brysbaert et al., 2018). We extracted pitch, jitter, shimmer, and harmonic-to-noise ratio from participants' picture descriptions per 10 ms using openSMILE (Eyben et al., 2013). Pitch values in hertz were converted to semitones (st) using individuals' 10th percentile values to normalize physiological differences among children. We ran Wilcoxon tests to compare groups and given our small sample size, we reported  $p$ -values that were not yet corrected for multiple comparisons.

Results: Compared with TD children, children with ASD produced content words that are typically acquired later in life ( $p=0.029$ ; Fig.1A). ASD children produced more “hm”s ( $p=0.008$ ; Fig.1B), negations ( $p=0.002$ ; Fig.1C), and words longer than six characters ( $p=0.013$ ; Fig.1D), and fewer partial words ( $p=0.042$ ; Fig.1E) than TD children. ASD children's pitch changed more abruptly ( $p=0.038$ ; Fig.2A) than TD children's pitch, and they produced higher mean and interquartile ranges (IQR) of jitter, a measure of irregularities in pitch, than TD children (mean:  $p=0.027$ , Fig.2B; IQR:  $p=0.038$ , Fig.2C).

Conclusions: Autistic children described the same picture using more difficult words than TD peers, and produced prosody that changed more abruptly. These speech-language characteristics may contribute to the anecdotal impression that some children with ASD communicate like “little professors”, and could represent a quantifiable linguistic subgroup of children that could benefit from supports tailored to their specific profiles.

**508.010** (Virtual Poster) Cloze Probability in Visual and Linguistic Narrative Comprehension in Individuals with Autism

S. Kubinski<sup>1</sup>, N. Cohn<sup>2</sup>, T. Brothers<sup>3</sup> and E. L. Coderre<sup>1</sup>, (1)University of Vermont, Burlington, VT, (2)Tilburg University, Tilburg, Netherlands, (3)Tufts University, Medford, MA

Background: Language comprehension is facilitated by the prediction of upcoming words in a sentence or narrative. To measure the predictability of a word, cloze probabilities are utilized. Words that are “high-cloze” are more predictable given the context of the preceding sentence than words that are “low-cloze”. In studies using event-related potentials (ERPs), the amplitude of the N400 ERP component is reduced for high cloze words compared to low cloze words. Although this effect was first described in the psycholinguistic literature, recent evidence has shown that the N400 is modulated by cloze for both linguistic and visual stimuli: in typically developing (TD) individuals, the N400 amplitude is reduced for high-cloze words/events compared to low-cloze words/events, reflecting a facilitation in semantic processing. Individuals with autism have been shown to have difficulties with predicting incoming information. This may contribute to difficulties with narrative comprehension in these individuals; however, to date there have been no studies exploring this possibility in the context of narrative comprehension in either linguistic or visual domains.

Objectives: The objective of these studies was to compare predictive processes between individuals with autism and TD individuals during narrative comprehension in visual and linguistic modalities.

Methods: In separate studies, participants were shown either linguistic narratives or visual comic strips consisting of three conditions: low cloze words/comic panels, high cloze words/panels, and anomalous words/panels (in which the target word/panel was incongruent with the narrative context). ERP data was analyzed in response to the target word/panel. In the linguistic domain, 21 TD adults (mean age 26, range 18-51; 16 females, 5 males) and 21 adults on the autism spectrum (mean age 33, range 18-64; 8 females, 12 males, 1 trans male) were tested; in the visual domain, 22 TD adults (mean age 26, range 18-50; 17 females, 5 males) and 22 adults on the autism spectrum (mean age 30, range 17-53; 9 females, 11 males, 1 trans male) were tested. Across studies, groups were matched on verbal and non-verbal IQ and on receptive language abilities. Repeated-measure ANOVAs were run on average ERP amplitudes in 100 ms time windows from 200-600 ms.

Results: For TD individuals, low cloze stimuli elicited larger N400 amplitudes than high cloze stimuli from 400-600 ms in the linguistic domain and from 500-600 ms in the visual domain. This replicates prior research demonstrating cloze effects across modalities. However, individuals with autism showed slightly smaller and earlier N400 modulations by cloze: from 200-400 ms in the linguistic domain and 300-400 ms in the visual domain.

Conclusions: We conclude that predictive processing may use different neural mechanisms in individuals with autism compared to TD individuals. In both linguistic and visual modalities, TD individuals showed greater negative amplitudes for low cloze stimuli, meaning that unpredictable stimuli are harder to integrate. However, in both modalities individuals with autism showed reduced and earlier N400 effects, suggesting differences in predictive processing. This may point to a contributing factor underlying narrative comprehension difficulties across modalities in many individuals with autism.

**508.011** (Virtual Poster) Combining Speech and Language Features Improves Automated Autism Detection

A. C. Salem<sup>1</sup>, H. MacFarlane<sup>2</sup>, L. Chen<sup>1</sup>, M. Asgari<sup>1</sup> and E. Fombonne<sup>3</sup>, (1)Oregon Health & Science University, Portland, OR, (2)Oregon Health & Science University (OHSU), Portland, OR, (3)Department of Psychiatry, Oregon Health & Science University, Portland, OR

---

Background: Variability in expressive and receptive language, difficulty with pragmatic language, and prosodic difficulties are all features of Autism Spectrum Disorder (ASD). Quantifying language and voice characteristics is an important step for measuring outcomes for autistic people, yet clinical measurement is cumbersome and costly. Better outcome measures of communication skills are needed. Using Natural Language Processing (NLP) methods and a harmonic model of speech, we analyzed language transcripts and audio to generate automated measures of communication ability.

Objectives: 1. Examine the discriminant validity of automated speech and language measures; 2. combine speech and language features into one model to look for any increase in classification accuracy over the independent models; 3. conduct exploratory analyses of the clinical characteristics and activity metadata for all models.

Methods: 158 participants (88 ASD, 70 non-ASD) ages 7 to 17 were evaluated with the Autism Diagnostic Observation Schedule (ADOS-2), module 3. ADOS tasks were transcribed following modified SALT guidelines. Transcripts and audio of one ADOS task (Friends and Marriage Conversation) were automatically analyzed to generate seven Automated Language Measures (ALMs) and ten prosodic speech measures for each participant. The ALMs (Mean Length of Utterance in Morphemes (MLUM), Number of Different Word Roots (NDWR), um proportion, content maze proportion, unintelligible proportion, c-units per minute (CPM), and repetition proportion) and speech measures (Cepstrum, Delta Cepstrum, Delta Delta Cepstrum, Log Spectral Entropy, F0, Jitter, Shimmer, Harmonic-to-Noise Ratio (HNR), H1H2, and Root Mean Square (RMS)) were analyzed using Support Vector Machines (SVMs), a linear binary classifier. The models incorporated leave-one-participant-out cross validation to reduce overfitting.

Results: Both the ALM and speech models performed well at correctly identifying ASD individuals, achieving sensitivities of 0.7727 and 0.7955 respectively. The ALM model was much better than the speech model at correctly identifying non-ASD individuals (specificities of 0.8286 and 0.5714 respectively). Overall accuracy was 0.7975 and 0.6962, respectively. The combined model showed substantial improvement over both the individual models, with a sensitivity of 0.8864 and a specificity of 0.800, and overall accuracy of 0.8481.

The speech model caught ASD participants with higher CCC-2 scores and ADOS RRB scores, lower ADOS SA scores, who were older and had higher IQ, used more c-units, a larger number of total words, and had a longer activity time. The ALM model caught ASD participants with lower CCC-2 scores, higher ADOS SA and RRB scores, who were younger and had lower IQ, used fewer c-units, fewer total words, and had a shorter activity time.

Conclusions: We showed that a defined set of language- and acoustic-based outcome measures have the independent discriminant validity to correctly classify individuals with and without ASD. The automated language model caught younger individuals with shorter language samples and an overall lower language ability. The automated speech model caught older individuals with overall higher language ability. The combined model shows an increase in both accuracy and sensitivity over the individual models, indicating the value of evaluating communication ability more broadly.

**508.012** (Virtual Poster) Comparing in Developmental Profile of Minimally Verbal Children

S. Suswaram<sup>1</sup> and N. Brady<sup>2</sup>, (1)Speech-Language-Hearing: Sciences & Disorders, University of Kansas, Lawrence, KS, (2)University of Kansas, Lawrence, KS

---

Background: Child development researchers agree that cultural differences influence child development (Halpin et al., 2019). However, relatively little is known about the influences of cultural environments on children with Autism Spectrum Disorders and minimal verbal abilities (MV-ASD; Maltman et al., 2021). Around 30% of individuals with ASD fail to develop verbal communication skills and use 30 or less functional words for interactions throughout their lives (Barokova et al., 2021). Comparing developmental abilities of children with MV-ASD from diverse cultural backgrounds might provide the research community preliminary evidence of potential benefits of certain cultural practices for facilitating communication development in children with MV-ASD. The current study compares children with MV-ASD from India, a Low- and Middle-Income Country (LMIC) and the U.S., a High-Income Country.

Objectives: Comparing and identify differences in developmental profiles of children with MV-ASD from India (n = 35) and the U.S. (n = 35).

Methods: We compared two groups of children with MV-ASD on their developmental profiles as measured by the Vineland Adaptive Behavioral Scale, 3<sup>rd</sup> Edition (Vindland-3; Sparrow, Cicchetti, & Balla, 2005) using the Mann-Whitney U test. Specifically, we compared the groups on

Vineland-3 scores associated with communication: receptive, expressive, written; daily living skills: personal, domestic, community; socialization: interpersonal relationship, play and leisure, and coping mechanism.

**Results:** *Demographic distribution:* The two groups did not significantly differ on children's age and gender, number of siblings, number of family members, age at diagnosis, type of intervention available, weekly duration of the intervention services available, parent education, parents' marital status, and parents' general health conditions. The groups significantly differed on parent employment and child education.

*Developmental profiles:* As anticipated, the two groups of children did not differ on their expressive language abilities but differed on their receptive language  $U(N=70) = 443.00, z = -1.992, p < .046$ , interpersonal relationship  $U(N=70) = 424.50, z = -2.215, p < .027$ , play and leisure  $U(N=70) = 355.00, z = -3.033, p < .002$ , and coping mechanism  $U(N=70) = 395.00, z = -2.566, p < .010$  scores on Vineland-3. Children from India consistently scored higher on receptive ( $M = 35.91, SD 11.518$ ), intrapersonal ( $M = 24.14, SD 6.132$ ), play ( $M = 18, SD 4.814$ ), and coping skills ( $M = 14.74, SD 5.153$ ) than children in the U.S. that scores lower scores on average on their receptive ( $M = 29.97, SD 13.942$ ), intrapersonal ( $M = 21.06, SD 7.00$ ), play ( $M = 15.63, SD 9.714$ ), and coping skills ( $M = 12.94, SD 7.296$ ).

**Conclusions:** Despite limited educational opportunities, children from India scored higher than children in the U.S. on their receptive and social skills. Future studies should examine differences in social-cultural environments that place children in India at an advantage over children within the U.S. for developing adaptive behavioral abilities.

#### **508.013** (Virtual Poster) Differentiating Among Low, Medium, and High "Um" Users with ASD and ADHD

C. Boo<sup>1</sup>, N. S. McIntyre<sup>2</sup>, P. Mundy<sup>3</sup> and L. R. Naigles<sup>1</sup>, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)School of Communication Sciences and Disorders, University of Central Florida, Orlando, FL, (3)University of California at Davis, Davis, CA

**Background:** Many studies have highlighted challenges with pragmatic language among school-aged children with autism spectrum disorder (ASD) and Attention Deficit/Hyperactivity Disorder (ADHD). For example, several recent studies report that children with ASD/ADHD differ from their TD peers in production of filled pauses (FPs) such as "um", which has a listener-oriented function, but not "uh", which serves a self-regulatory function (Clark & Fox Tree, 2002; Irvine et al., 2016; Gorman et al., 2016). However, not all investigations have reported this difference (Boo et al., 2021), and few have examined in depth what contributes to children with ASD producing fewer "ums".

**Objectives:** To investigate the production of FPs ("uh"/"um") among school-aged children with ASD and/or ADHD, by considering the roles of language and diagnostic severity as predictors.

**Methods:** Participants included 52 verbally fluent children with ASD ( $Mage = 11.8, SD = 2.3$ ), 24 children with ADHD ( $Mage = 12.0, SD = 2.3$ ), and 22 TD children ( $Mage = 12.5, SD = 2.3$ ). Children were within their age-appropriate range of non-verbal IQ. Language samples were collected during a virtual reality paradigm where children viewed a classroom while answering questions from an experimenter in a conversational format. Children's responses were recorded and transcribed. Transcribers specifically differentiated between "uh" and "um" tokens. Proportions of "uh" and "um" tokens per utterance were computed.

**Results:** Overall, children from all three groups produced comparable rates of "uh" tokens per utterance,  $p = 0.586$ . However, significant group differences emerged in "um" tokens per utterance,  $F(2, 97) = 3.509, p = 0.034, \eta^2 = 0.069$ , with the ASD group ( $M = 0.28, SD = 0.23$ ) producing significantly fewer "um" tokens per utterance than the TD group ( $M = 0.45, SD = 0.38$ ),  $p = 0.026$ . Post hoc analyses were conducted to determine how many children per group produced a low ( $M = 0 - 0.142$ ), medium ( $M = 0.143 - 0.417$ ), and high ( $M > 0.418$ ) proportion of "ums". These categories were created by a 3-way roughly equal split of the proportions of 'um' usage based on the TD group. The chi-square analyses revealed that the distribution of low, high, and medium "um" users significantly differed by group,  $\chi^2(4) = 10.033, p = 0.040$ , with the ASD and ADHD groups having significantly more low "um" users than the TD group (Figure 1). Low, medium, and high "um" users across the three groups did not significantly differ in Conners-3 or ADOS scores; however, they significantly differed in verbal IQ (VIQ) scores,  $F(2, 97) = 7.617, p < 0.001, \eta^2 = 0.138$ , with the low and medium "um" users having significantly lower VIQ scores than high "um" users,  $ps < 0.05$ .

**Conclusions:** Akin to previous studies, school-aged children with ASD and ADHD produced significantly fewer "um" tokens during conversation. However, our findings suggest that the lack of production of "um" is not necessarily associated with autistic characteristics; instead, it is associated with verbal abilities as measured by VIQ. This is also supported by the lower "um" use by the ADHD group.

#### **508.014** (Virtual Poster) Downward Entailment in Mandarin-Speaking High-Functioning Children with Autism Spectrum Disorders

J. Wei<sup>1</sup> and Y. E. Su<sup>2</sup>, (1)Central South University, Changsha, China, (2)Child Language Lab, School of Foreign Languages, Central South University, Changsha, Hunan, China

**Background:** Children with autism spectrum disorders (ASD) have been documented to have profound semantic impairments compared to their relative syntactic strengths (Boucher 2012; Naigles & Taks 2017). Downward entailment, i.e., licensing the inference from sets to subsets, as a core semantic property in human language could be used to uncover children with ASD's semantic knowledge. This study is designed to see whether children with ASD have impairments in the core semantic property of downward entailment.

**Objectives:** This study investigates the semantic properties of downward entailment in Mandarin-speaking high-functioning children with ASD (HF-ASD) through comparison with typically developing (TD) children. Experiment 1 assessed their knowledge of *wh*-word *shenme* 'what' in two

different linguistic contexts: the predicate phrase of *meiyouren* 'nobody' versus *meigeren* 'everyone', as in sample sentence (1) and (2). Sample (1) means that no sheep bought any vegetable. Sample (2) means that what kind of vegetable did every sheep buy? Experiment 2 examined children's interpretation of the disjunction word *huozhe* in the predicate phrases of *meiyouren* versus *meigeren*, as in sample sentences (3) and (4). Sample (3) means that (a) no dwarf bought a mirror **and** (b) no dwarf bought a chair. Sample (4) means that every dwarf bought a vase or a mirror. We tested whether children with HF-ASD possessed core semantic knowledge of downward entailment as their TD peers.

**Methods:** Using a Computer-based Question-Statement Task (Su et al. 2014) and a Computer-based Truth-Value Judgement Task (Su 2015), we tested 27 3-7-year-old children with HF-ASD (mean age = 5;7) and matched 25 3-6-year-old TD children (mean age = 5;1). Specifically, we tested their knowledge of *wh*-word *shenme* in experiment 1 and the disjunction word *huozhe* in experiment 2, respectively, in both downward-entailing and non-downward entailing contexts.

**Results:** When *shenme* was in the predicate phrase of *meiyouren*, children with HF-ASD rejected the test sentences 57.4% of the time whereas TD children rejected the test sentences 86% of the time ( $\chi^2=9.477$ ,  $df=4$ ,  $p=.05$ ). However, when it was in the predicate phrase of *meigeren*, both the TD group and the ASD group accepted the test sentences 92%, 95.4% of the time, respectively ( $\chi^2=1.134$ ,  $df=3$ ,  $p=.769$ ). When *huozhe* appeared in the predicate phrase of *meiyouren*, children with HF-ASD rejected the test sentences 78.7% of the time whereas TD children rejected the test sentences 95% of the time ( $\chi^2=9.455$ ,  $df=4$ ,  $p=.051$ ). However, when it was in the predicate phrase of *meigeren*, both the ASD group and the TD group accepted test sentences 92%, 94.4% of the time, respectively ( $\chi^2=1.615$ ,  $df=3$ ,  $p=.656$ ) (Figure 1).

**Conclusions:** Taken together, 3-7-year-old Mandarin-speaking children with HF-ASD performed similarly to matched TD controls in demonstrating semantic knowledge of non-downward entailing structures but they possibly had delayed knowledge of downward entailing structures. Future studies on older children with HF-ASD's knowledge of downward entailment are needed to see whether or not there is indeed a developmental pattern in their semantics of downward entailment.

#### **508.015 (Virtual Poster)** Examining Language and Communication in Autistic People with Complex Needs – a Systematic Review of Procedural and Measurement Issues and Practice

**S. Donald<sup>1</sup>, S. B. Gaigg<sup>2</sup>, A. Remington<sup>3</sup> and N. Edwards<sup>1</sup>**, (1)City University of London, London, United Kingdom, (2)Autism Research Group, City, University of London, London, United Kingdom, (3)UCL Centre for Research in Autism and Education, London, United Kingdom

#### **Background:**

Approximately 50% of autistic individuals have intellectual disabilities and 30% remain minimally-verbal throughout life. This group is grossly under-represented in research due to methodological challenges and inconsistencies in definitions of intellectual disability and minimal verbal ability. We therefore know least about language and communication functioning in those who demonstrate the most significant difficulties in these areas.

#### **Objectives:**

To review the literature on language and communication function in autistic individuals with complex needs and answer the following questions to derive recommendations for best practice in this area of research:

- 1) What strategies are used for engaging, recruiting and retaining autistic participants with limited speech and/or intellectual disability in research?
- 2) What tools have been used with this population to capture language and communication skills?
- 3) How are minimal language and intellectual disability defined and operationalised?

#### **Methods:**

Systematic searches were conducted in March/April 2021 using a comprehensive list of search terms to describe participants who would come under an umbrella of minimal verbal ability and/or intellectual disability. Full details of the search strategy and review methodology can be found on the registered review protocol (PROSPERO 2021 CRD42021236135).

#### **Results:**

Of 5914 studies initially identified, 195 met all inclusion criteria. Most research has focussed either on interventions to develop expressive language or to characterise language impairment in relation to other features of autism. There remains limited research on the use of AAC. Research Question 1: Reporting on strategies for recruiting, retaining and engaging participants was generally very limited and factors that may contribute to participant exclusions are currently being identified through data extraction. Research Question 2: 49 different language/communication measurement tools were used across studies, most often focussing on expressive language and/or using subsections of broader cognitive tools. The properties and quality of all tools used are now being evaluated using the COSMIN (COnsensus-based Standards for the selection of health Measurement INstruments) framework to develop recommendations concerning their use. Research Question 3: Definitions and constructs of minimal language and intellectual disability have shifted over time, with a clearer distinction between minimal spoken language as opposed to general language delay or impairment emerging only over the past decade. Research in this area has grown significantly over the same period, with definitions and preferred measurement tools becoming more homogenised, largely in response to seminal papers by Bal et al., 2016; Kasari et al., 2013; Tager-Flusberg & Kasari, 2013.

## Conclusions:

Minimally-verbal autistic people remain underrepresented in research, although progress in this area has accelerated over the last decade. Current publications provide little information about the strategies used to effectively engage and retain participants in research. The use of multiple measurement tools and inconsistencies in definitions of minimal verbal ability and intellectual disability makes it difficult to compare findings across studies. Based on the findings, recommendations will be formulated on how to build on recent progress to further accelerate our understanding of language and communication skills in those with the most significant difficulties in these areas.

## **508.016** (Virtual Poster) Examining the Influence of Bilingualism on the Narrative, Social and Pragmatic Abilities of School-Aged Children on the Autism Spectrum

**M. L. Beauchamp**<sup>1</sup>, S. Rezzonico<sup>2</sup>, M. Elsabbagh<sup>3</sup>, P. Mirenda<sup>4</sup>, T. Bennett<sup>5</sup>, E. Duku<sup>6</sup>, S. Georgiades<sup>7</sup>, C. M. Zwaigenbaum<sup>13</sup>, (1)Research Institute- McGill University Health Centre Montreal, Montreal, QC, Canada, (2)École d'orthophonie et d'audiologie, Université de Montréal, Montreal, QC, Canada, (3)Neurology and Neurosurgery, McGill University, Montreal, QC, Canada, (4)University of British Columbia, Vancouver, BC, Canada, (5)Offord Centre for Child Studies, McMaster University, Hamilton, ON, CANADA, (6)Offord Centre for Child Studies, McMaster University, Hamilton, ON, Canada, (7)McMaster Autism Research Team, McMaster University, Hamilton, ON, Canada, (8)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (9)The Hospital for Sick Children, Toronto, ON, Canada, (10)The Hospital for Sick Children Research Institute, Toronto, ON, Canada, (11)University of Ottawa, Ottawa, ON, Canada, (12)Tel-Aviv University, Tel-Aviv, Israel, (13)University of Alberta, Edmonton, AB, Canada

---

## Background:

Narratives refer to speech acts conveying information about series of related events that occur in a specific chronological order. They generally include an objective and a set of actions to reach this objective. Narrative skills are important language abilities and serve a vital communicative function. They may also foster psychological and emotional identity, and are linked to academic achievement. In children on the autism spectrum (AS) challenges with narratives, particularly macrostructure (story cohesion and coherence), are frequently reported, and may be linked to social skills.

Children on the AS can become proficient bilinguals and for many, bilingualism is critical to their wellbeing. They may also benefit from stronger social and pragmatic skills than their monolingual autistic peers. However, little is known of narrative skills in bilingual children on the AS, or of the potential beneficial effects of bilingualism on those skills.

## Objectives:

Within this context, our study examined the narrative (i.e., microstructure: structural language, and macrostructure), social and pragmatic skills of bilingual and monolingual children on the AS, and whether narrative skills were influenced by social and pragmatic abilities. Based on the relation between social, pragmatic, and narrative skills on the one hand, and bilingualism and social skills on the other, we predicted that bilinguals would have (a) stronger social and pragmatic skills and (b) stronger macrostructure skills. We also predicted an association between these variables.

## Methods:

The narrative, social, and pragmatic skills of 54 bilinguals and 80 monolinguals on the AS who participated in the *Pathways in Autism* project (mean age: 10.8 months; mean NVIQs: 98 and 93 respectively) were examined using the *Expression, Reception and Recall of Narrative Instrument*, the *Vineland Adaptive Behavior Scales, Second Edition-Interpersonal Domain*, and the *Comprehensive Assessment of Spoken Language* respectively. Parent questionnaires were used to determine language group assignment and estimate children's language exposure(s). For bilinguals, exposure to the language of testing ranged between 42%-94%.

Performances of bilingual and monolingual children on measures of narrative, social, and pragmatic skills were compared using Bayesian t-tests. Regression analyses were completed to examine relations between variables. Exploratory data will be presented from a transcript analysis study examining other aspects of narratives.

## Results:

There were no significant group differences for measures of microstructure or social skills. However, we found a significant negative relation between estimated exposure to the language of testing and pragmatic abilities, and a negative trend between language exposure and macrostructure, suggesting that children who had similar amounts of exposure to both languages had stronger pragmatic and macrostructure skills. We also found a relation between story-recall and pragmatic skills, which was not influenced by language group status.

## Conclusions:

Our findings suggest that some bilinguals on the AS may experience stronger pragmatic and narrative skills, but these may be mediated by the amount of dual-language exposure. Our findings may inform clinicians' expectations when assessing and working with bilingual children. They also underscore the influence that different bilingual experiences have on certain abilities, and the importance of considering such differences in both clinical and research settings.

**508.017 (Virtual Poster)** Identifying Profiles of Grammatical Production in Autistic Children Via Cluster Analysis

A. Mankovich<sup>1</sup>, K. Wittke<sup>2</sup>, J. E. Blume<sup>3</sup>, A. Mastergeorge<sup>4</sup>, A. Paxton<sup>1</sup> and L. R. Naigles<sup>1</sup>, (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)University of Connecticut, Storrs, CT, (3)Human Development and Family Sciences, TTU HDFS, Lubbock, TX, (4)Human Development and Family Sciences, Texas Tech University, Lubbock, TX

---

**Background:**

Vast heterogeneity of grammatical abilities exists among autistic children (Kjelgaard & Tager-Flusberg, 2001; Roberts et al., 2004; Wittke et al., 2017). Previous research has demonstrated individual variability on broader measures (e.g., standardized tests, mean length of utterance [MLU]); however, more detailed analyses are needed to investigate why some children habitually produce short/telegraphic utterances. Categorical recurrence quantification analysis (RQA) offers a novel approach to understand the nature of these production difficulties by quantifying the structure within categories. Previous applications to language often quantified grammatical alignment between two speakers (Dale & Spivey, 2005, 2006), but we evaluate changes within individual children at the level of grammatical form classes.

**Objectives:**

We deploy RQA measures plus an iterative clustering algorithm to determine whether we can detect underlying structures that might differentiate amongst children with ASD.

**Methods:**

The present study uses a subset of the Autism Phenome Project dataset ( $n = 31$ ,  $M_{age} = 72.71$  months, 10 females,  $M_{NVIQ} = 95.32$ ,  $SD = 19.39$ ;  $M_{TOTALADOS} = 12.19$ ,  $SD = 4.86$ ). Language sample transcriptions were parsed for MLU and percent ungrammatical utterances (%UU) and annotated for the form classes within noun and verb phrases (see Figure 1). We performed RQA on the form class data. RQA measures instances of pairs of repeated units over time by creating recurrence plots (RP), which are subsequently quantified through recurrence rate (RR) and determinism (DET). RR calculates the percentage of the RP containing filled-in points; high RR indicates frequent reuse of form class units. DET measures the structure of repeated sequences, which are visible on the RP as larger box structures rather than single dots. High DET indicates that children repeat form class combinations. Analyses differentiated between noun phrase (NP), verb phrase (VP), and all other form classes; we evaluated differences between clusters by RQA measures.

**Results:**

See Figure 1 for a visualization of the clusters [ $k = 2$ ] and Figure 2 for exemplar RPs. Analyses reveal %UU does not differentiate between clusters [ $p = .75$ ], at least not with this sample. Cluster 1 repeats NP and VP units more often [ $M_{NPRR} = 6.22$ ;  $t(48) = 3.33$ ,  $p < .001$ ;  $M_{VPRR} = 2.59$ ;  $t(48) = 2.35$ ,  $p < .05$ ] than cluster 2 [ $M_{NPRR} = 4.85$ ;  $M_{VPRR} = 2.06$ ]. Cluster 2 repeats many more NP and VP unit combinations [ $M_{NPDET} = 26.57$ ;  $t(48) = -4.01$ ,  $p < .001$ ;  $M_{VPDET} = 23.90$ ;  $t(48) = -7.42$ ,  $p < .001$ ] and possesses larger MLUs [ $M_{MLU} = 5.5$ ;  $t(48) = -6.87$ ,  $p < .001$ ] than cluster 1 [ $M_{NPDET} = 19.18$ ;  $M_{VPDET} = 14.62$ ;  $M_{MLU} = 3.40$ ]. Cluster analyses suggest that children with higher DET also have larger MLUs, signaling that larger DET indeed reflects greater sophistication in grammatical constructions (i.e., better production).

**Conclusions:**

We use cluster analyses on RR and DET for NP and VP form classes to quantitatively identify different kinds of productivity among children with ASD. Findings underscore the value of using RQA metrics as more fine-grained measures of grammatical production for extricating variability through the use of multifaceted data.

**508.018 (Virtual Poster)** Initiation Strategies of Bilingual and Monolingual Children with Autism Spectrum Disorders in a Verbal Fluency Task

A. M. Gonzalez Barrero, A. Gores and M. Mongeau, School of Communication Sciences and Disorders, Dalhousie University, Halifax, NS, Canada

---

**Background:** Verbal fluency tasks provide key information regarding individuals' lexico-semantic and executive functioning skills (Shao et al., 2014). Prior research has found that monolingual children and adults tend to outperform their bilingual peers on this task. Different hypotheses have been postulated to explain bilinguals' lower performance (e.g., reduced vocabulary hypothesis, Bialystok et al., 2008). Of interest, a study examining verbal fluency in school-age children with Autism Spectrum Disorders (ASD) found that bilingual children with ASD produced more words than their monolingual peers with ASD, when participants were matched on vocabulary skills (Gonzalez-Barrero & Nadig, 2017). However, there were no significant differences between groups in two cognitive strategies previously examined in individuals with ASD (e.g., Begeer et al., 2013): switching (i.e., the number of switches between categories, such as switching from farm animals to jungle animals) or clustering (i.e., the number of words produced within a specific cluster). Thus, it remains to be examined what specific cognitive strategy yields the increased performance of bilingual children with ASD compared to their monolingual peers. Given the lack of studies including bilingual children with ASD, more research is needed to better understand how these children approach verbal fluency tasks which tap into key semantic and executive functioning skills; two common areas of difficulty for individuals on the autism spectrum (Craig et al., 2016).

**Objectives:** The current study aimed to examine the language skills and initiation abilities of bilingual and monolingual children with ASD on a verbal fluency task going beyond the typical measures analyzed in this task, to better characterize the linguistic and cognitive profile of bilingual children with ASD.

**Methods:** Twenty school-aged children with ASD (10 monolinguals, 10 bilinguals) participated in the study. Children were given 1 minute to name all the elements they knew for a given category (e.g., animals). Items produced in the bilingual children's dominant language were compared to those produced by monolingual children in their single language. Participants were closely matched on key variables that influence verbal fluency performance (i.e., age, gender, vocabulary, socio-economic status, nonverbal-IQ and ASD symptomatology). A time-bin analysis, where the one-minute task was broken up into three time bins of 20 seconds, was conducted to compare the performance of the bilingual children with ASD to that of their monolingual peers with ASD.

**Results:** Preliminary results showed that the bilingual group produced significantly more words (1.4 words) than the monolingual group during the first 20 seconds of the task ( $p = .04$ ). No statistically significant differences between groups were found on the other time bins analyzed.

**Conclusions:** Findings from this study are in line with prior evidence suggesting that bilingualism is not detrimental for the language or cognitive skills of children with ASD (Drysdale et al., 2015), and provide novel evidence concerning the linguistic profile and initiation abilities of children with ASD growing up in bilingual contexts.

**508.019 (Virtual Poster)** Mental State Verbs Expressed By Children on the Autism Spectrum: A Syntactic Perspective  
*E. Macaruso, L. Wisman Weil and R. J. Luyster, Communication Sciences and Disorders, Emerson College, Boston, MA*

---

**Background:**

Verbs representing mental states are syntactically complex because they may occur with sentential complements, which are phrases that may independently function as grammatical sentences. For example, "Jack thinks his father is at home" contains the sentential complement "his father is at home." Research indicates that typically developing children use sentential complements at age four, frequently with mental state verbs (MSVs). For children on the autism spectrum, evidence indicates delays with mental state language but relative strengths in language form; recent evidence favors sentential complement training to support sentential complement use and false-belief task performance. This study investigates the relationship between MSV and sentential complement production by children on the autism spectrum. This novel approach capitalizes on implicit indicators of mental state knowledge; that is, elevated use of sentential complements for MSVs specifically provides insights into a child's understanding of the uniqueness of mental state verbs.

**Objectives:**

The study aims to explore (1) how sentential complement usage aligns with overall language skills and (2) the rate of sentential complement use with and without MSVs. In addressing aim #1, we quantify the relationship between sentential complement production and widely-used language indicators (i.e., mean length of utterance in morphemes [MLUm] and type-token ratio [TTR]). In addressing aim #2, we compare the rate of sentential complement occurrence with MSVs versus with non-MSVs. We hypothesize that (1) sentential complement use will be positively associated with MLUm and negatively associated with TTR, and (2) sentential complements will occur more frequently with MSVs than with non-MSVs.

**Methods:**

Language samples from 9-year-olds on the autism spectrum ( $N = 10$ , 10 male) were transcribed from videos of either Module 2 ("phrase speech") or Module 3 ("fluent speech") of the Autism Diagnostic Observation Schedule (ADOS) or ADOS-2, from an existing dataset (Lord et al., 2006). Utterances were coded for morphosyntax and variables including sentential complements and MSVs. Within-subjects nonparametric analyses were used, given the sample size.

**Results:**

Wide individual variability in MSV and sentential complement expression was evident. Non-parametric correlations demonstrated that sentential complement frequency was positively correlated with MLUm ( $\rho = .936, p < .01$ ) and negatively correlated with TTR ( $\rho = -.809, p < .01$ ). Sentential complements occurred with MSVs more than with non-MSVs (Related-Samples Wilcoxon Signed Ranks Test,  $N = 9, z = -2.100, p = .036$ , 2-tailed).

**Conclusions:**

As expected, sentential complement usage was associated with overall language skills for each subject. Moreover, *differential* sentential complement usage was evident; as hypothesized, participants produced sentential complements at a higher rate with MSVs than non-MSVs. This finding is similar to typically developing samples and indicates a relative strength in sentential complement production among participants. These results suggesting that children on the autism spectrum have an understanding of the syntactic "uniqueness" of MSVs may lead to evidence-based interventions capitalizing on this strength. While further research is needed to address sample size and coding limitations, this investigation introduces a new possible avenue to measure mental state knowledge in autism.

**508.020 (Virtual Poster)** Metaphors Interpretation Using Comparison and Structure Mapping Processes Among Adolescents with ASD and Theirs Siblings  
*O. E. Hetzroni<sup>1</sup> and I. Segal Palensia<sup>2</sup>, (1)Special Education, University of Haifa, Haifa, Israel, (2)University of Haifa, Haifa, Israel*

---

**Background:** Metaphors incorporate language abilities that include symbolic understanding created through processes of structural mapping used to form relations such as categories, analogies, and other knowledge-based structures that encompass properties that are related in complex manners. Structure mapping is a core cognitive process that enables creation of analogies and metaphors, during which different structures of knowledge are aligned, and compared, relevant relations are identified and transferred to form new coherent language structures. Metaphors can be interpreted as attributes based on perceptual characteristics, or using relations based on relational structures that encompass the components of the metaphor. The ability to use and understand metaphors increases, with reciprocal interactions between age language and cognition. Analogies and metaphors contribute to the acquisition of abstract concepts by paralleling between relational structures. Research investigating metaphors among individuals with ASD demonstrate mixed results in development, use, and interpretation of metaphors. For example, in one study comparing children with and without ASD, structural mapping and the development of understanding metaphors were significantly different.

**Objectives:** The purpose of this study was to investigate interpretation of three types of metaphors among adolescents with and without ASD, and siblings of adolescents with ASD: (1) Metaphors as attributes, whereas the base and the target mostly share perceptual qualities and attributes (e.g., “Jelly beans are like balloons”); (2) Relational metaphors that are mostly relational in nature (e.g., “A hat is like a roof”); and (3) double metaphors, in which the base and the target share many attributes and relational qualities (e.g., “a kite is like a bird”).

**Methods:** Fifty adolescences ages 14-18 participated in the study: 20 adolescences with ASD, 10 adolescences that have siblings with ASD, and 20 adolescences with TD. All participants completed a structural mapping assignment aimed to identify perceptual and conceptual targets in uncertainty and certainty conditions; and a task in which they were asked to interpret a set of 24 metaphors (8 of each type) that were presented both in a visual and auditory manner with a request to provide an interpretation of the metaphor and to rank the adequacy of the statement as a metaphor.

**Results:** All participants completed the assignments. Each of the interpretations and the rankings were coded and evaluated. Preliminary results reveal no significant differences between the three groups in interpretations and ranking of metaphors. Preliminary analyses of specific interpretations and ranking provided by the participants demonstrate unique styles in interpretations and in ranking and in the explanations provided among the group of adolescents with ASD. In the structural mapping task, participants in the three groups selected perceptual targets in uncertainty condition but differed in the certainty condition.

**Conclusions:** Similarly to previous studies, groups differed in the certainty but not in the uncertainty condition in the structural mapping task. There were some similarities in the interpretations among adolescents across the three groups which could be related to the levels of knowledge in the understanding of metaphors. Examples of differences and unique interpretations will be discussed, and examples will be provided.

**508.021 (Virtual Poster)** Patterns of Finger-Tracking in Italian Early Readers with Autism Spectrum Disorder

C. Marzi<sup>1</sup>, A. Narzi<sup>2</sup>, M. Ferro<sup>3</sup>, G. Masi<sup>1</sup>, A. Milone<sup>2</sup>, V. Viglione<sup>2</sup>, S. Pelagatti<sup>1</sup>, I. Tomassini<sup>1</sup> and V. Pirrelli<sup>1</sup>, (1)University of Pisa, Pisa, Italy, (2)IRCCS Stella Maris Foundation, Pisa (Calambrone), Italy, (3)CNR Institute for Computational Linguistics, Pisa, Italy

**Background:** Of late, the synergistic interaction of eye and hand movements in the exploration of a visual scene displayed on a computer touchscreen was shown to provide a congruent signature of the “attention maps” of subjects with autism spectrum disorders (ASD). A familiar context where this visual and tactile interaction is exploited is when children use the finger of their dominant hand to point the letters of written words as they are reading, particularly at early stages of their literacy development. In the present work, a dedicated app running on a common tablet is used to capture and analyse the finger-tracking behaviour of children with ASD while they are reading few episodes of a connected text on the tablet touchscreen. The reader’s voice is also recorded through the tablet built-in microphone. The sliding movements of the finger across the tablet touchscreen are discretized into a series of densely distributed “touch events”, which are then mapped onto the text lines in much the same way eye fixations are projected onto a sequence of words using an eye-tracker. Reading texts are linguistically annotated, to control for levels of reading difficulty, and finger-tracking times are associated with linguistic glosses.

**Objectives:** Investigate patterns of finger-tracking as a potential non biological marker for identification of children with ASD

**Methods:** A preliminary analysis is offered of evidence of the finger-tracking behaviour of 20 Italian children with high functioning ASD, aged 7-11 years, while they are engaged in reading. A grade-matched control group of children with typical development was included. Patterns of finger-tracking are assessed in connection with three complementary aspects of reading behaviour: (1) word recognition, (2) pace of reading of multi-word intonation units, and (3) text comprehension, controlled by asking children a few multiple-choice questions on text content after each reading session.

**Results:** Considerable variation in levels of reading ability was observed in the ASD sample, with a few children showing clear evidence of impaired reading comprehension. However, fluent readers with ASD exhibit the same correlation between accurate decoding (assessed by measuring per-word reading speed) and high levels of reading comprehension found in controls. Likewise, decoding rates were found to significantly increase with increasing grade levels, following the typical developmental pattern observed in controls. On a less local level of linguistic analysis, the reading pace of ASD readers fails to be modulated according to major syntactic structures, punctuation marks and direct speech turns, an effect concomitant with a flat prosodic intonation of oral reading.

**Conclusions:** Preliminary findings confirm the heterogeneous nature of reading skills in children with ASD, showing that the use of a tablet screen as a tactile interface for visual perception analysis can offer a robust experimental protocol for large-scale, multimodal collection of naturalistic data for extensive assessment of readers with ASD.

**508.022 (Virtual Poster)** Scalar and Non-Scalar Implicatures in Preschool Mandarin-Speaking Children with Autism Spectrum Disorder

Y. Jiang<sup>1</sup> and Y. E. Su<sup>2</sup>, (1)Central South University, Changsha, China, (2)Child Language Lab, School of Foreign Languages, Central South University, Changsha, Hunan, China

**Background:** Conversational implicatures include two kinds of implicatures: (1) scalar implicatures (SIs) based on lexical scales (e.g., the quantifier ‘some’ implies ‘not all’, and the number ‘three’ implies ‘not four’) and (2) non-scalar implicatures (non-SIs) based on the specific contexts (e.g., saying ‘The cat got an apple’ implies ‘not an apple and a pear’) (Horn, 1972). The consistent success in SIs was hardly seen in preschool typically developing (TD) children and those with ASD, whereas non-SIs were only observed in TD children (Mazzaggio et al., 2021; Zhao et al., 2021). However, no study has systematically investigated these two types of implicatures in preschool Mandarin-speaking TD children and children with ASD.

**Objectives:** We tested the interpretation of SIs (including quantifiers and numbers) and non-SIs by Mandarin-speaking preschool TD children and children with ASD, to examine their pragmatic abilities of computing implicatures as well as the link with Theory of Mind (ToM), receptive vocabulary and non-verbal IQ.

**Methods:** We recruited 20 TD children and 13 high-functioning children with ASD, matched on age, but not on scores of ToM, the Chinese Peabody Picture Vocabulary Test (C-PPVT), and the Chinese Raven’s Matrices Progressive Test (CRT) (Table 1). Using the computer-based truth value judgment task (Su & Su, 2015), the experimenter presented the stories to children through Microsoft PowerPoint, and then asked children to judge the truth values of prerecorded test sentences describing the outcome of the stories.

**Results:** A Bayesian linear mixed effects model suggested that ASD group did worse than TD group in computing implicatures. TD group’s total accuracy of both SIs,  $V = 8.5$ ,  $p < 0.001$ , and non-SIs was significantly higher than that of the ASD group,  $V = 0$ ,  $p < 0.001$ . For SI subtests, both groups got significantly higher accuracy in number than quantifier, TD group:  $V = 2$ ,  $p < 0.05$ ; ASD group:  $V = 6.5$ ,  $p < 0.01$ . TD group also performed better than ASD group in both number,  $V = 80$ ,  $p < 0.01$ , and quantifier,  $V = 13.5$ ,  $p < 0.001$ . However, although TD group got significantly higher accuracy in non-SIs than SIs,  $V = 26$ ,  $p < 0.05$ , ASD group showed a reverse pattern,  $V = 5$ ,  $p < 0.01$  (Figure 1). The other two models of ASD revealed a significant effect of TOM in the accuracy of two implicature tasks,  $SE = 0.09$ ,  $p < 0.05$ , and two SI sub-tests,  $SE = 0.15$ ,  $p < 0.001$ , a significant interaction of task and ToM,  $SE = 0.11$ ,  $p < 0.001$ , and a significant interaction of SI sub-test and ToM,  $SE = 0.19$ ,  $p < 0.05$ . By contrast, TD group did not reveal any significant effect or interaction with ToM. No significant effect or interaction with C-PPVT or C-Raven scores was found.

**Conclusions:** Preschool Mandarin-speaking TD children showed pragmatic awareness of both SIs and non-SIs, but the ASD children exhibited difficulty, especially with the non-SIs and the SIs of quantifiers. The pragmatic impairment in ASD may be related to their ToM deficits.

#### **508.023 (Virtual Poster) Sex Differences in Pronoun and Maze Usage in the Language of Children with Autism Spectrum Disorder**

**G. O. Lawley<sup>1</sup>, S. Bedrick<sup>2</sup> and E. Fombonne<sup>3</sup>,** (1)Computer Science and Electrical Engineering, Oregon Health & Science University, Portland, OR, (2)Department of Medical Informatics and Clinical Epidemiology, Oregon Health & Science University, Portland, OR, (3)Department of Psychiatry, Oregon Health & Science University, Portland, OR

**Background:** Research on sex differences in the language of children with Autism Spectrum Disorder (ASD) has been limited. Song et al. (2020) found that “we” pronoun (1<sup>st</sup> person plural pronouns; e.g., “we”, “ours”) and “they” pronoun (3<sup>rd</sup> person plural pronouns; e.g., “they”, “their”) usage differs amongst ASD and TD girls and boys. In addition, studies have shown that maze (i.e. intervals of disfluent speech) usage rates distinguish ASD and TD children. However, whether these differences are influenced by sex has not been investigated.

**Objectives:** To compare usage rates of (1) “we” and “they” pronouns, and (2) mazes in ASD and TD girls and boys.

**Methods:** A total of 140 children, 98 ASD (17 girls) and 42 TD (22 girls), aged 7 to 15 years old, were included. All had full-scale IQ  $\geq 70$ . Analyses were performed on transcribed Autism Diagnostic Observation Schedule (ADOS), Module 3 sessions. Transcription was completed according to modified Systematic Analysis of Language Transcripts (SALT) guidelines by trained transcribers who were blind to the participants’ diagnostic status and intellectual abilities. Four ADOS conversation tasks were analyzed: Emotions; Social Difficulties and Annoyance; Friends, Relationships, and Marriage; Loneliness.

We calculated the total number of times each participant said a “we” pronoun, “they” pronoun, and maze. We fit three logistic regression models (Poisson distribution) with total “we”, “they”, or maze as the response variables and the total number of overall tokens as the offset. Each model included age, full-scale IQ, diagnosis, sex, and a diagnosis and sex interaction term. Pairwise Estimated Marginal Means (EMM) were compared post-hoc.

**Results:** Diagnosis and sex significantly predicted “we” frequency (ASD < TD,  $p < .001$ ; male < female,  $p < .001$ ). There was no significant effect of the diagnosis and sex interaction (see Figure 1). Post-hoc comparisons revealed that ASD girls significantly differed in “we” frequency from TD girls and ASD boys but not from TD boys (TD girls > ASD girls = TD boys > ASD boys,  $p < .0001$ ).

Diagnosis and sex also significantly predicted “they” frequency (ASD < TD,  $p < .05$ ; male < female,  $p < .001$ ). The diagnosis and sex interaction did not have a significant effect (see Figure 1). Post-hoc analyses revealed that ASD boys differed in “they” frequency from ASD girls and TD girls (ASD girls > ASD boys,  $p = .001$ ; TD girls > ASD boys,  $p < .0001$ ).

Lastly, diagnosis and sex significantly predicted maze frequency (ASD > TD,  $p < .001$ ; male < female,  $p < .001$ ). There was a significant effect of the diagnosis and sex interaction ( $p < .001$ ; see Figure 2). Post-hoc analyses revealed that maze frequency significantly differed amongst all subgroups except for TD girls and boys (ASD girls > ASD boys > TD boys = TD girls,  $p < .0001$ ).

Conclusions: Preliminary analyses showed that sex significantly effected “we”, “they”, and maze frequency of ASD and TD participants. Because analyses did not omit instances where “they” pronouns were referring to inanimate objects (e.g., “those shoes”), these results should be interpreted with caution.

**508.024** (Virtual Poster) Similarities and Differences in the Generation of a Common Ground in ASD and TD

**E. Karin<sup>1</sup>**, R. Geva<sup>2</sup> and N. B. Bauminger-Zviely<sup>3</sup>, (1)School of Education, Bar Ilan University Israel, Ramat - Gan, Israel, (2)Psychology Department, Bar-Ilan University, Ramat-Gan, Israel, (3)School of Education, Bar-Ilan University, Ramat Gan, Israel

---

**Background:**

Common ground (CG) is generated when two interlocutors build shared knowledge and concepts during a reciprocal conversation (Clark, & Wilkes Gibbs, 1986). The understanding of CG's development and the factors that contribute to its generation process in Typically developing (TD) individuals is limited, and even more so in individuals that have core pragmatic deficit in social discourse (Bauminger-Zviely, 2013) like those on the autism spectrum(ASD). Understanding common ground more fully may shed light upon ASD's discourse difficulties and their influence on social interaction.

**Objectives:**

To examine a developmental curve of CG by group (CAASD/TD (via the individual growth curve model (Hoffman, 2015). CG was estimated by individual's intercept and slope variables including CG-time duration and CG-number of words. We also tested the contribution of verbal (IQ, language quality) and cognitive (executive function, theory of mind) mechanisms to the generation of CG.

**Methods:**

Study included 148 children and adolescents (6-16-years, 30 girls and 118 boys), 84 cognitively able (IQ>70) with ASD (CAASD) (IQ=103.88, CA=11.11) and 64 TD controls (IQ=114.53, CA=10.73). Groups matched on IQ and CA. Peer dyads were paired based on gender, IQ, and Chronological Age (CA). Study measures included a dyadic communicational CG task in which children described 10 different Tangram shapes to each other, six times (changing roles as follower and leader). Shapes were placed behind a screen, unseen to followers. We calculated the total number of words for each turn and each turn's total duration. We also counted children's phrases' type according to simple combination (short sentence that includes only one noun and one description) and complete phrases (description of the shape on the card as a complete pattern) for each CG-turn. In addition, we used parents' reports to evaluate children's two cognitive mechanisms, Theory of mind (TOM) (TOMI- Theory of Mind Inventory) and Executive Function (EF) (BRIEF - Behavior Rating Inventory of Executive Function).

**Results:**

Interestingly, even though children with CAASD produced more words and it took them longer to generate common ground at the first turn (the intercept), both groups showed similar developmental curve (slopes) in which they reduced the number of words and time duration from turn 1 to 6. Overall, both the verbal and cognitive mechanisms contributed to the generation of CG. Simpler combinations, complete phrases and better TOM and EF abilities contributed to more efficient CG in CAASD dyads, while all but EF predicted more efficient CG in TD group.

**Conclusions:**

The present study was conducted in a semi-natural conversational environment between dyads of peers and showed CAASD's ability to spontaneously learn through interaction and produce shared common ground. It opens new channels of research on the contribution of peer interaction to spontaneous learning in ASD. More so, the integration of language (phrase type) and cognitive (ToM, EF) mechanisms into social intervention models may suggest new ways to enhance the level of dialogue and social interaction core deficits in ASD.

**508.025** (Virtual Poster) The Use of Syntactic Bootstrapping in Verb Learning of Mandarin-Exposed Preschool Children with Autism Spectrum Disorder

**J. Su<sup>1</sup>**, Y. E. Su<sup>2</sup> and L. R. Naigles<sup>3</sup>, (1)Central South University, Changsha, China, (2)Child Language Lab, School of Foreign Languages, Central South University, Changsha, Hunan, China, (3)Psychological Sciences, University of Connecticut, Storrs, CT

---

**Background:**

Grammar is usually reported to be a strength in children with autism spectrum disorder (ASD, Tager-Flusberg, 2001; Naigles & Tek, 2017), but few studies have directly investigated the degree to which the grammar of children with ASD is abstract. Naigles et al. (2011) found that English-exposed preschool children with ASD used *syntactic bootstrapping*, via transitive frame, to conjecture causative meaning of novel verbs. However, questions still remain concerning the cross-linguistic viability of syntactic bootstrapping in ASD, especially in languages allowing pervasive ellipsis of verb arguments (e.g., Mandarin Chinese). This study explored Mandarin-exposed preschool children with ASD's use of syntax (including both transitive and intransitive frames) as a cue for verb learning.

**Objectives:**

Using Intermodal Preferential Looking paradigm (IPL; Naigles & Tovar, 2012), this study investigated whether Mandarin-exposed preschool children with ASD demonstrated syntactic bootstrapping, i.e., mapping novel verbs in transitive frames onto causative meaning and those in intransitive frames onto non-causative meaning.

#### Methods:

Participants included 11 Mandarin-exposed children with ASD aged  $62.91 \pm 13.82$  months and 15 younger Typically Developing (TD) children aged  $30.80 \pm 4.55$  months ( $p < .001$ ). The two groups were matched on expressive vocabulary (ASD:  $590.82 \pm 160.64$  words, TD:  $597.53 \pm 208.69$  words) and mean length of three longest utterances (MLU3); (ASD:  $5.52 \pm 0.98$ , TD:  $4.88 \pm 2.04$ ). Participants listened to sentences with a novel verb in transitive (e.g., 'the duck is *pou4*ing the bunny') or intransitive frame (e.g., 'the duck and the bunny are *ban2*ing') paired with two simultaneously performed causative and non-causative actions, and then they heard neutral sentences with the novel verb (e.g., 'look, *pou4*') paired with side-by-side separate causative and non-causative scenes.

#### Results:

For the percent looking to match measure, ANOVAs yielded a main effect of trial,  $F(1, 20) = 11.52$ ,  $p < .05$ , with no group effect. Follow-up t-tests showed that TD group demonstrated syntactic bootstrapping in both transitive and intransitive conditions, while ASD group only did so in intransitive condition (all tests 1-tailed). Specifically, TD group looked significantly longer at the causative scene during the test versus control trials when novel verbs appeared in transitive condition, total test:  $t(15) = 2.79$ ,  $p < .01$ , 2<sup>nd</sup> half of test:  $t(15) = 4.24$ ,  $p < .001$ , and they looked significantly longer at the non-causative scene in intransitive condition,  $t(15) = 1.93$ ,  $p < .05$ . Moreover, ASD group significantly preferred the non-causative scene during the 2<sup>nd</sup> half of the test versus control trials in intransitive condition,  $t(11) = 2.25$ ,  $p < .05$ . Additionally, for the ASD group, children with longer MLU3 performed better on syntactic bootstrapping in intransitive trials,  $r = .704$ ,  $p = .016$ , and the 2<sup>nd</sup> half of transitive trials,  $r = .613$ ,  $p = .045$ .

#### Conclusions:

While TD children used both transitive and intransitive frames to bootstrap verb meaning, Mandarin-exposed preschool children with ASD only utilized the intransitive frame in syntactic bootstrapping. In contrast to English-exposed children with ASD's strengths in using the transitive frame in syntactic bootstrapping (Naigles et al. 2011), Mandarin-exposed preschoolers with ASD's stronger utilization of the intransitive frame might be due to the disparity in the language environment, i.e., postverbal NPs is a stronger cue for transitive verbs in English than in Mandarin Chinese, 87% vs 39% (Naigles & Hoff-Ginsberg, 1995; Lee & Naigles, 2005).

#### **508.026 (Virtual Poster)** Frequency of Household Reading Predicts Receptive and Expressive Language Development over One Year for Autistic Toddlers

**J. R. Mathee-Scott<sup>1</sup>, T. Reuter<sup>2</sup>, S. Ellis-Weismer<sup>3</sup>, J. Saffran<sup>3</sup> and J. Edwards<sup>4</sup>**, (1)Communication Sciences & Disorders; Waisman Center, University of Wisconsin-Madison, Madison, WI, (2)Waisman Center, Madison, WI, (3)University of Wisconsin-Madison, Madison, WI, (4)University of Maryland, College Park, MD

**Background:** The importance of household reading for supporting language development has been well-established within typical development (Gilkerson et al., 2017) and prior findings suggest shared book reading interventions may facilitate language growth in children with autism spectrum disorder (ASD) (Boyle et al., 2019). There is an important link missing from the current literature: the impact of naturalistic reading in the home, absent of explicit reading intervention, on autistic children's language development remains largely unknown.

**Objectives:** Assess whether household book reading (i.e., caregivers' reported frequency of reading to their child at bedtime) predicts autistic toddlers' receptive and expressive language development.

**Methods:** Participants were 57 toddlers with ASD, who took part in a larger study with two longitudinal timepoints. An experienced clinician confirmed ASD diagnoses using the ADOS, ADI-R, and clinical experience. Toddlers were 24–36 months old at Time 1 ( $M = 30.4$ ,  $SD = 3.38$ ) and 37–50 months old at Time 2 ( $M = 43.8$ ,  $SD = 3.49$ ). To evaluate whether frequency of household reading might support toddlers' language development, we analyzed questionnaire data from Time 1 and standardized assessment data from both timepoints.

**Results:** We took a generalized linear model approach to predicting language development over time, analyzing receptive and expressive language separately, as in previous studies (Haebig et al., 2013). Based on related research (Raikes et al., 2006) our focal predictor in both models was Reading at Home, indexed by parent-reported frequency of bedtime reading with their child. Akin to prior studies (Haebig et al., 2013), we used difference scores to assess language development from Time 1 to Time 2. We measured Receptive Language via PLS-5 Auditory Comprehension raw scores and Expressive Language via PLS-5 Expressive Communication raw scores and calculated difference scores, subtracting Time 1 from Time 2. Covariates included parent-reported number of children's books at home, years of maternal education, and ASD severity (ADOS-2, Lord et al., 2012). Results revealed positive associations between Reading at Home and Receptive Language Difference Score ( $\beta = 3.14$ ,  $t = 9.91$ ,  $p < .01$ , Fig.1) as well as Expressive Language Difference Score ( $\beta = 1.77$ ,  $t = 7.42$ ,  $p < .001$ , Fig.2), and a negative association between ASD Symptom Severity and Expressive Language Difference Score ( $\beta = -1.76$ ,  $t = 6.72$ ,  $p < 0.05$ ).

**Conclusions:** This study provides the first evidence to date that naturalistic parent-child reading may bolster receptive and expressive language development in autistic toddlers, adding to a body of evidence that parent-child reading may support language more broadly (e.g., Karrass & Braungart-Rieker, 2005). By examining caregivers' everyday behaviors, this study adds a crucial piece of evidence to findings from controlled

interventions (e.g., Boyle et al., 2019). Naturalistic parent-child reading appears to support toddlers' emergent language skills, possibly by exposing them to a greater diversity of words (Montag et al., 2015) or by honing joint attention abilities that in turn facilitate learning (Ellis Weismer & Kover, 2015). Although the precise mechanisms remain to be discovered, the current study's message to caregivers is clear: Read to your autistic toddler.

**508.027** (*Virtual Poster*) Efficacy of High-Tech Alternative and Augmentative Communication (Avaz) for Children with Disabilities: A Qualitative Case Study in Northern India during Covid-19 Pandemic  
*D. Nair, Latika Roy Foundation, Dehradun, India*

Background:

In disabilities such as cerebral palsy and autism spectrum disorder, deficit in communication skills is one of the core symptoms. Furthermore, while Covid-19 may have been a boon for some families, for children with special needs it has been challenging. With intervention services moving predominantly to a virtual mode, high technology AAC has been efficacious for some families.

Objectives: The current study aims to check the effectiveness of Avaz application (a picture-based learning and communication tool) for children with disabilities from 7-18 years of age.

Methods:

6 participants were selected for the current study, 2 children between 7-14 years and 4 children between 15-18 years. The children were selected on the basis of their financial status (low to middle socio-economic strata), cognition (average intelligence IQ = 85-95), motor abilities (extremely poor motoric abilities led to exclusion), family support and education background of families. Avaz, a high-technology communication tool was the selected application. Participants were introduced to Avaz in their classrooms by the speech therapist and special educator via a tablet. The order of introduction for AVAZ was generalized for all participants, beginning with yes/no answers, followed by core words and moving on to more complex grammar and syntax depending on the individual's level. Each participant's family was involved for at least 2 sessions initially and a minimum of 10 sessions specific to AVAZ were taken involving the special educator in all.

Results:

Mean (SD) age of all participants in the study was 13.16 (4.26). The current study proved to show Avaz as a reliable mode of communication for individuals with various disabilities ranging from language disorders such as autism spectrum disorder to neuromotor disorders like Cerebral Palsy. It revealed that using the app improved social skills as well as overall expressive communication. A total of 10 questions were asked for each level (yes/no being the first, core words next) to assess consistent and correct responses. 6/6 participants responded correctly and consistently for questions using yes or no keys, 90% correct responses were observed for core words and nouns. 75% correct responses were observed for answers requiring verbs.

Conclusions:

Given the virtual mode may continue, Avaz app can be recommended as a mode of intervention for children over a wide age range with different disabilities and/or impairments. The app's features help improve an individual's social and communication adeptness along with being an educational tool in an inclusive therapy setup. This study concludes that a preliminary framework can be developed for individuals having varying special needs using AAC.

## Diagnostic, Behavioral & Intellectual Assessment

### PANEL — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

#### 208 - Quantitative Traits in ASD Research: Addressing Measurement, Etiology, and More

**Panel Chair:** Kristen Lyall, A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

**Discussant:** Kristen Lyall, A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

**208.001** (*Panel*) Harnessing the Quantitative Trait Indexed By the Social Responsiveness Scale to Elucidate the Developmental Sub Structure of Autism

*J. N. Constantino, Washington University School of Medicine, St. Louis, MO*

Background: Data has accumulated on the familial aggregation and transmission of the quantitative trait indexed by the Social Responsiveness Scale (SRS).

**Objectives:** To systematically examine hypotheses regarding the manner in which inherited liability confers developmental susceptibility to autism spectrum disorders (ASD).

**Methods:** Synthesis of a large body of genetic epidemiologic research implementing the Social Responsiveness Scale, contextualized by knowledge from key frontiers of contemporary science on autism and related disorders.

**Results:**

(1) Autism, even when defined according to less-than-perfect parameterizations of the condition, is highly heritable, on the order of 85% in the general population (Sandin et al., 2014), and most affected children are born to unaffected parents; (2) Sub clinical variations of the characterizing traits and features of autism aggregate in the unaffected family members of affected individuals, and such variations are continuously- distributed population wide (Wagner et al., 2019); (3) Within families in which autism recurs, the individual symptom profiles of co-affected family members paradoxically *diverge* (Spiker et al., 2002; Mazefsky et al., 2008; Castelbaum et al., 2020); (4) The many disparate *single-gene* conditions that lead to the convergent syndrome of autism are a) almost never inherited (rather *de novo*); and b) almost always associated with intellectual disability (Myers et al., 2020); (5) What predicts the recurrence of autism in families are joint elevations of heritable early developmental liabilities—*some non-specific to autism*—which can occur in different combinations or permutations in individual patients (Constantino et al., 2017; Constantino, 2019), and which appear independently-heritable (Pohl et al., 2019) and continuously-distributed in the general population.

**Conclusions:**

Autism heterogeneity may most reliably be parsed (“fractionated” as it were) before it occurs, not after, and in accordance with the inherited liabilities that led to it; traces of which may be partially or completely lost or distorted after the condition itself emerges. The current (and finite) slate of predictors include variation in social reciprocity (transmitted intergenerationally and indexed by the Social Responsiveness Scale), attention, hyperactivity, social visual orientation, motor coordination, tactile sensitivity, and cerebellar-dependent learning (Constantino et al., 2021). To the extent that the common allelic variations that give rise to familial autism are polygenic and incremental, they have been evolutionarily retained population wide, and are much better understood when studied across the wide range of variation they manifest in nature than at the tail of the distribution. In ways that are reminiscent of the Heisenberg Uncertainty Principle, the closer the tail is approached, the more the interpretation of observations is obscured—for most neuropsychiatric disorders this is likely explained by increased vulnerability to stochastic influences in clinical versus typical populations (Mazefsky et al., 2008; White, 2019; Castelbaum et al., 2020), and by the developmental consequences of impairment.

---

**208.002 (Panel) A Validation Study of Abbreviated Versions of the SRS and Implications for Epidemiologic Analysis**

**K. Lyall, A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA**

---

**Background:** The Social Responsiveness Scale (SRS) is a 65-item measure yielding a continuous score capturing autism-related traits. Score subsets of the SRS have been analytically examined but administration of shortened versions has not been evaluated in validation studies.

**Objectives:** The goal of this study was to compare distributional properties and predictive ability of two shortened versions of the SRS to the full 65-item SRS, in both a clinical and general population setting.

**Methods:** Study participants were drawn from the AJ Drexel Autism Institute clinic (n=154) and Kaiser Permanente Northern California (n=201) and block randomized to receive either the 16-item short SRS, a newly developed computer adaptive testing (CAT)-SRS, or the full SRS. Total scores across the three SRS administration methods were scaled to facilitate comparisons. Scores were plotted to assess distributional properties, while Receiver Operating Characteristic (ROC) analysis was used to estimate Area Under the Curve (AUC) and address predictive ability.

**Results:** Overall, distributional properties of the three administration methods were highly comparable, with shortened measures demonstrating similar ability to capture the range of the distribution and case non-case separation as the full SRS. In addition, AUC values were high (0.91-0.97) and comparable across the administration methods, though there was evidence of difference in predictive ability across measures for females (AUC for full SRS=0.99 vs 0.84 for short). Within individual comparisons of short vs full scores (available only for participants at the general population site), suggested underestimation of actual full SRS scores with the CAT-SRS.

**Conclusions:** Our findings broadly support the construct validity and performance of shortened SRS versions examined here, though the full measure may be needed to more accurately assess traits consistent with ASD diagnosis in females. This work suggests opportunities for collection of ASD-related phenotype in settings where participant burden or feasibility considerations may have otherwise prohibited such measurement.

---

**208.003 (Panel) Maternal Autistic Traits and Infant Brain and Behavioral Development**

**J. B. Girault, Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC**

---

**Background:** Autistic traits aggregate in first-degree family members of individuals with autism spectrum disorder (ASD). Younger siblings of children with ASD represent a familial high-risk (HR) group, and within HR families, quantitative autistic traits (QATs) may serve as useful, cost-effective early markers of inherited genetic liability for autism. Linking familial QATs to individual variation in early brain imaging and behavioral markers of ASD in HR infants has important implications for both etiology and prediction. If family traits account for significant variation in HR infant development, this would not only identify which phenotypes track with inherited risk for ASD and warrant further genetic dissection and mechanistic study, but it could also yield insight into individualized areas of concern relevant to early intervention.

**Objectives:** In the present study, we investigated associations between QATs in mothers and fathers and global brain volumes and behavioral development in their HR offspring.

**Methods:** Ninety-seven (97) high-risk siblings of children with ASD and 49 low-risk controls (LR-Neg) were included in this study. Clinical best estimate diagnosis was made at 24 months using DSM-IV-TR criteria; 20 HR children were diagnosed with ASD (HR-ASD), the remaining 68 did not met criteria (HR-Neg). Parent QATs were measured using the total score from the Social Responsiveness Scale, Second Edition (SRS-2). Parents were scored using the Informant Report form when completed and available, but if no Informant Report was available, Self-Report forms were used. Toddler verbal and non-verbal developmental quotients (VDQ, NDVQ) were derived from assessment with the Mullen Scales of Early Learning, and autism severity was measured using the ADOS calibrated severity score at 24 months. Total brain volume (TBV), gray matter volume (GMV), and white matter volume (WMV) were derived from MRI scans at 24 months. Linear models were used to examine associations between parental QATs (separately) and toddler brain and behavior variables, adjusting for sex, age, study site, and group (HR-ASD, HR-Neg, LR-Neg), including a group x parent QAT score interaction term.

**Results:** A significant group x maternal QAT interaction was found for TBV ( $b = 0.70$  (0.17, 1.21),  $p = 0.009$ ), GMV ( $b = 0.71$  (0.15, 1.27),  $p = 0.014$ ), and WMV ( $b = 0.71$  (0.21, 1.21),  $p = 0.006$ ) at 24 months, such that higher QATs were associated with larger brain volumes in HR-ASD toddlers, compared to LR-Neg. Pearson correlations revealed that maternal QATs explained 25% of the variance in toddler TBV ( $r = 0.50$ ,  $p = 0.05$ ). Higher maternal QATs were also associated with lower VDQ scores in HR-ASD offspring compared to LR-Neg ( $b = -0.47$  (-0.80, -0.14),  $p = 0.005$ ). No associations were found between maternal QATs and child autism severity or NVDQ. Paternal QATs were not significantly associated with child brain or behavior.

**Conclusions:** Maternal, but not paternal, autistic traits were predictive of toddler brain volume and verbal cognition during toddlerhood. These findings suggest that quantitative variation in subthreshold ASD traits in mothers explain variation in certain aspects of neurodevelopment in offspring.

#### **208.004 (Panel) Measuring Social Responsiveness in the Context of Intellectual Disability**

**C. M. Taylor<sup>1</sup>, M. I. Brown<sup>1</sup>, H. R. Fisher<sup>1</sup>, L. Walsh<sup>1</sup> and J. N. Constantino<sup>2</sup>, (1)Geisinger, Lewisburg, PA, (2)Washington University School of Medicine, St. Louis, MO**

**Background:** The use of parent-report questionnaires in the diagnosis of autism spectrum disorder (ASD) is relatively common. The Social Responsiveness Scale (SRS) is a frequently used clinical and research tool to identify the presence and severity of impairment in social communication, as well as the presence of restricted interests and repetitive behaviors. Despite adequate sensitivity and specificity among clinically selected samples (Constantino & Gruber, 2012), many parent-report ASD-screening tools such as the SRS do not adequately distinguish between presence and absence of ASD in individuals with intellectual disability (ID) (Thurm et al., 2019).

**Objectives:** The purpose of this study was to identify the impact of cognitive functioning on SRS scores.

**Methods:** Children presenting for diagnostic evaluation at a neurodevelopmental clinic were included in this analysis ( $n = 1,544$ ). All children in this sample completed a comprehensive neurodevelopmental evaluation for autism spectrum disorder. Diagnostic evaluations were completed by experienced professionals in developmental disabilities, including psychologists and neurodevelopmental pediatricians.

**Results:** We used multiple linear regression to estimate the unique effects of ASD and mild/moderate ID diagnoses on SRS T-scores. Children who were diagnosed with ASD scored significantly higher on the SRS ( $B = 5.86$ ,  $SE = 0.68$ ,  $t = 8.59$ ,  $p < .001$ ). Children diagnosed with mild or moderate ID also scored higher on the SRS ( $B = 6.56$ ,  $SE = 0.80$ ,  $t = 8.16$ ,  $p < .001$ ), regardless of ASD. These effects were also found while controlling for differences in age and sex. We also found this effect for ID on each of the five SRS treatment domain scores. Children presenting for diagnostic visits who were diagnosed with ID without ASD had clinically elevated SRS scores ( $M = 74.83$ ,  $SD = 11.39$ ,  $n = 203$ ) which were similar to those for children without ID who were diagnosed with ASD ( $M = 73.61$ ,  $SD = 12.35$ ,  $n = 883$ ). Next, we estimated the sensitivity and specificity for SRS scores as a predictor of ASD separately for children with or without ID. Despite strong sensitivity for SRS scores for both children with ID (96%) or without ID (85%), specificity was poor within both groups (11% and 27%, respectively). Among children with ID without ASD, 56% had clinically elevated scores on the SRS (T-score  $\geq 60$ ). This proportion of false positives was nearly three times that for children without ID (20% of children without ASD or ID had clinically elevated SRS scores). Specificity for ASD in the ID cohort only exceeded 50% when using the SRS severe risk cut score (T-score  $\geq 76$ ).

**Conclusions:** Our results suggest that elevated SRS scores may not be specifically attributable to ASD within neurodevelopmental clinic settings. Instead, we find that SRS scores may also be elevated due to other factors including ID. These results suggest that available ASD parent report diagnostic questionnaires are insufficient for differentiating between presence and absence of ASD in individuals with mild to moderate ID. There is a critical need to develop and validate diagnostic questionnaires to assess ASD symptomology in cognitively impaired cohorts.

### **PANEL — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT**

#### **211 - Advancing Understanding of Neurogenetic Syndromes through Novel Analytic and Measurement Approaches**

**Panel Chair: Antonio Hardan, Psychiatry & Behavioral Sciences, Stanford University, Stanford, CA**

**Discussant: Mustafa Sahin, Boston Children's Hospital, Boston, MA**

**211.001 (Panel)** Developing and Validating Touch Screen Tasks As Digital Biomarkers and Objective Outcome Measures for Neurodevelopmental Conditions and Rare Genetic Syndromes

**E. Loth<sup>1</sup>, J. Kozielec<sup>2</sup>, A. Pilkington<sup>3</sup>, A. N. de Rothschild<sup>4</sup>, A. Fritz<sup>5</sup>, A. Goodwin<sup>6</sup>, A. Azor<sup>7</sup>, P. F. da Costa<sup>8</sup>, E. J. Jones<sup>9</sup> and R. Leech<sup>8</sup>,** (1)*Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology, and Neuroscience, King's College London, London, United Kingdom,* (2)*Department of Forensic and Neurodevelopmental Sciences, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom,* (3)*Institute of Psychiatry, Psychology & Neuroscience, King's College London, UK, London, United Kingdom,* (4)*Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom,* (5)*Kings College London, London, United Kingdom,* (6)*Centre for Neuroimaging Sciences, King's College London, London, United Kingdom,* (7)*Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom,* (8)*Imperial College London, London, United Kingdom*

**Background:** The era of transdiagnostic, precision medicine and “big data” approaches to neuropsychiatry requires reliable, valid, and scalable tests that can be used in individuals with diverse neurodevelopmental conditions across all age and ability levels. For example, large-scale genetic studies require phenotypic characterisation of individuals with genetic syndromes as well as family members. Clinical trials rely on objective outcome measures that overcome “placebo effects”, are sensitive to change, reliably correlate with relevant clinical features and link to underlying mechanisms. To date, we do not have a validated test battery that consistently assesses fundamental social, emotional, cognitive and sensory processes in children and adults. In particular, sensitive tests for people with severe intellectual disability (ID), as often comorbid with genetic syndromes, are missing.

**Objectives:** This project aimed to develop, optimise and validate a suite of touch screen tests for individuals with neurodevelopmental conditions and rare genetic syndromes for use as digital biomarkers and/ or objective outcome measures. Our tests combine animated, interactive cartoons and cutting-edge artificial intelligence approaches to assess five fundamental transdiagnostic processes (social, emotional, cognitive, motivational, and sensory).

**Methods:** We created three companion versions: “Pip and the Brain Explorers” for preschoolers (3-6 years) and children with ID, 2. “Time Trekkers” for school-going children (aged 6-12 years) and “Brain Train”, for adolescents and adults from 13 years. Cartoons, demonstrations, practice trials, and inbuilt rewards are used to increase motivation, comprehension and test for “pre-requisite” processes (e.g., categorisation) needed to complete tasks. We used Bayesian Optimization<sup>1</sup> to adjust task difficulty to one’s prior performance history. This approach imports the structure of some IQ tests to the social and emotional domains. Some tests ‘back-translated’ behavioural assays used in animal models of rare genetic syndromes (social novelty task<sup>2</sup>) or use psychophysical methods (frequency discrimination task). Task development has been carried out in an iterative manner. Validation criteria include 1) data acquisition rates, 2) psychometric properties, 3) assessment procedures (i.e. researcher administered vs. tested at home by parents), and 4) the effect of version/ surface features. If a task does not meet our criteria (e.g., acquisition rates below 80%), it is revised, and the new version tested anew.

**Results:** We created 13 subtests of the preschool version, 8 subtests of the schoolgoing version and 6 subtests of the adolescent/ adult version. The preschool version was tested in 82-123 children aged 30- 60 months (including 34 with autism and/ or ID, ~70 were recruited via AIMS-2-TRIALS PIP, 50 children tested online in the UK). Acquisition rates of 10 subtests ranged from 91-100%. By changing the narrative and surface features of a social reward learning task (from “Milkman” to “Come-play-with-me”) we increased acquisition rates in 3-4 year olds from 68% to 91%. Split-half reliability ranged from 87-.95. Two subtests with acquisition rates <80 are being revised.

**Conclusions:** We provide ‘proof-of-concept’ that we can reliably assess these fundamental processes in preschool children with neurodevelopmental conditions, including ID. We will further report on ongoing efforts of validation, standardisation and comparison with the school-going and adolescent/ adult versions.

**211.002 (Panel)** Development of a Neurobehavioral Evaluation Tool for Neurogenetic Syndromes Associated with Autism

**T. W. Frazier<sup>1</sup>, A. Y. Hardan<sup>2</sup>, E. Youngstrom<sup>3</sup> and M. Uljarevic<sup>4</sup>,** (1)*Psychology, John Carrol University, Cleveland, OH,* (2)*Psychiatry & Behavioral Sciences, Stanford University, Stanford, CA,* (3)*University of North Carolina at Chapel Hill, Chapel Hill, NC,* (4)*School of Psychological Sciences, University of Melbourne, Stanford, CA, Australia*

**Background:** Neurodevelopmental genetic syndromes (NDGS) associated with autism have low prevalence with isolated cases geographically distributed throughout the world. Many NDGS show a wide range of functioning from substantial cognitive and functional impairments with significant autism symptoms to cognitive and functional levels closer to the neurotypical range. As a result, neurobehavioral assessment is challenging and many traditional measures have limited applicability. Thus, there is a great need for neurobehavioral measures that were expressly developed to measure key cognitive, emotional, and functional domains relevant to NDGS patients and families.

**Objectives:** The primary aim was to develop and validate a neurobehavioral evaluation tool (NET) that includes two components: informant (parent)-report survey scales and patient-completed webcam performance measures. The study was designed to assess a range of psychometric properties, including: scale structure, reliability, construct validity, and sensitivity to change.

**Methods:** The development phase of the study included a set of 9 clinician-scientist experts and 10 parent/caregiver informants from 5 NDGS groups (PTEN, SYNGAP1, ADNP, SCN2A, and NFIX/Malan Syndrome) as well as 1 clinician-scientist and 1 parent/caregiver informant for idiopathic ASD. Participants provided input on the most crucial neurobehavioral domains and content areas as well as quantitative and qualitative input on item appropriateness and wording. Simultaneously, concept elicitation interviews were conducted with PTEN patients and parent/caregiver informants to

identify key neurobehavioral domains relevant to this patient group. Data from these processes were combined to generate a concept map and to inform final scale and item development.

**Results:** Thirteen neurobehavioral domains were rated as having medium to high importance for NDGS patients and qualitative data from concept elicitation interviews supported the selection of these domains and informed specific content areas for item coverage. Of the 13 most highly rated domains, 11 were selected for NET survey scale development and the remaining two were determined to be best evaluated with existing clinical methods (e.g., seizures – EEG evaluation; speech/language – patient-completed testing). The final 11 survey scales were generally brief (15 to 35 items) with good but not complete content coverage of key constructs within each domain. Final items selected were rated as easy to understand and highly relevant to each domain and NDGS patient group. NET patient-completed webcam performance measures were created for 4 cognitive paradigms: social attention, processing speed, receptive vocabulary, and single-word reading. Preliminary testing indicated that many patients could complete valid evaluations the first three paradigms with the fourth paradigm being more challenging and appropriate only for individuals with higher cognitive levels.

**Conclusions:** The development phase of NET is complete, yielding 11 informant (parent)-report survey scales and 4 patient-completed webcam cognitive paradigms. The next phase of development will involve collection of both NET components from more than 300 patient/informant pairs from each of these above groups as well as 120 sibling and unrelated healthy controls (ages 3-45) at baseline, 1-month follow-up, and 4-month follow-up. These data will be crucial for validating the NET measures, determining any needed adjustments, and providing key psychometric properties to support future implementation in research and, eventually, in clinical practice.

**211.003 (Panel)** The Sensory Assessment for Neurodevelopmental Disorders (SAND) in Neurogenetic Syndromes: Natural History, Response to Treatment, and Relationships with Core Symptoms

**P. M. Siper<sup>1</sup>, C. F. Layton<sup>2</sup>, T. Levy<sup>1</sup>, J. Zweifach<sup>1</sup>, S. Sethuram<sup>3</sup>, J. H. Foss-Feig<sup>1</sup>, J. D. Buxbaum<sup>4</sup> and A. Kolevzon<sup>1</sup>,** (1)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Department of Pediatrics, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY

---

**Background:** Sensory reactivity symptoms represent one of the earliest clinically observable predictors of a neurodevelopmental disorder and are widely reported in autism spectrum disorder (ASD) and related conditions. There is a growing body of evidence describing sensory differences in neurogenetic syndromes, including syndrome-specific phenotypes. However, little is known about how these symptoms progress over time, respond to treatment, or relate to other core ASD symptoms. Identifying factors that may predict prognosis could lead to earlier and more specific interventions for populations with a high likelihood of longstanding sensory symptoms.

**Objectives:** To examine the utility of the Sensory Assessment for Neurodevelopmental Disorders (SAND) as a method to objectively measure natural history, treatment response, and relationships with core ASD symptoms in two neurogenetic syndromes: Phelan-McDermid syndrome (PMS) and Activity-Dependent Neuroprotective Protein (ADNP) syndrome.

**Methods:** The SAND is a clinician-administered observation and corresponding caregiver interview that quantifies sensory hyperreactivity, hyporeactivity and seeking within visual, tactile, and auditory modalities. The SAND was administered to 33 children with PMS ( $M_{age} 6.33 \pm 2.58$ ) and 23 with ADNP syndrome ( $M_{age} 7.09 \pm 3.37$ ) in the context of ongoing phenotyping studies. To date, longitudinal data was collected from 6 children followed for three visits at least one year apart. The SAND was also piloted in two recent clinical trials, including 4 children with PMS receiving recombinant human growth hormone (rhGH) for 12 weeks, and 10 children with ADNP syndrome receiving a single-dose of ketamine (0.5 mg/kg) infused intravenously over 40 minutes and followed four weeks post-infusion. Relationships between the SAND and the Aberrant Behavior Checklist (ABC) Lethargy/Social Withdrawal subscale, a primary outcome in both studies, were examined using the full sample.

**Results:** Natural history data suggested, on average, total scores were relatively stable over time. Symptom presentation within individuals was notably stable, particularly hyporeactivity. Low levels of sensory seeking at baseline remained stable. In contrast, high levels of sensory seeking at baseline varied, with one participant showing an increase in symptoms and another displaying improvement followed by worsening symptoms.

PMS clinical trial data indicated improvement in hyporeactivity symptoms in 3 of 4 participants following rhGH treatment. Results from the ADNP trial indicated significant improvement in SAND Total Score from Baseline to Week 1 ( $p=.025$ ) and Baseline to Week 4 ( $p=.05$ ). Hyperreactivity ( $p=.048$ ) and Seeking ( $p=.036$ ) also improved significantly from Baseline to Week 4.

In the PMS group, ABC Lethargy/Social Withdrawal significantly correlated with SAND Total Score ( $r=.521, p=.002$ ), Hyperreactivity ( $r=.354, p=.043$ ) and Hyporeactivity ( $r=.360, p=.04$ ) scores. Similarly, ABC Lethargy/Social Withdrawal scores significantly correlated with SAND Total Score ( $r=.577, p=.004$ ) and Hyporeactivity ( $r=.606, p=.002$ ) scores.

**Conclusions:** Findings demonstrate novel applications of the SAND in neurogenetic syndromes and demonstrate the potential of this measure as a tool to capture change over time and in response to treatment. A shift from our reliance on subjective caregiver questionnaires to objective multimodal approaches as offered by the SAND may improve our understanding of sensory phenotypes and relationships with core symptoms while offering an important new endpoint for use in clinical trials.

**211.004 (Panel)** Developing Computational Infrastructure for Better Characterization of Clinical Variance in Repetitive Behaviors Among Individuals with Neurogenetic Syndromes

**Background:** A number copy number variants (CNVs) have been shown to represent an increased risk for autism spectrum disorder (ASD). It has been argued that taking a genetic-first approach and characterizing the specific phenotypes associated with specific CNVs holds a significant promise for a better understanding of mechanisms behind ASD heterogeneity. However, studies to date have utilized case-control designs comparing these individuals with small, non-representative idiopathic ASD samples. Normative modelling represents a powerful example of precision medicine as it establishes reference standards in a specific group thus allowing precise anchoring of each individual's performance against established standard. However, there have been no attempts to date to utilize this method to quantify whether CNVs differ in their specific symptom profiles from what would be expected from a large heterogeneous cohort of age, sex and IQ matched ASD individuals.

**Objectives:** Current investigation aimed to develop reference standards that would enable clinicians and researchers to quantify individual differences in specific restricted and repetitive behaviors (RRB) subdomains in individuals with neurogenetic syndromes against models of expected age-, cognitive functioning- and sex-related trends seen in idiopathic ASD.

**Methods:** Normative tables and individual percentile scores for Repetitive Behavior Scale-Revised (RBS-R) subscales were derived using the data from 17,581 ASD youth without reported genetic syndromes ( $M_{age} = 8.24$  years,  $SD_{age} = 4.06$ ;  $n = 3,395$  females,  $n = 14,186$  males) from the Simons Foundation Powering Autism Research for Knowledge (SPARK) database. Developed percentile scores were used to characterize RRB profiles among individuals with a range of genetic syndromes (e.g., 22q11.2 deletion and duplication syndrome, Fragile X Syndrome, PTEN mutation, Tuberous Sclerosis Complex [TSC]) and ASD diagnosis from the SPARK database ( $n = 457$ ;  $M_{age} = 8.55$  years,  $SD_{age} = 3.81$ ;  $n = 138$  females).

**Results:** Generalised additive models (GAM) were used to model the linear and non-linear associations between RBS-R subscales with sex, age and cognitive functioning in idiopathic cohort. Male sex was associated with higher repetitive motor behaviors (RMB) and restricted interests and lower compulsions and self-injurious behaviors (SIB). RMB showed a mostly linear (negative) association with age, other RRB domains showed more complex and non-linear associations. All RRB domains showed a significant linear association with cognitive functioning. Based on GAMs, we developed normative models for idiopathic autism for each of the RBS-R subscales and utilized derived models to determine whether certain neurogenetic syndromes significantly deviated from expected distribution of RBS-R scores for idiopathic autism given the individual's sex, age, and cognitive functioning. While a number of neurogenetic syndromes (e.g., 1q21.1 duplication, 22q11.2 duplication, 15q deletion and duplication) had comparable severity of different RRB subdomains as seen in idiopathic ASD, other syndromes had either uniformly more severe RRB (e.g., Angelman syndrome, 22q11.2 deletion) or showed higher severity for only certain RRB subdomains (e.g., TSC for motor stereotypies and self-injurious behaviors). There were significant individual differences within each neurogenetic syndrome.

**Conclusions:** This study provides a computational approach that will serve as a unique open-source resource for future clinical and research work focused on understanding clinical profiles among individuals with neurogenetic syndromes associated with ASD.

## ORAL SESSION - 5A — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

### 305 - Important Demographic Considerations in ASD Diagnosis: A Deeper Dive

#### 305.001 (Oral) Racial Disparities in the Clinician-Reported Validity of Autism Diagnostic Evaluations

**C. Nadler<sup>1</sup>, L. Wiggins<sup>2</sup>, M. S. Durkin<sup>3</sup>, N. Reyes<sup>4</sup>, S. Rosenberg<sup>5</sup>, L. Eck<sup>6</sup>, J. Daniels<sup>7</sup> and R. Fitzgerald<sup>8</sup>**, (1)*Children's Mercy Kansas City, Kansas City, MO*, (2)*Centers for Disease Control and Prevention, Atlanta, GA*, (3)*Population Health Sciences, University of Wisconsin School of Medicine and Public Health, Madison, WI*, (4)*JFK Partners, University of Colorado Anschutz Medical Campus, Aurora, CO*, (5)*University of Colorado Anschutz Medical Campus, Aurora, CO*, (6)*Washington University School of Medicine, St. Louis, MO*, (7)*University of North Carolina at Chapel Hill, Chapel Hill, NC*

**Background:** Non-Hispanic Black (NHB) and Hispanic/Latino children are diagnosed with autism spectrum disorder (ASD) later than non-Hispanic White (NHW) children. Inequities in community identification and referral practices can limit access to timely supportive services and produce downstream disparities in health outcomes for individuals from marginalized communities across the lifespan. Most investigations focus on broad associations between sociodemographic characteristics and outcomes to describe disparities, with few opportunities to examine how specific clinical elements within “gold-standard” autism diagnostic processes may influence disparities observed at the group level.

**Objectives:** This study examined associations between family sociodemographic factors (i.e., race/ethnicity, parental education, income) and clinician ratings of the quality and validity of the data from their own administrations of the Autism Diagnostic Interview-Revised (ADI-R) and Autism Diagnostic Observation Schedule (ADOS).

**Methods:** The Study to Explore Early Development (SEED) is a multi-site case-control study of children evaluated between 30-68 months of age. Mothers completed the Social Communication Questionnaire (SCQ) to determine ASD risk. Children with elevated SCQ scores or previous ASD diagnosis participated in an evaluation that included the Mullen Scales of Early Learning (MSEL), ADI-R, and ADOS. The ADOS and ADI-R were administered by SEED clinicians who achieved research reliability status and engaged in quarterly calibrations throughout the study period to minimize coding discrepancies. Clinicians also completed ratings of the “quality and validity” of each ADOS/ADI-R administration, ranging from 0-3 (“Invalid/Very Poor Quality” to “Good Quality”). We built separate ordinal logistic regression models for the ADI-R and ADOS. The outcome was clinician-rated validity of the assessment data. The primary predictor in each model was race/ethnicity of the mother (ADI-R) or child (ADOS). We

considered covariates including maternal education, family income (percentage of the Federal Poverty Level), SEED study site, maternal age, child sex, MSEL composite, and mother-reported autism symptomology via the Social Responsiveness Scale (SRS).

Results: Demographic and validity data were available for 1,078 families who completed the ADI-R and/or ADOS; in both samples, 45% of mothers identified as NHW and 28% as NHB. Clinicians (n=27) rated approximately 80% of ADI-R and ADOS data as “Good Quality.” In the unadjusted ADI-R model, clinicians were significantly less likely to rate interview data as “Good Quality” for NHB mothers relative to NHW mothers (OR 0.33, 95% CI 0.23-0.46); this association remained after adjusting for covariates (aOR 0.35, 95% CI 0.23-0.52). We observed no other maternal race/ethnicity associations in ADI-R data. For the ADOS, validity ratings did not differ significantly by child race/ethnicity for any group, including NHB children (aOR 0.89, 95% CI 0.58-1.37).

Conclusions: Under rigorously controlled administration conditions, clinicians’ ADOS validity ratings did not differ by child race/ethnicity, but clinicians were 65% less likely to rate ADI-R data from NHB mothers as “Good Quality” compared to data from NHW mothers. Clinician implicit bias, measurement inadequacies, and other unmeasured factors may contribute to these contrasting patterns. These findings raise critical questions about how real or perceived differences in the validity of standardized (and unstandardized) autism diagnostic interviews may be an unaddressed mechanism of downstream disparities.

### **305.002 (Oral)** Evaluation of Racial and Sex Bias in the Autism Diagnostic Observation Schedule: An Item-Response Theory Analysis

**L. Kalb**<sup>1,2,3</sup>, **V. Singh**<sup>2</sup>, **J. S. Hong**<sup>2,4</sup>, **C. B. Holingue**<sup>2,5</sup>, **N. N. Ludwig**<sup>6</sup>, **P. Danika**<sup>2,4</sup>, **R. Reetzke**<sup>2,4</sup>, **A. Gross**<sup>7</sup> and **R. Landa**<sup>2,4</sup>, (1)Department of Mental Health, Johns Hopkins School of Public Health, Baltimore, MD, (2)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (3)Department of Neuropsychology, Kennedy Krieger Institute, Baltimore, MD, (4)Department of Psychiatry and Behavioral Sciences, Johns Hopkins University School of Medicine, Baltimore, MD, (5)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (6)Neuropsychology, Kennedy Krieger Institute, Baltimore, MD, (7)Johns Hopkins School of Public Health, Baltimore, MD

---

Background: There are long-standing disparities in the prevalence of Autism Spectrum Disorders (ASD) across race and sex. Males are three to four times more likely to be diagnosed with ASD than females and under-identification of ASD has been consistently reported in minority racial groups (Jo et al., 2015). There are many mechanisms that drive disparities, including lack of access to care, stigma, and developmental literacy (Zelege et al., 2019). Standardized diagnostic assessments may also contribute to disparities in the timing and accuracy of an ASD diagnosis. However, few studies have examined if these disparities arise partially from systematic biases in the Autism Diagnostic Observation Schedule-Version 2 (ADOS-2), the gold standard measure of ASD. To date, only one study has examined ADOS measurement bias at the item-level, by sex and race, using item response theory (Harrison et al., 2017). While that study found minimal biases, it has several significant methodological limitations (e.g., use of an outdated version of the ADOS, small non-White sample sizes) that are overcome by the present study.

Objectives: To examine differential item functioning of ADOS-2 items across sex (females compared to males) and race (Black/African American compared to Whites) using an item response theory framework.

Methods: In this cross-sectional study, 6269 children, ages 1-17 years (M = 6.8y, SD = 3.3y; 59.3% White, 22.0% Black/AA, 79.6% Male), were evaluated for ASD between 2014 and 2020 at an ASD specialty clinic located in the Mid-Atlantic region of the US. Item-level biases across ADOS-2 harmonized algorithm items, including social affect (SA; 10 items) and restricted/respective behaviors (RRB; four items), were evaluated across Modules 1-3. Measurement bias was identified by examining differential item functioning (DIF), within an item-response theory framework, using an ordinal logistic regression model. Statistical significance was determined by a likelihood ratio chi-square test, while R-squared, regression coefficients, and salient DIF analyses were used to examine the magnitude and direction of DIF.

Results: For race, nine unique items exhibited significant DIF ( $p < .05$ ). Almost all of the items with DIF involved SA, however no single item showed DIF consistently across all modules. Most items with DIF (seven out of nine) had higher difficulty in Black/African Americans compared to Whites. For sex, five unique items showed significant DIF. Most items with DIF involved RRB (three out of five). Stereotyped language evidenced DIF across all five algorithms. Greater difficulty for females (compared to males) was most often observed, especially for Module 3. While greater item difficulty resulted in underestimation of ASD severity, the magnitude of DIF was small for both race and sex.

Conclusions: Findings suggest the ADOS-2 does not have widespread systematic measurement bias across race (Black/African American compared to Whites) or sex (female compared to male). However, the findings raise some concerns about under detection of SA for Black/African American, and RRB for females, particularly in Module 3. Consistent measurement bias involving stereotyped language, for females across all Modules, warrants particular attention and further research.

### **305.003 (Oral)** Are the Diagnostic Rates of Autistic Females Increasing? an Examination of State-Wide Trends

**C. Harrop**<sup>1</sup>, **C. B. Klein**<sup>2</sup>, **O. C. Putnam**<sup>1</sup>, **E. M. Lamarche**<sup>2</sup> and **L. G. Klinger**<sup>1</sup>, (1)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC, (2)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC, (3)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC

---

Background:

Autism spectrum disorder (ASD) has been considered a “male dominant” condition, with a ratio weighted in 4:1 in favor of males (Baio et al., 2018; Fombonne, 2009; Maenner et al., 2020). However, research suggests that autistic females are underdiagnosed and misdiagnosed, with an estimated sex ratio closer to 3:1 based on recent meta-analytic studies (Loomes et al., 2017). Autistic females are diagnosed, on average, two years later than their male peers, particularly when they present with minimal language delays (Begeer et al., 2013; Duvekot et al., 2017; Harrop et al., 2021; McCormick et al., 2020; Salomone et al., 2015).

## Objectives:

The purpose of this study was to examine historical trends in the diagnosis of autism in females across the past two decades. Specifically, (1) whether more females are being diagnosed over time and (2) whether the number of late diagnosed females (females diagnosed in adolescence and adulthood) has increased.

## Methods:

Data for this study was drawn from diagnostic evaluations conducted across statewide outpatient clinics operated by the University of North Carolina TEACCH Autism Program. To evaluate historic trends in diagnosis, we used data from January 2000 to September 2021. Data from 10,028 participants (males = 8135, females = 1893) were included in the initial analyses. Our analysis focused on the rates of females diagnosed over time, the age of diagnosis by assigned sex over time, and the proportion of late diagnosed individuals (13 years and above) by time and assigned sex.

## Results:

The proportion of females receiving first time diagnoses increased over time from 15% between 2000-2005 to 24.55% after 2016 ( $X^2 [3, N = 10,028] = 63.66, p < .001$ ; Table 1). The average age of diagnosis for females across the whole sample was 10 months later than males ( $F = 67.30, p < .001$ ; Table 1). The age of diagnosis overall increased overtime ( $F = 10.78, p < .001$ ), with later diagnoses from 2011 onwards relative to 2000 - 2010. This was driven by an interaction between sex and date ( $F = 5.29, p = .001$ ), with the age of diagnosis for females increasing at a greater rate over time. More females were late diagnosed ( $X^2 [1, N = 10,028] = 64.65, p < .001$ ; Table 1), with the proportion of late diagnosed females increasing more over time.

## Conclusions:

The proportion of autistic females diagnosed at state-wide autism centers has increased steadily over a 20-year period. This increase of females receiving their initial diagnosis from 2016 onwards likely reflects greater societal knowledge of how ASD may manifest differentially in females. The rate of females diagnosed in adolescence and adulthood has also rapidly increased during this time. While these statewide trends are encouraging, efforts must be made to identify autistic females earlier to improve their access to appropriate supports and to provide a sense of identity (Bargiela et al., 2016). Future work includes the analysis of IQ and autism severity data to understand if the profile of females entering TEACCH clinics has changed overtime, accounting for some of the findings reported here.

### **305.004** (Oral) Community-Referral Vs. Siblings with Familial Risk for Autism Spectrum Disorder: Clinician Certainty in the Diagnosis of Toddlers

**E. McQueen<sup>1</sup>, H. Walum<sup>1</sup>, A. Klin<sup>1</sup>, W. Jones<sup>1</sup>, S. P. White<sup>2</sup> and C. Klaiman<sup>3</sup>,** (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Emory University School of Medicine, Atlanta, GA, (3)Marcus Autism Center, Emory University, Atlanta, GA

**Background:** The differential diagnosis of autism spectrum disorder (ASD) is multifaceted and heterogeneous, often resulting in uncertainty of a toddler's diagnosis (Rogers et al., 2016, Penner et al., 2017, Matson et al., 2012). Increased uncertainty could prolong timing of diagnosis and access to intervention, known to negatively impact children's outcomes (Zwaigenbaum et al., 2015). In community-referred toddlers and preschool-aged children, McDonnell et al. showed that clinicians made 60% of ASD diagnoses with complete certainty (2019). ASD core symptoms (social affect, restricted/repetitive behaviors (RRBs)) are shown to be the strongest predictors of clinician certainty when making a diagnosis (Hedley et al., 2016). Given the complicated, heterogenous and broader autism phenotype often seen in siblings at elevated likelihood for ASD (older sibling with an ASD diagnosis; EL-ASD) (Chawarska et al., 2014), here we investigate whether clinician certainty in the diagnosis of ASD differs by risk status and whether factors, such as specific autism symptomatology, language and cognitive ability increase or decrease certainty.

**Objectives:** This study specifically explores differences between community-referred, EL-ASD and non-ASD toddlers in the predictive value of symptomatology on diagnostic certainty.

**Methods:** Participants included community-referred toddlers with ASD ( $n=110$ ,  $M_{age}(SD)= 24.35(3.47)$  months), EL-ASD siblings ( $n=59$ ,  $M_{age}(SD)=23.95(3.31)$  months), and a chronological age-matched sample of typically developing toddlers (non-ASD) ( $n= 85$ ,  $M_{age}(SD)= 23.51(1.98)$  months). Receptive and expressive language and cognitive ability was assessed with the Mullen Scales of Early Learning. Diagnostic confirmation was made via clinician best estimate using the ADOS-2 toddler module, parent interview and observations. Clinician diagnostic certainty was rated on a 5-point scale (complete certainty described as '81-100%: extremely certain of diagnostic presentation').

**Results:** Certainty was evaluated in relation to group and diagnostic status (community-referred ASD, EL-ASD, non-ASD). Chi square analyses showed that clinicians were more certain in diagnosing ASD in community referrals over EL-ASD and non-ASD diagnosis ( $\chi^2=19.56, p<0.001$ ). Community-referral diagnoses made with complete certainty (90%) were greater than that of EL-ASD (62.7%) and non-ASD diagnoses (74.1%). ADOS-2 social affect, RRBs, and algorithm scores all significantly correlated with clinician certainty across groups. However, RRB scores were the largest predictor of diagnostic certainty in community referred diagnosis ( $r_t=0.372, p<0.001$ ); while total algorithm scores were the greatest predictor for EL-ASD and non-ASD toddlers ( $r_t(EL-ASD)=0.424, p<0.001$ ;  $r_t(non-ASD)=-0.259, p=0.005$ ). In addition to RRBs, receptive language, not expressive or cognitive ability, predicted diagnostic certainty in community-referred toddlers ( $r_t=-0.194, p<0.001$ ).

Conclusions: These results aid in our understanding of the discrepancies in diagnostic certainty of ASD in community-referred, EL-ASD, and non-ASD toddlers and the challenge clinicians face in differential diagnosis. Community-referred increased symptomatology and certainty in diagnosis possibly indicates a “wait-and-see” model where complete symptomatology is already present prior to referral, resulting in delayed intervention. ASD symptomatology, particularly RRBs, may be attenuated in EL-ASD, which could negatively impact diagnostic certainty and highlights the importance of continued observation of children at familial risk for ASD. Preliminary analyses indicate the need to better understand the diagnostic features predicting clinician certainty, in order to increase access to interventions as soon as symptoms begin to emerge.

## POSTER SESSION — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

### 409 - Diagnostic, Behavioral & Intellectual Assessment I

#### 409.025 (Poster) Factors Affecting Parental Quality of Life in Young Children with Autism Spectrum Disorder in Singapore

Y. Q. Kang<sup>1</sup>, R. Aishworiya<sup>2</sup>, S. C. Chong<sup>1</sup>, K. Mulay<sup>1</sup>, T. S. Lim<sup>1</sup>, M. Y. Tan<sup>3</sup>, J. Kiing<sup>1</sup> and J. Y. Bong<sup>3</sup>, (1)National University Hospital, Singapore, Singapore, (2)Paediatrics, National University Health System, Singapore, Singapore, (3)National University Hospital Singapore, Singapore, Singapore

#### Background:

Parents of children with autism spectrum disorder (ASD) tend to experience greater parenting stress and psychological ill-effects. Quality of Life (QoL) of parents is a critical outcome measure when supporting families of children with ASD. Identifying specific child factors which impact parental QoL, a culturally sensitive construct, can facilitate targeted intervention strategies.

#### Objectives:

To identify child and family factors associated with parental QoL of parents of children with ASD.

#### Methods:

This cross-sectional study was conducted at a tertiary developmental pediatric centre in Singapore from September 2019 and August 2021. Inclusion criteria was 1. Parent with a child with ASD aged between 5 and 8 years, and 2. Child diagnosis of ASD following clinical evaluation by a developmental pediatrician and/or formal psychological evaluation with the Autism Diagnostic Observation Schedule. Parents completed the Quality of Life in Autism Questionnaire (QoLA), parent version. The QoLA contains 2 subscales: part A measures parental self-rated QoL (score range 28-140, higher scores denote greater perceived QoL); part B measures perceived problems due to child's ASD-related behaviors (score range 20-100, higher scores denote fewer perceived problems due to behavior). Parents also answered a family demographic questionnaire, Repetitive Behavior Questionnaire-2 and Social Responsiveness Scale (SRS). Standardized child assessments included the Vineland Adaptive Behavior Scales (VABS-2), Mullen Scales of Early Learning (MSEL), Kaufman Brief Intelligence Test (KBIT) and Weschler scales of Intelligence. Descriptive statistics and linear regression were used to identify variables associated with QoLA scores.

#### Results:

Parents of 81 children (85.2% male, mean age 6.2 years, SD 1.9) completed the study. After controlling for gender and family history of autism, QoLA part A scores were higher (greater parental perceived QoL) in parents whose children had greater rigidity and adherence to routine on the RBQ ( $B=1.401$ ,  $p=0.021$ ). Family financial insecurity ( $B=22.8$ ,  $p=0.009$ ) and lower VABS socialisation scores ( $B=-0.535$ ,  $p=0.038$ ) were predictive of higher QoLA part B scores indicating less perceived problematic behaviours by parents. Scores on the KBIT, Weschler scales, MSEL and SRS were not significantly associated with the QoLA scores. Age when child started therapy was also not significantly associated with QoLA scores.

#### Conclusions:

Rigidity in children with ASD with greater adherence to routine may contribute to better parental quality of life due to predictability of child's preferences and behaviors. Children from families with financial insecurity may be receiving more community support or targeted early intervention leading to problematic child behaviors being less of a problem. Interestingly, parents of children with better VABS socialization score had greater difficulties with their behaviors; this could reflect lesser targeted intervention due to better functional skills. In keeping with literature, child cognition and language ability did not significantly affect parental quality of life in our cohort. Regardless of child's cognition and adaptive skills, asking parents specifically about challenging behaviors and addressing them can help improve parental QoL. Further research will focus on 1) qualitative examination for the reasons of these associations, 2) understanding how these factors affecting parental QoL differ between Asian and non-Asian parents.

#### 409.026 (Poster) A Promising New Measure for Quantifying Emotion Dysregulation in Toddlers and Preschoolers: Development and Psychometrics of the Emotion Dysregulation Inventory – Young Child

T. N. Day<sup>1</sup>, L. Yu<sup>2</sup>, C. L. Neece<sup>3</sup> and C. A. Mazefsky<sup>1</sup>, (1)Department of Psychiatry, University of Pittsburgh School of Medicine, Pittsburgh, PA, (2)University of Pittsburgh School of Medicine, Pittsburgh, PA, (3)Psychology, Loma Linda University, Loma Linda, CA

**Background:** Emotion dysregulation (ED) is thought to mechanistically underlie the high rates of psychiatric comorbidity in Autism Spectrum Disorder (ASD). By school age, the rate of clinically impairing ED is four times higher in ASD than general population children. The Emotion Dysregulation Inventory (EDI) was designed and validated as a highly efficient, sensitive outcome measure to characterize ED in youth ages 6+. Preliminary evidence documents that ED is also part of the early ASD phenotype. However, there is very limited research quantifying early ED, likely because there are no validated measures of ED in early childhood for ASD.

**Objectives:** This presentation will describe the adaptation process for the Emotion Dysregulation Inventory – Young Child (EDI-YC), following PROMIS guidelines. It will identify the final factor structure of the EDI-YC and the best performing items.

**Methods:** The EDI-YC item bank was generated by inclusion of relevant items from the original EDI and the generation of new items. Expert review and cognitive interviews were conducted to refine the item content, wording, and establish construct validity. The final 48 items were tested in 1,095 children ages 2-5 for psychometric analysis, which included three samples: (1) 914 young children with ASD recruited via the Simons Foundation Powering Autism Research for Knowledge (SPARK) online registry; (2) 58 young children with non-ASD intellectual disabilities (IDD) recruited via a university registry and a state-funded early intervention program; and (3) 123 young children with ASD and non-ASD IDD participating in intervention studies focused on mindfulness-based stress reduction for parents. Preliminary factor analyses were conducted on the SPARK sample (438 cases for EFA, 444 for CFA), as data merging is being finalized for the other two samples.

**Results:** A two-factor solution emerged as most meaningful. 33 items loaded on factor 1 and 12 items loaded on factor 2, with a loading of  $>0.45$ . The factors were consistent with the original EDI: (1) Reactivity, which captures rapidly escalating, intense, and poorly regulated negative affect; and (2) Dysphoria, which reflects sadness, low positive affect, and unease. Some items overlapped with the best-performing items for the original EDI (e.g., does not seem to enjoy anything) and others were newly added items conceptualized to be relevant for young children (e.g., requires preparation before a new activity or transition to avoid a tantrum or meltdown). We will re-run these analyses with the two additional samples, which are enriched for diversity (i.e., specifically non-ASD IDD and race/ethnicity) before finalizing the factor structure. Item Response Theory and Differential Item Functioning analyses will also be completed to identify the final items (all data are collected, analyses ongoing). Norms will be created based on a general population sample of 1000 children.

**Conclusions:** Results from the SPARK sample are promising. They provide preliminary evidence that the ED construct is comparable in early and later childhood. Additionally, early results support the utility of the EDI-YC for use in children ages 2-5 with ASD. The EDI-YC and EDI will be psychometrically linked to enable progress monitoring and longitudinal studies across childhood.

#### **409.027 (Poster) Adaptive Behavior in School-Age Autistic Males and Females**

**C. B. Klein<sup>1</sup>, C. Harrop<sup>2</sup>, O. C. Putnam<sup>2</sup>, B. Tomaszewski<sup>1</sup>, E. M. Lamarche<sup>1</sup> and L. G. Klinger<sup>3</sup>, (1)TEACCH Autism Program; Psychiatry, University of North Carolina, Chapel Hill, NC, (2)Department of Allied Health Sciences, University of North Carolina - Chapel Hill, Chapel Hill, NC, (3)TEACCH Autism Program; Psychiatry, UNC TEACCH Autism Program, Chapel Hill, NC**

**Background:** Due to rising diagnostic rates of autistic females, it is important to assess whether sex differences may be underlying adaptive behavior differences in ASD (See Lawson, 2019 for review). Findings on whether autistic females have more difficulty than males in adaptive behavior have been mixed (Howe et al., 2015; Ratto et al., 2018; White et al., 2017; Mandic-Maravic et al., 2015; Zwaigenbaum et al., 2012). Further, there is limited consensus on the roles of autism traits and co-occurring psychopathology on adaptive behavior (Duncan & Bishop 2015; Tillmann et al., 2019; Yerys et al., 2019). However, few studies have included sufficient numbers of autistic females to assess whether this relationship varies by sex.

**Objectives:** To better understand (1) sex differences in adaptive behavior and internalizing/externalizing behavior in school-aged autistic children and (2) the relationships between adaptive behavior and internalizing/externalizing behavior.

**Methods:** Data for this study was drawn from the University of North Carolina TEACCH Autism Program database of individuals receiving clinical services. Participants were 236 autistic youth (Males=180; 76%; Females=56; 24%) ages 6-18 years who completed the school-age Child Behavior Checklist (CBCL), the Adaptive Behavior Assessment System (ABAS-3), and an IQ test. Sex differences in CBCL, Childhood Autism Rating Scale (CARS), and adaptive behavior scores were compared using Mann-Whitney U tests. Chi-square tests were used to test for sex differences in the presence of an adaptive behavior deficit (i.e., an IQ gap; Duncan & Bishop, 2015). Linear regression tested the effects of internalizing and externalizing problems above and beyond age, sex, IQ, and CARS score on adaptive behavior.

**Results:** There were no significant differences between males and females in adaptive behavior standard score ( $U=4585.00, p=.308$ ), internalizing problems T-score ( $U=4656.00; p=.389$ ), externalizing problems T-score ( $U=4833.00; p=.642$ ), or CARS T-score ( $U=4528.00; p=.599$ ; see Table 1 and Figure 1). Mean scores of adaptive behavior (Males  $M=73.18, SD=11.28$ ; Females  $M=71.82, SD=10.43$ ) were in the low range (i.e., within 70-80) for both groups. The proportion of children with IQ-adaptive behavior deficits (79%) did not differ between males and females ( $\chi^2 [1, N=156]=.709, p=.40$ ). Age ( $b=-.55, t(223)=-2.37, p=.02$ ), IQ ( $b=.23, t(223)=6.53, p<.001$ ), and externalizing problems ( $b=-.22, t(229)=-2.96, p=.003$ ) significantly predicted adaptive behavior standard scores ( $F(6, 223)=9.83, p<.001$ ), with an adjusted  $R^2$  of .19 when holding sex, CARS score, and internalizing problems constant.

**Conclusions:** Males and females showed similar levels of overall adaptive behavior, internalizing and externalizing problems, and autism features. Notably, the mean adaptive behavior score was in the low range, with a gap between adaptive behavior and IQ present in most of the children regardless of sex. Other than age and IQ (Duncan & Bishop, 2015; Tillmann et al., 2019), little research has identified other measures associated with adaptive behavior. The current study suggests that externalizing behavior merits further investigation with future research identifying specific components of externalizing behavior that may predict adaptive behavior.

**409.028 (Poster)** Adaptive Functioning and Autism Symptomology As Correlates of DSM-5 Severity Levels in a Clinical Sample  
**C. Gilchrist<sup>1</sup>, R. Sumner<sup>1</sup>, J. M. Campbell<sup>2</sup> and L. Gardner<sup>1</sup>,** (1)Johns Hopkins All Children's Hospital, St. Petersburg, FL, (2)Psychology, Western Carolina University, Cullowhee, NC

---

**Background:** The diagnostic criteria for Autism Spectrum Disorder (ASD), as presented in the *Diagnostic and Statistical Manual of Mental Disorders, Fifth Edition* (DSM-5; American Psychiatric Association, 2013), features level of support ratings for social communication (SC) and restrictive and repetitive behaviors (RRB). The specifiers require clinicians to delineate between three classifications: Level 1 ("Requiring support"), Level 2 ("Requiring substantial support"), and Level 3 ("Requiring very substantial support") in both SC and RRB. The DSM-5 descriptions of SC and RRB levels of support are conceptual in nature, but research supports clinical characteristics related to levels of support including intellectual and adaptive functioning, and scores on autism-specific measures (e.g., ADOS-2). Higher levels of support for SC and RRB domains have been associated with intellectual impairment, delayed adaptive skills, and elevated scores on autism-specific measures.

**Objectives:** The purpose of the current study is to determine how individuals with mixed levels of impairments across adaptive and ASD symptomology were classified by DSM-5 levels of support in both SC and RRB as a result of a comprehensive diagnostic evaluation.

**Methods:** Adaptive and autism symptomology scores were contrasted across SC and RRB groups for 158 children (mean age = 41.28 months; 80.8% male) with ASD diagnosed at an academic medical center. Adaptive functioning was measured by the parent report Adaptive Behavior Assessment System, Third Edition (ABAS-3; Harrison & Oakland, 2015). Autism-specific symptomology was assessed using the Childhood Autism Rating Scale, Second Edition (CARS-2; Schopler et al., 2010). Autism diagnoses and levels of support for SC and RRB were determined by an interdisciplinary assessment team.

**Results:** Approximately 81.4% of autistic children were identified as needing Level 3 support in SC and RRB. A chi-square test of independence revealed a significant relationship between SC and RRB coding,  $\chi^2(4, N = 158) = 84.03, p < .001$ , and no individuals were identified as needing RRB Level 1 support, and SC Level 3 support. Two children were identified as needing RRB Level 3 support and SC Level 1 support. After excluding multivariate and univariate outliers, 158 participants were available for multivariate analysis of variance (MANOVA) and direct discriminant analysis (DDA). MANOVA and DDA revealed both SC and RRB groups showed a graded pattern of higher adaptation/lower autism severity to lower adaptation/higher autism severity from Level 1 to Level 3.

**Conclusions:** DSM-5 criteria for determining levels of support in SC and RRB currently lack explicit guidance or practice recommendations for distinguishing between levels based on quantifiable data. The present study contrasted adaptive scores and autism-specific symptomology across SC and RRB groups in a clinical sample. The majority of children were identified as needing Level 3 support for both SC and RRB, and two were rated as needing a combination of Level 1/Level 3 supports across domains. A graded pattern of higher adaptation/lower autism severity to lower adaptation/higher autism severity from Level 1 to Level 3 was found across SC and RRB domains. Findings identify quantifiable clinical factors that may be helpful in determining appropriate levels of support when diagnosing ASD.

**409.029 (Poster)** Age and Gender Implications on the Symptom Presentation for Autism  
**H. Adams<sup>1</sup> and R. Jamison<sup>2</sup>,** (1)University of Kansas Medical Center, Kansas City, KS, (2)Center for Child Health and Development, Pediatrics, University of Kansas Medical Center, Mission, KS

---

**Background:** Prevalence rates (CDC, 2018) suggest 1 in 38 males and 1 in 152 females have an autism diagnosis, a significant discrepancy based on gender. The most consistently reported differences in diagnostic symptoms are apparent in the Restricted, Repetitive Behaviors and Interests (RRBs) category. For example, Hiller and colleagues (2014) found that a child was 10 more times likely to be a girl than a boy if they did not meet threshold for RRBs on diagnostic criteria. It has been theorized that this lack of representation in diagnosis may be due to a phenomenon called "camouflaging" where females mask their autistic difficulties, thereby making a diagnosis harder to ascertain.

**Objectives:** This study examines symptom presentation and diagnostic differences between males and females evaluated for autism. Furthermore, research questions examined the potential influence of gender and/or age on meeting specific diagnostic criteria for diagnosis of autism as well as co-existing mental health conditions.

**Methods:** We conducted a retrospective chart review for 2,044 children and adolescents referred for interdisciplinary autism evaluation at an academic medical center (mean age=6.13) that included autism assessments to determine the presence of DSM-5 criterion and diagnosis. A portion of the sample also included assessment of co-existing internalizing and externalizing symptoms and/or mental health disorders. The sample consists of primarily White (~65%; ~35% racial/ethnic minority) and male (75.1%, 24.9% female) individuals. We utilized descriptive statistics and Chi Square Tests to examine potential differences in referral rates, diagnoses, and presentation of autism related symptoms across age groups and gender.

**Results:** Overall referral rates were consistent with autism prevalence documented in the literature, ~75% of those referred were male as compared to ~25% female (Chi-squared=515.008,  $p < .001$ ). Although significant differences in the overall referral rates of males and females, rate of autism diagnosis within genders were relatively similar across the sample. Chi Square Tests revealed an age by gender interaction such that elementary aged females were significantly less likely to be referred as well as diagnosed compared to elementary aged males and that regardless of referral rates, females were more likely to be diagnosed than males within the high school age range. Females had higher rates of meeting DSM-5 Criteria A than males within their high school years. Contrary to hypotheses, females did not demonstrate higher rates of overall DSM-5 Criteria B across age ranges, however they were less likely to meet the individual criterion B3.

**Conclusions:** Initial findings suggest minimal gender differences across our sample in the proportion of autism diagnosis in males compared to females. There are however meaningful gender differences in rates of diagnosis considering age groups with school age females less likely to receive

a diagnosis and high school females more likely to receive the diagnosis. More research is needed to examine symptom presentation across age ranges and gender and diagnostic criteria. We anticipate that this could be due to the presentation of symptoms and that girls may start to present more “typical” autism symptoms as they age contributing to exacerbated social impairments and mental health concerns.

**409.030 (Poster)** Agreement of Parent-Reported Cognitive Level with Measured IQ Among Children with Autism Spectrum Disorder

**C. M. Lee<sup>1</sup>, A. N. Esler<sup>2</sup>, L. Green Snyder<sup>3</sup>, C. M. Taylor<sup>4</sup> and S. Consortium<sup>1</sup>, (1)Department of Pediatrics, University of Minnesota - Twin Cities, Minneapolis, MN, (2)University of Minnesota, Minneapolis, MN, (3)Simons Foundation, New York, NY, (4)Geisinger, Lewisburg, PA**

---

**Background:**

Cognitive ability is critical when examining behavior and causative factors in research on autism spectrum disorder (ASD), but many large-scale studies have inherent logistical and practical barriers to completing standardized cognitive testing. Alternatively, many studies have used parent-reported cognitive ability in place of direct testing; however, few studies have compared agreement of parent report with direct cognitive testing. Understanding the agreement of parent-reported cognitive ability with direct testing is important not only to the validity of large-scale studies but also to the implications for education and treatment choices families may make.

**Objectives:**

The purpose of this study is to evaluate the agreement between parent report and direct assessment of child cognitive abilities in a large cohort of individuals with ASD.

**Methods:**

1,555 children with ASD from the online SPARK study were included. Full-Scale IQ (FSIQ) scores from clinic medical records were compared to data from three parent-reported estimates of cognitive impairment: 1) diagnosis of intellectual disability (ID/Cognitive Impairment), 2) presence of cognitive delay (Cognitive Level), and 3) their estimate of the IQ test result if available (Cognitive Score). Parent report of an ID diagnosis, a “significantly below age level” on Cognitive Level, or a reported test result of IQ < 70 on Cognitive Score were coded as “matching” if consistent with their clinic records of IQ < 70. Binary logistic regression was used to explore how demographic factors, ASD symptoms on the Social Communication Questionnaire (SCQ), and adaptive skills on the Vineland Adaptive Behavior Scale (VABS) were associated with parental accuracy.

**Results:**

Participants were 81.74% male with a mean age of 6.9 years (SD 3.91). Parent report of Cognitive Score revealed the best agreement (74.13% with 317 responses), followed by Cognitive Level (64.10% with 780 responses) and ID/Cognitive Impairment (57.68% with 1,555 responses). Significant age differences were noted (age at survey and cognitive testing,  $ps < .0001$ ) with an increased agreement for children older than 5 years (68.81 – 76.21%). The SCQ total score and FSIQ significantly impact the agreement of ID/Cognitive Impairment ( $R^2 = 0.251$ ) with lower SCQ and higher FSIQ associated with the better agreement. Better adaptive skills, higher FSIQ, and lower verbal IQ are associated with better agreement on Cognitive Level ( $R^2 = 0.259$ ). Higher FSIQ and lower verbal IQ are associated with better agreement on Cognitive Score ( $R^2 = 0.413$ ).

**Conclusions:**

Parental accuracy in estimating their children’s cognitive level was shown to be generally good in a large online cohort, but dependent upon how cognitive ability was queried using survey methods. Child age, verbal IQ, and adaptive skills influenced the agreement between parent-reported and measured IQ. These findings suggest that parent-reported cognitive level can be an effective way to obtain an accurate estimate of whether cognitive impairment may be present, and different query methods will be more or less accurate depending on the characteristics of target samples. The implications of these findings, concerning the influence of a parent’s estimate of their child’s abilities upon treatment, education, and other life choices, warrant further study.

**409.031 (Poster)** An Exploration of a General Social Outcome Measure

**N. Buranova<sup>1</sup>, J. Stichter<sup>2</sup> and M. Stormont<sup>3</sup>, (1)Special Education, University of Missouri, Columbia, MO, (2)University of Missouri, Columbia, MO, (3)University of Missouri, Columbia, Columbia, MO**

---

**Background:** Social skills impairments are central to several disabilities including autism spectrum disorder (ASD). Social skills deficits are linked to academic failures, antisocial behavior, drug abuse (Snyder et al, 2003), and may lead to increased risk for dropout and a higher rate of bullying at school (Zablotsky et al., 2014). To identify and/or develop social skills interventions to support students, reliable assessment tools that can be implemented with rigor and fidelity are necessary. There is a lack of assessment tools that are sensitive to social changes in an individual's behavior (Anagnostou et al., 2015; Salvia & Ysseldyke, 2007). In our presentation, we aim to present the psychometric properties of a performance-based assessment, the General Social Outcome Measure (GSOM) which evaluates the change in social skills performance for students receiving social competence intervention.

**Objectives:** The General Social Outcome Measure (GSOM) is a performance-based measurement tool that was designed to assess the change in social skills performance during and after the intervention for students with social skills challenges. In the current study, the psychometric properties of the GSOM, including a total score, and social communication domains (SCDs), were examined.

**Methods:** The data for the current study was obtained during a federally funded four-year cluster-randomized trial completed to evaluate the Social Competence Intervention. The participants for the study were recruited from 34 middle schools in one Midwestern state. A total of 283 middle school students participated in the study. The following measures were used in the study: General Social Outcome Measure (GSOM), Children's Communication Checklist-2 (CCC-2; Bishop, 2006), School Social Behavior Scales (SSBS; Merrell, 2002), Autism Diagnostics Observation Schedule-2 (ADOS-2; Lord, et al., 2012). Data analysis steps included psychometric analyses to determine reliability and validity as well as an exploratory analysis of groups differences on key variables.

**Results:** The data analysis established good internal consistency for the total GSOM score and for the conversational reciprocity construct. Correlational analyses were conducted with the GSOM and the CCC-2, SSBS, and the ADOS-2. A limited correlation was found between the GSOM and the SSBS and GSOM and CCC-2. A small but significant correlation was documented between the GSOM and the ADOS-2 with higher GSOM total scores (higher social competence) associated with lower ADOS-2 scores. Additional analyses found that individuals with different levels of symptomatology according to the ADOS-2 (moderate or high) differed significantly on the GSOM total score.

**Conclusions:** The results provide support for the reliability of the total GSOM, as well as the separate domain of Conversational Reciprocity. The GSOM could be utilized to monitor students' progress over time and allow making instructional decisions based on the results of the assessment (e.g., plan for the intervention, adjust/change the intervention, etc.). With the implementation of the GSOM, educators and clinicians have the opportunity to assess students' skills before the intervention and then right after it which allows them to adjust their instructional programming or clinical intervention and plan accordingly.

**409.032 (Poster)** Applying a Service Design Framework to Teleassessments: Incorporating Both Family and Assessor Points-of-View  
**L. V. Ibanez<sup>1</sup>, S. Scott<sup>2</sup>, N. Berger<sup>3</sup>, M. Petrucci<sup>4</sup>, D. M. Tagavi<sup>5</sup>, Y. G. Dai<sup>6</sup>, J. Birudavol<sup>7</sup>, A. Morelos<sup>7</sup>, C. Schubert<sup>8</sup>, A. Wainer<sup>8</sup>, B. R. Ingersoll<sup>9</sup>, A. S. Carter<sup>10</sup> and W. L. Stone<sup>11</sup>**, (1)UW READi Lab, Seattle, WA, (2)University of Washington, Seattle, WA, (3)Rush University Medical Center-AARTS Center, East Lansing, MI, (4)University of Massachusetts, Boston, MA, (5)University of California, Santa Barbara, Santa Barbara, CA, (6)University of Massachusetts- Boston, Boston, MA, (7)University of Massachusetts Boston, Boston, MA, (8)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (9)Psychology, Michigan State University, East Lansing, MI, (10)Department of Psychology, University of Massachusetts Boston, Boston, MA, (11)Psychology, University of Washington, Seattle, WA

---

#### Background:

The COVID-19 pandemic accelerated telehealth innovation and practices for ASD and social communication assessments, including the development of new/adapted protocols (Berger et al., 2020) to meet safety and social distancing demands. To optimize the adaptation of a new teleassessment protocol for both families and assessors, the current study applied a service design framework to maintain technical/construct validity, while maximizing feasibility (e.g., research logistics, technology set-up) and family acceptability (e.g., managing parent coaching/instructions and burden).

#### Objectives:

- Adapt teleassessment protocol from highly expert setting (lab with assessment team) to naturalistic environment (in-home with parent)
- Contribute a new teleassessment protocol, technology package, and approach for developing and evaluating such tools

#### Methods:

The service design approach focuses on developing a positive experience from the family point-of-view while addressing the technical rigor and feasibility needs from the assessor point-of-view, including the technological supports needed to facilitate the interactions between the two user types. The specific process comprises 3 primary and iterative stages: Discover/Ideate (scope the context and generate possible solutions), Develop/Adapt (converge on and refine solution), Deploy/Evaluate (pilot and receive feedback on solutions from end users). These stages were navigated in parallel for both the teleassessment and technology package and were transactional/interactive such that decisions made for each component influenced the other.

#### Results:

**Teleassessment protocol.** As part of Discover/Ideate stage, the assessor team re-examined key social-communication target outcomes (i.e., joint attention, imitation, intentional communication) and conducted an extensive comparative review of existing validated measures (e.g., Communication Play Protocol; Adamson & Bakeman, 2016) that parents would be able to implement in-home. In Develop/Adapt stage, the team converged on further modification of the CPP as the primary solution/approach. As a key step, the team engaged in role playing/internal rehearsal and script review to identify flow, parent instructions, toy sets, and related initial gaps in validity and feasibility. Finally, in Deploy/Evaluate stage, the teleassessment was piloted with families to generate observations about the elicited behaviors (including their frequency) for construct validity and obtain parent feedback on administration pain points such as instruction comprehension and manageability of toy sets.

**Technology video package.** In Discover/Ideate stage, the team identified existing high quality video recording systems originally developed for home security and educational research (i.e., Ubiquiti Technology; video conferencing w/ Kubi on iPads). Hardware was uniquely configured to support viability for teleassessments. In Develop/Adapt stage, both tech systems were piloted through role playing/internal rehearsal among different staff member homes to determine which package would maximize portability, set-up feasibility, camera angles, video quality, broadband accessibility and

to identify potential challenges once deployed in families' homes. Finally, in Deploy/Evaluate stage, a customized Ubiquiti configuration was piloted with families, along with the teleassessment, to closely examine system reliability and receive feedback on set-up feasibility

#### Conclusions:

As the field goes back to the "drawing board" to develop assessments that can be implemented using telehealth, a service design approach can optimize such tools to meet the needs of both families and assessors, which may lead to improved scalability in both research and "real-world" clinical settings.

#### **409.033 (Poster)** Autism Assessment from Home: Inter-Rater Reliability of the Remote, Caregiver-Facilitated CARS-2 Observation during COVID-19

**J. R. Bertollo<sup>1</sup>, J. Albright<sup>1</sup>, A. V. Dahiya-Singh<sup>1</sup>, M. Fok<sup>2</sup>, E. A. DeLucia<sup>1</sup>, J. N. Constantino<sup>3</sup> and A. Scarpa<sup>1</sup>,** (1)Department of Psychology, Virginia Polytechnic Institute and State University, Blacksburg, VA, (2)Department of Psychology, Virginia Tech, Blacksburg, VA, (3)Washington University School of Medicine, St. Louis, MO

---

**Background:** The COVID-19 pandemic has resulted in an unparalleled dependence on telehealth. In particular, assessing autism spectrum disorder (ASD) remotely during COVID-19 has left providers in the field to use their best clinical judgment without reliable or validated remote observations that span childhood and adolescence. This is a critical gap given that evidence-based ASD assessment typically includes a direct observation measure in addition to a developmental interview with a caregiver. However, the gold-standard observation tool for in-person assessment (i.e., the Autism Diagnostic Observation Schedule – 2nd Edition [ADOS-2]) cannot be conducted validly via telehealth or with facial coverings in-person. As such, our team adapted the Childhood Autism Rating Scale, 2<sup>nd</sup> Edition (CARS-2) Observation for use as a remote, caregiver-facilitated observation during COVID-19.

**Objectives:** To demonstrate initial inter-rater reliability in clinician coding of the remote, caregiver-facilitated CARS-2 Observation.

**Methods:** Participants included 15 children (ages 2-13 years,  $M=7.92$ ; 33.3% female) who completed a caregiver-facilitated CARS-2 Observation from home as part of a broader tele-assessment pilot study. The CARS-2 Observation codes a brief play and interaction-based observation according to the first eight items of the CARS-2, each of which is coded on a 4-point scale (i.e., 1-4) with half-point increments. The clinician overseeing the administration for a given child coded the observation immediately after the administration. During a follow-up team meeting, a group of graduate trainees ( $n=3$ ) and a licensed clinical psychologist then watched the administration video together, each independently coded the administration, and then discussed discrepancies in their codes. This resulted in a set of eight consensus codes for each child's CARS-2 Observation. Inter-rater reliability was then calculated by comparing each of the codes selected by that child's clinician to each of the corresponding consensus codes determined by the full team and dividing by eight items. A clinician's code for an item was considered to be in agreement if it was within one-half point of the corresponding consensus code.

**Results:** Agreement between a clinicians' eight individual codes and each of the eight corresponding team consensus codes was 91.67% on average, ranging from 75 to 100%; their agreement with the group on their individual codes met or exceeded 87.5% (i.e., 7 of 8 items) for 13 of 15 participants. Intraclass correlation ( $ICC=.97$ ) was excellent between a clinician's total score and the team's consensus total score.

**Conclusions:** Reliable methods of remotely observing characteristics of autism have become more necessary during the COVID-19 pandemic, but remain invaluable tools for assessing hard-to-reach populations generally, such as families in rural locations or where providers are scarce. With the use of consensus coding, the current study demonstrated high reliability between raters on the caregiver-facilitated CARS-2 Observation. However, training materials and videos do not exist at present to train clinicians on these scoring procedures. As such, future work will focus on creating training materials for free and wide dissemination, which will allow clinicians to demonstrate their reliability in rating and operate as independent raters thereafter, thereby alleviating the need for lengthy consensus coding after each administration.

#### **409.034 (Poster)** Almost ASD : When Autistic Construction Is Incomplete and Quickly Reversed

**N. Gaddour<sup>1</sup>, T. Brahim<sup>2</sup>, A. Guedria<sup>3</sup> and R. Bourourow<sup>1</sup>,** (1)University Hospital F. Bourguiba, Monastir, Tunisia, (2)PSYCHIATRY, UNIVERSITY OF MONASTIR, MONASTIR, Tunisia, (3)University of Monastir, Monastir, Tunisia

---

#### Background:

Accumulated evidence suggests that autism results from a diachronic process originating from genetic vulnerability and precipitated by diverse environmental constraints towards autistic mechanisms. Many clinical findings from the last 5 years from many practitioners describe incomplete autistic processes that are reversed quickly before the criteria of an ASD can be fully met.

**Objectives:** to describe a clinical population of children with incomplete clinical history of autism

#### Methods:

systematic review of clinical records of all children with developmental delays and learning challenges and survey of clinicians managing children with developmental problems in the region of Sousse and Monastir, Tunisia, over years 2018 to 2020

## Results:

Even though most of current diagnoses are ADHD, specific learning disorders or language developmental disorders, at least 10% of patients are found with a history of autistic symptoms between 1 and 2 years (mainly extensive repetitive play such as spinning or alignment, withdrawal, different degrees of echolalia or pronoun reversal, sensory overreaction, delayed pointing and other non verbal communication milestones). These symptoms often remain for some weeks or months and partially disappear. Often, clinician label these situations as autistic traits or broad autism phenotypes or use metaphors such as “your child touched autism and bounced back”

Conclusions: This population with border-line clinical picture can shed more light on vulnerability to ASD and its study may lead to important secondary prevention strategies

### **409.035** (Poster) Catatonia Associated with ASD: Correlates and Treatment Orientations

**N. Gaddour<sup>1</sup>** and **R. Bourourou<sup>2</sup>**, (1)University Hospital F. Bourguiba, Monastir, Tunisia, (2)University of Monastir, Monastir, Tunisia

---

## Background:

Although catatonia is found in 4 to 12% of patients with ASD, no clear recommendations are established regarding its assessment and treatment in the context of ASD. Its onset is often sudden and unexpected and adds an important burden to the management of the condition

## Objectives:

to describe clinical features, correlates, treatment and outcome of patients with ASD and catatonia

## Methods:

clinical case descriptions of the 4 patients with ASD that developed catatonia from the clinical population of University Hospital Fattouma Bourguiba, Monastir, Tunisia.

## Results:

Catatonia onset was at age 7 to 10 years, with a quick installation of motor symptoms such as “freezing” and keeping postures, important regression of language and interaction, and extreme slowness in daily routines. An episodic evolution was noted although without a specific time or season for catatonia. Treatment consisted in benzodiazepines (Lorazepam) and antipsychotics, with moderate improvements. Regardless of the previous developmental level, important losses in communication and cognitive skills persisted after catatonia

## Conclusions:

Catatonia is a serious condition complicating some cases with ASD that needs specific attention and care. Persistence of developmental losses and regressions after its improvement may mean that profound intricacies with autistic etiological mechanisms

### **409.036** (Poster) Characterization of ASD Symptomatology in Individuals with CHAMP1 Disorder

**M. M. Sardis<sup>1</sup>**, **B. Lerman<sup>2</sup>**, **P. M. Siper<sup>2</sup>**, **D. Halpern<sup>2</sup>**, **J. Zweifach<sup>2</sup>**, **J. H. Foss-Feig<sup>2</sup>**, **J. D. Buxbaum<sup>2</sup>**, **A. Kolevzon<sup>2</sup>** and **T. Levy<sup>2</sup>**, (1)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (3)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY

---

## Background:

*CHAMP1* is a gene associated with chromosomal segregation and neurodevelopment. Mutations in *CHAMP1* are rare and result in intellectual disability, delayed speech, hypotonia, dysmorphic features, microcephaly, and over-friendly behavior. While a few studies have documented the phenotype of this rare disorder, no studies to date have characterized autism spectrum disorder (ASD) traits.

## Objectives:

To characterize ASD symptomatology in individuals with CHAMP1 disorder. We describe our remote diagnostic procedure and highlight measures of repetitive behavior and social inhibition.

## Methods:

Data was prospectively collected from eleven participants with CHAMP1 disorder between the ages of 1.6 to 28.3 years (10.7 ± 7.8).

A psychiatric evaluation, the Childhood Autism Rating Scale (CARS<sup>obs</sup>), the Autism Diagnostic Interview-Revised (ADI-R), the Social Responsiveness Scale, 2<sup>nd</sup> edition (SRS-2), and the Repetitive Behavior Scale- Revised (RBS-R) were used to identify features of autism. A best estimate ASD diagnosis was determined by a team of psychiatrists and psychologists to reach a DSM-5 consensus diagnosis.

#### Results:

Overall, 3/9 (33%) participants met DSM-5 criteria for ASD. Clinicians deferred one participant for later testing due to young age and another participant for later testing when in-person assessments are feasible.

On the CARS<sup>obs</sup>, 3 individuals met for severe ASD and 2 for mild-moderate ASD. Five participants did not surpass the threshold for ASD. The CARS<sup>obs</sup> correctly classified 80% of participants.

On the ADI-R, 7/10 participants surpassed the cutoff in all ADI-R domains. All 10 met cutoff in the Development domain, 9 in Restricted and Repetitive Behavior, 8 in Social, and 9/10 in Communication. The ADI-R correctly classified 70% of participants.

On the SRS-2, 5/10 participants' total T scores fell in the severe range, 3 in the moderate range, and 2 in the normal range. The mean total T score was  $73.5 \pm 11.4$ . The mean overall SRS-2 score for the three individuals with ASD was  $74.3 \pm 8.7$  and for the six without ASD was  $71.8 \pm 13.7$ . There was no significant difference in overall SRS-2 scores between those with and without ASD ( $p=1.00$ ).

Finally, on the RBS-R, the Total Raw Score ranged from 2 to 71 ( $29.4 \pm 19.8$ ) out of a maximum score of 129. The cohort had the highest scores in the Ritualistic domain, followed by the Restricted Behavior and Sameness Behavior domain. The mean Overall Repetitive Behavior score did not differ for the three participants with ASD ( $39.3 \pm 27.7$ ) and for the six without ASD ( $28.2 \pm 16.2$ ). There was no significant difference in overall RBS-R scores between the groups with and without ASD ( $p=0.714$ ).

#### Conclusions:

When in-person assessments are not feasible, remote administration of ASD diagnostic assessments provides useful metrics to determine diagnostic status for most participants. Autism features such as impaired social responsiveness and repetitive behaviors appeared at similar rates in individuals with CHAMP1 disorder regardless of autism status. Autism symptoms in individuals with CHAMP1 disorder require more in-depth evaluation to provide higher quality care. Further research with a larger sample and in-person phenotyping is needed to enhance our understanding of ASD in CHAMP1.

#### **409.037 (Poster)** Children with ASD Have Differences in Index-Level IQ Structure Despite Unaffected Full Scale IQ

**M. A. Levine<sup>1</sup>, H. Chen<sup>2</sup>, E. Wodka<sup>3</sup>, B. Caffo<sup>2</sup> and J. B. Ewen<sup>4</sup>**, (1)Developmental Neurology, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Biostatistics, Johns Hopkins University, Baltimore, MD, (3)Center for Autism and Related Disorder, Kennedy Krieger Institute, Baltimore, MD, (4)School of Medicine, Johns Hopkins University, Baltimore, MD

**Background:** It has long been known that individuals with ASD perform differently on IQ tests, showing both diagnosis-typical differences in some cognitive abilities compared to others, as well as overall greater variability across subscores. In particular, individuals with ASD have consistently demonstrated alterations in working memory and processing speed. The concept of IQ rests on empirical covariance among individual performance on various tasks (Spearman's  $g$ ), and increased subscore variability in ASD brings into question whether this construct is as relevant in ASD as in the broader population.

**Objectives:** Our goal was to examine how the factor structure of subtests functions in ASD and compares with the published scoring rubric, with the theoretical aim of understanding the relevance of Spearman's  $g$  in ASD and the practical aim of identifying needs for ASD-specific revisions to the scoring rubrics of IQ tests.

**Methods:** We conducted confirmatory factor analyses on three cohorts of 8-12-year-old children: children with ASD administered the Wechsler Intelligence Scale for Children, Fourth Edition (WISC-IV) (N=131), typically developing (TD) children administered the WISC-IV (N=209), and children with ASD administered the Wechsler Intelligence Scale for Children, Fifth Edition (WISC-V; N=83). Four factors were specified in all analyses. (WISC-V has five published index scores, and a five-factor analysis did not alter the conclusions below.) These data-driven factors were then compared to the manualized indices using Pearson correlation.

**Results:** All three cohorts showed strong correlations between data-derived  $g$  and FSIQ: WISC-V ASD group ( $r=0.98, p<0.01$ ), the WISC-IV ASD group ( $r=0.97, p<0.01$ ), and the WISC-IV typically developing group ( $r=0.96, p<0.01$ ). In the TD WISC-IV group, the data-driven factors were tightly correlated with the manual-derived indices. However, in the WISC-V ASD group (see Table 1) and the WISC-IV ASD group (see Table 2), the correlations between the data-driven factors and the manual-derived indices were weaker and did not have a 1:1 (factor-to-index) correspondence like the typically developing group. Instead, the Working Memory Index correlated with several data-driven factors.

**Conclusions:** The hierarchical structure of intelligence as implemented in the Wechsler tests does not fit neatly with empiric factorization of the ASD group. Working memory in particular plays a role in convoluting the published indices in the ASD group, which puts at risk clinical interpretations made from any single index score alone. The strong relationship between overall FSIQ scores and the data-driven  $g$  in all three groups, however, suggests soundness of the FSIQ score. These results could prompt ASD-specific redesign (e.g., refactoring) of Wechsler tests within ASD samples

and the subsequent study of the clinical relevance of any resulting index scores.

**409.038 (Poster)** Comparing Executive Functioning across Clinical Groups: ASD, ADHD, and ASD + ADHD

**A. G. Carroll** and L. Newell, *Indiana University of Pennsylvania, Indiana, PA*

---

**Background:** Autism Spectrum Disorder (ASD) and Attention-Deficit/Hyperactivity Disorder (ADHD) are common childhood psychiatric diagnoses. Deficits in executive function (EF) abilities, which impact the way in which people respond to and interact with the world, have been frequently identified in children with both disorders. However, EF performance in comorbid ASD and ADHD (ASD + ADHD) has received less attention in research and literature.

**Objectives:** The current study explored EF performance on specific measures in a group of children ages 6:0 to 17:11 with ASD + ADHD compared to ASD or ADHD alone using data from comprehensive evaluations conducted at an outpatient clinic from October 2014 to March 2020. The impact of psychiatric medication status, cognitive ability, age, and sex on EF performance in clinical groups was also investigated.

**Methods:** The current study used deidentified archival data that were collected from comprehensive psychiatric diagnostic assessments conducted at an outpatient clinic during which children received diagnoses of ASD and/or ADHD. Assessments included data from an initial parent intake and additional assessment appointments. A variety of psychological assessments, including a cognitive measure, the WCST, BRIEF or BRIEF-2, and Conners-3, were administered by trained clinicians to appropriately answer diagnostic questions. There were 121 total participants, including 39 in the comorbid group, 31 in the ASD group, and 51 in the ADHD group.

**Results:** The results suggested that, overall, children with ASD tended to show the least EF impairment compared to ADHD and ASD + ADHD. The comorbid group generally exhibited the greatest EF impairment, though children with ADHD and ASD + ADHD exhibited more similar performance than compared with the ASD group. All groups exhibited clinically and/or statistically significant EF impairments compared to population norms.

**Conclusions:** These findings highlight the importance of adequately assessing for both ASD and ADHD in children, especially because of their high co-occurrence and potentially more complex symptom picture. While there are symptoms common in both ASD and ADHD that can be addressed through treatment, targeting EF deficits in ASD + ADHD may uniquely address a nexus of difficulties that are seen in both diagnoses alone and were generally demonstrated to feature greater impairment in the comorbid group. EF is related to a host of critical outcomes, such as those in the social, academic/educational, and vocational realms (Diamond, 2013; Miller & Hinshaw, 2010), highlighting the value of interventions in this area. The findings of this study suggest that clinicians should be aware that the EF profile of children with comorbid ASD + ADHD may be more impaired than these diagnoses alone, particularly on parent-report measures and when compared to ASD only. While EF difficulties are not diagnostic on their own, EF measures are often used during evaluations, and the results of this study help to further elucidate an EF profile for children with comorbid ASD + ADHD.

**409.039 (Poster)** Comparison of Age of Diagnosis and Sex Differences in Parent Report of Autism Characteristics

**C. Shulman**, *The School of Social Work, The Hebrew University of Jerusalem, Jerusalem, Israel*

---

**Background:**

Early diagnosis has been associated with better outcomes for children with autism spectrum disorder (ASD), but there is a group of children who receive an initial ASD diagnosis after preschool (Ozonoff et al., 2018). The children who receive an ASD diagnosis after the age of five includes girls, who typically receive an ASD diagnosis later than boys, as well as some boys whose difficulties perhaps only present as ASD as social demands exceed their abilities. Both these groups miss opportunities for early supports which could positively affect their developmental trajectories. It is critical that researchers and clinicians understand the characteristics of this later diagnosis group in order to identify the subtleties of their ASD.

**Objectives:**

The main objective of this study is to compare ASD symptomatology in girls and boys who receive an early diagnosis (between the ages of 3-6) to the ASD characteristics of boys and girls who receive their initial ASD diagnosis later (between the ages of 8-11). Information regarding the participants was collected through parental report using the Autism Diagnostic Interview-Revised (ADI-R: Rutter et al., 2003) at initial diagnosis in a similar number of boys and girls matched for chronological age and intellectual ability. The aim of this unique research is to identify which profiles relate to female ASD symptomatology and which are associated with a later diagnosis. It is possible that current diagnostic instruments are not sensitive enough to detect the subtleties of ASD symptoms in children who receive a later diagnosis, and given the fact that girls often receive an ASD diagnosis later than boys, the focus on sex differences is particularly informative.

**Methods:**

Eighty children were divided into four groups. Forty boys and 40 girls were matched on cognitive functioning and age; twenty boys and 20 girls received their initial ASD diagnosis between the ages of 3-5 (early diagnosis group), and 20 boys and 20 girls received their initial ASD diagnosis of autism between the ages of 8-11 (later diagnosis group). Analyses of group comparisons were performed between males and females and between early and later diagnosis, as well as for all four groups. All information was gathered from parents' report on the ADI-R.

**Results:**

Significant differences emerged on specific ADI-R items. Preschool-aged girls had fewer circumscribed interests than participants in all other groups. Girls of all ages offered more comfort and spontaneously imitated others' actions more than boys did. The only significant difference between the early and later diagnosis groups emerged in the communication domain, with significantly more pathology emerging in the early diagnosis group.

#### Conclusions:

The results of this study suggest that age and sex have a differential impact on ASD expression, with some items reflecting differences among boys and girls at all ages and others reflecting differences between early and later diagnosis. The reexamination of diagnostic profiles taking age of diagnosis and sex into account should be a research priority, in order to correctly diagnose boys and girls as early as possible.

#### **409.040 (Poster)** Compliance of ASD Management to International Guidelines in a Low-Income Country

**T. Brahim<sup>1</sup>, F. Ayari<sup>2</sup>, R. Nabli<sup>3,4</sup>, A. Guedria<sup>5</sup> and N. Gaddour<sup>6</sup>**, (1)PSYCHIATRY, UNIVERSITY OF MONASTIR, MONASTIR, Tunisia, (2)Monastir, faculté de médecine de Monastir, Monastir, Tunisia, (3)CENTRE HOSPITALIER DU ROUVRAY, Sotteville-les-Rouen, France, (4)Centre Hospitalo-universitaire Fattouma Bourguiba, Monastir, Tunisia, (5)University of Monastir, Monastir, Tunisia, (6)University Hospital F. Bourguiba, Monastir, Tunisia

---

#### Background:

Recommendations in the areas of ASD (Autism Spectrum Disorder) are constantly evolving and changing based on advances in scientific research. In our Tunisian context, we are faced with cultural and financial barriers which often hamper the application of these Guidelines.

#### Objectives:

To Describe the management of patients diagnosed with ASD in the child psychiatry out-patient unite of Monastir, Tunisia, and to compare the results to international recommendations

#### Methods:

this is a retrospective descriptive study, covering all patients diagnosed with ASD during the years from 2010 to 2016, at the child psychiatry unit of Monastir, Tunisia. patients were identified using the consultation's digital archives. Data were collected via files' search. Five hundred eighty-seven patients were enrolled. Average age was  $4.02 \pm 2.3$  years; with two extremes 1 year and 19 years, with a sex ratio 4/1 predominantly male.

#### Results:

The diagnosis was made in all patients according to the DSM criteria (IV-R or 5 depending on the year of diagnosis). Only 22% of patients had an ADI-R and ADOS assessment. Screening by m-CHAT was carried out in 5% of patients. Neuropsychological evaluation was done in 25% of the cases. Karyotype was carried out in 67% of cases. 36% of the cases benefited from an EEG. Auditory evoked potential was prescribed in 35% of cases, brain imaging in 15% of cases and metabolic screening in 17% of cases. Parental guidance and modeling was carried out on all patients. Sixty percent of patients received speech therapy. Eighteen percent of cases had specialized education. Occupational therapy was done in 6% of cases. In 45% of cases a drug was prescribed to the patient.

#### Conclusions:

The current management in the child psychiatry consultation unit in Monastir, Tunisia, is far from being in line with international recommendations. These results emphasizes the importance of developing recommendations more suited to the financial and cultural reality of low-income countries.

#### **409.041 (Poster)** Confirmatory Factor Analysis of the CARS2-ST in Virtual Autism Evaluations with Measurement Invariance for White and Non-White Children

**N. C. Russell, K. G. Stephenson, M. Norris, E. Kryszak, C. Albright and E. Butter**, Nationwide Children's Hospital, Columbus, OH

---

**Background:** The CARS2-ST, which typically incorporates direct observation and caregiver interview, is frequently used to aid diagnostic decision-making in autism spectrum disorder (ASD) evaluations. With the COVID-19 pandemic, and the need to conduct such evaluations virtually, it is important to understand the utility of such an application of the CARS2-ST, compared to in-person observation. Specifically, understanding whether the factor structure of the CARS2-ST is similar, whether observations are completed virtually or in-person, can help elucidate its utility in identifying the range of symptoms contributing towards an ASD diagnosis. In addition, consideration of cultural factors (e.g., race, social norms) is important in understanding the validity of the CARS2-ST and its factor structure. We hypothesized that the factor structure of the virtual observation CARS2-ST would demonstrate similar model fit to the in-person CARS2-ST rating found by Moulton et al. (2019).

**Objectives:** We examined the Moulton et al. (2019) three-factor model for the CARS2-ST: Social Communication, Stereotyped Behaviors and Sensory Sensitivities, and Emotional Reactivity. Measurement invariance (MI) was utilized to determine the appropriateness of this model for groups of White and Non-White children.

**Methods:** Participants were 320 children ( $M_{Age} = 48.23$  months,  $SD_{Age} = 23.13$  months) who participated in online autism evaluations during the COVID-19 pandemic. Information used to complete the CARS2-ST was obtained via observation of a caregiver-administered, play-based assessment and a clinical interview with their caregiver. Confirmatory factor analysis (with the *lavaan* package in R) was used to test both a single-factor model and the Moulton et al. (2019) three-factor model. Full information maximum likelihood estimation was used. The sample was then split into White ( $n = 204$ ) and Non-White (e.g., Black, African American, Hispanic, Native American;  $n = 105$ ) groups; MI between these two groups was assessed at configural, metric, and scalar levels.

**Results:** The Moulton et al. (2019) three-factor model had a better fit than the single-factor model, using standard fit indices. Using the three-factor model to assess MI, both the White ( $CFI = 0.91$ ,  $TLI = 0.89$ ,  $RMSEA = 0.80$ ) and Non-White groups ( $CFI = 0.95$ ,  $TLI = 0.93$ ,  $RMSEA = 0.69$ ) demonstrated acceptable model fit. At the configural level, the data had acceptable model fit ( $CFI = 0.92$ ,  $TLI = 0.90$ ,  $RMSEA = 0.77$ ). Moving to the metric model showed acceptable change in model fit ( $\Delta CFI = -0.011$ ,  $\Delta RMSEA = 0.002$ ,  $\Delta SRMR = 0.017$ ) as did the scalar model ( $\Delta CFI = -0.003$ ,  $\Delta RMSEA = -0.002$ ,  $\Delta SRMR = 0.002$ ).

**Conclusions:** When completed based on virtual observations, scores on the CARS2-ST appear to adhere to the same factor structure as those based on in-person observations. This supports the validity of the CARS2-ST for use in ASD evaluations conducted virtually. For groups of White and Non-White children, this data suggests that the three-factor model of the CARS2-ST is appropriate and supports its use for these groups in virtual clinical autism evaluations. Further research should explore the suitability of the CARS2-ST in other groups and ways to further improve its construct validity across groups.

**409.042 (Poster)** Cross-Cultural Differences in Reporting Autistic Symptoms in Toddlers: A Study with the M-CHAT(-R) Data from Ten Countries D. Stevanovic<sup>1</sup>, M. Jiménez<sup>2</sup>, F. **Background:** Evidence has emerged over the past decade that reporting autism spectrum disorder (ASD) symptoms with available instruments may vary across regional and linguistically diverse samples. The extent to which differences in reporting ASD symptoms are inherent characteristics of the disorder, reflected in the variability in responding across cultures, or the effects of differential measurements with these instruments across cultures is still unclear. The Modified Checklist for Autism in Toddlers (M-CHAT), and its revised form (M-CHAT-R), are the most frequently used ASD screeners in toddlers, even from low-resource regions, and one of the most promising instruments to identify ASD risk.

**Objectives:** The aim of this study was to evaluate the endorsement rates of the M-CHAT(-R) items by parents/caregivers of toddlers with ASD from ten countries: Albania, Chile, Georgia, Macedonia, Malaysia, Mexico, Serbia, Turkey, United Kingdom (UK), and the United States of America (USA).

**Methods:** Data were aggregated for toddlers aged 14 – 36 months who participated in previous studies or completed screening and evaluation for clinical purposes: Albania ( $n = 17$ ), Chile ( $n = 15$ ), Georgia ( $n = 189$ ), Macedonia ( $n = 95$ ), Malaysia ( $n = 52$ ), Mexico ( $n = 46$ ), Serbia ( $n = 30$ ), Turkey ( $n = 150$ ), UK ( $n = 28$ ), and USA ( $n = 312$ ). Item endorsement was classified as low ( $< 30\%$ ), moderate ( $30-60\%$ ), or high ( $> 60\%$ ).

**Results:** All items had a low endorsement rate in at least one country and moderate to high in others. There were 14 items with a moderate to high endorsement rate in seven to nine countries. Of these, seven items had moderate to high across nine countries: *point to show* and *understand what is said* had a high endorsement rate for six (and moderate for three); *follow your gaze* and *get parent to watch* had high for five (and moderate for four); and *point to get help*, *brings things to show*, and *follow a point* had a high for four (and moderate for five). The other items with frequent moderate or high endorsements were *interest in other children* (for 8 countries), *play pretend* (for 8), *imitate action* (for 8) *respond to name* (for 7), *unusual finger movements* (for 7), *hearing concerns* (for 7), and *social referencing* (for 8). Looking at performance within countries, Mexico had moderate or high endorsement on all 20 items; Albania, Georgia, Macedonia, Serbia, and Turkey had moderate or high endorsement on 14-17 items; Chile, UK, and USA had moderate or high endorsement on 11-12 items; and Malaysia only had moderate endorsement on one item (and low on all others).

**Conclusions:** There were differences in responding to M-CHAT(-R) items related to typical behaviors affected in toddlers with ASD as well as atypical behaviors common in ASD by parents/primary caregivers across ten countries, which may indicate cross-country variations in the recognition and evaluation of early autistic symptoms in toddlers. Items related to joint attention, imitation, social engagement, and language comprehension may be less variable and potentially interpreted as universal atypical behaviors in toddlers with ASD.

**409.043 (Poster)** Developing the Signposting Questionnaire for Autistic Adults (SQ-A Adult)

**Background:** Brief, self-report questionnaires are increasingly used to help clinicians identify adults who may require in-depth assessment for autism spectrum disorder (ASD), as well as facilitate research, where detailed clinical information about autistic participants may be lacking. However, many current questionnaires (e.g., the 10-item Autism-Spectrum Quotient; AQ-10) are limited as they 1) do not map onto the latest DSM-5 criteria, and 2) have been designed by non-autistic clinicians and/or researchers alone, and thus often contain items that do not reflect autistic people's lived experiences.

**Objectives:** We aimed to adapt the Signposting Questionnaire for Autism (SQ-A; Jones et al., 2020), a questionnaire based on the DSM-5 criteria for ASD and previously used with parents of children, into a self-report questionnaire for use in adults. Specifically, we designed the new questionnaire, termed the SQ-A Adult, with direct input from autistic adults.

**Methods:** The study had two key phases. In phase 1, 18 DSM-5 items from a valid clinical interview (the Diagnostic Interview for Social Communication Disorders; Wing et al., 2002) – known to highly discriminate between autistic and non-autistic people (Carrington et al., 2015) – were converted into an 18-item self-report questionnaire for adults (SQ-A Adult). Four autistic adults provided input to adapt the wording of the items to better reflect autistic people's lived experiences. Subsequently, in phase 2, a large online sample of autistic and non-autistic adults ( $N = 302$ ), matched on age, sex, and IQ, completed both the original and adapted versions of the questionnaire, as well as the AQ-10. Autistic adults additionally rated their preference for the original or adapted wording of each item on a 5-point Likert scale and gave qualitative responses for their reasoning, thereby providing further input into the development of the measure.

**Results:** Autistic adults scored significantly higher on both the original and adapted versions of the SQ-A Adult compared to non-autistic adults, and the adapted version showed greater discrimination between autistic and non-autistic groups. Both original and adapted SQ-A Adult scores were also positively associated with AQ-10 scores, thus demonstrating the questionnaire's construct validity. Finally, quantitative and qualitative content analyses showed that autistic adults generally preferred the wording of the adapted items as they better reflect their lived experiences (for example, they better reflect individuals' desire for social relationships, despite social difficulties).

**Conclusions:** The SQ-A Adult, using the adapted wording, has the potential to be a valid, clinically useful questionnaire to assist in the diagnostic process, and in research. Our findings also highlight the utility of incorporating autistic people's lived experiences into the development of such questionnaires. Further research is required in larger samples to ascertain the psychometric properties of the SQ-A Adult and thus recommend its use in clinical and research settings.

**409.044 (Poster)** Development of a Novel Questionnaire for Assessment of Visual Processing in Children with Neurodevelopmental Disorders  
**F. L. Ratray**<sup>1</sup>, A. Smeets<sup>2</sup>, J. Nonweiler<sup>3</sup>, F. Happe<sup>4</sup>, M. Absoud<sup>5</sup> and S. Vitoratou<sup>1</sup>, (1)Social, Genetic and Developmental Psychiatry Centre, King's College London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Universitat Autònoma de Barcelona, Barcelona, Spain, (4)Social, Genetic and Developmental Psychiatry Centre, Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Department of Women and Children's Health, King's College London, London, United Kingdom

---

## Background:

Differences in visual processing are well-documented in autism. Visual symptoms such as light sensitivity or superior attention to visual detail may be experienced as detrimental or advantageous to quality of life. To our knowledge, no standardised parent-report measures exist that capture the range of visual behaviours seen in autistic children. Such a measure could aid mechanistic understanding of the association between visual processing and phenotypic behaviours, assist early diagnosis and guide intervention.

## Objectives:

To develop a valid and reliable parent-report measure (ViPro) that captures the breadth and specificity of visual behaviours seen in autistic children and adolescents.

## Methods:

The novel, 27-item ViPro questionnaire was developed following literature review and consultation with clinical and research neurodevelopment specialists. Using a cross-sectional design, ViPro was distributed via online survey to parents/carers ( $n=453$ ) of children, ages 4-15 years, with or without a neurodevelopmental condition (NDC). Established questionnaires measuring autism traits (SRS and AQ10) and response to visual input (5-item visual component from the SP2) were included in the survey. Reliability and exploratory factor analyses (EFA) of ViPro determined problematic items which were subsequently removed. A second sample of parents ( $n=160$ ) answered a revised 18-item ViPro, including 15 original items and 3 additional items following feedback from autistic individuals providing details of their visual experiences and parent consultation. Additional questionnaires measuring anxiety (SCAS), rigid and repetitive behaviour (RBQ2) and sleep patterns (CSDI) were also administered. Discriminant validity was assessed by comparing ViPro scores between diagnostic groups: ASD +/-ADHD; ADHD; and other (typically developing or neurodiverse but not ASD or ADHD). Construct validity of ViPro was ascertained via correlations with sensory and autism trait measures. EFA was conducted to determine factor structure and reliability.

## Results:

Factor analysis concluded to three-factors: visual hypersensitivity, detail-focus, and peripheral-vision stimulation. All factors had good internal consistency ( $\alpha = .78 - .82$ ) reflecting to the complete scale (.89). Importantly, significant group differences in mean ViPro total score were found, with the ASD group scoring higher than the ADHD group ( $U=1207$ ,  $p=.006$ ) and 'other' group ( $U=912$ ,  $p=.008$ ). Convergent validity was supported by a moderate significant correlation between RBQ2 and ViPro ( $r=.539$ ,  $p<.001$ ). Highly significant, albeit modest, correlations between total scores for the ViPro and the visual component of the SP2 ( $r=.340$ ,  $p<.001$ ), as well as the SRS ( $r=.368$ ,  $p<.001$ ) further indicates support for convergent validity with sensory and autism trait measures.

## Conclusions:

Analysis of the novel ViPro shows promising reliability and discriminant validity, suggesting visual behaviours characteristic of autism may be captured by this parent-report measure and quantitatively assessed. Involvement of the autistic community and broader support network in development of items has aided ViPro's acceptability and relevance. Future research should include confirmatory factor analysis to verify the three-factor structure observed and further validation in a large, neurodiverse paediatric population compared to typically-developing children.

### **409.045 (Poster)** Diagnosing Autism Spectrum Disorder in Phelan-Mcdermid Syndrome: Assessing the Utility of Gold-Standard Diagnostic Instruments

**M. Schreiber<sup>1</sup>**, S. Barkley<sup>1</sup>, J. Trayvick<sup>2</sup>, T. Levy<sup>1</sup>, J. Chung<sup>1</sup>, I. Wert<sup>1</sup>, I. Giserman-Kiss<sup>1</sup>, J. Zweifach<sup>1</sup>, D. Halpern<sup>1</sup>, J. H. Foss-Feig<sup>1</sup>, J. D. Buxbaum<sup>1</sup> and A. Kolevzon<sup>1</sup>, (1)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY, (2)Seaver Autism Center at the Icahn School of Medicine at Mount Sinai, New York, NY, (3)Neurodevelopmental and Behavioral Phenotyping Service, National Institutes of Mental Health, Bethesda, MD, (4)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY

**Background:** Phelan-McDermid syndrome (PMS) is a neurodevelopmental disorder resulting from the loss of function of the *SHANK3* gene. PMS is a relatively common cause of autism spectrum disorder (ASD) and intellectual disability, accounting for between 0.5% and 2.0% of cases (Costales & Kolevzon, 2015). The Autism Diagnostic Observation Schedule-2 (ADOS-2) is considered the gold-standard diagnostic tool for ASD, though final diagnosis is made through clinical judgement. The specificity of the ADOS-2 has been questioned in other disorders with intellectual delay as a prominent phenotype component. Particularly in patients with a mental age below 18 months, clinicians have advocated for metrics that better differentiate between intellectual delay and ASD-derived neurodivergence (Trelles & Thurm, 2018).

**Objectives:** This study aimed to assess (1) how diagnostic instruments function in correctly diagnosing ASD alongside clinical judgement, and (2) phenotypic differences between individuals with idiopathic ASD, non-ASD PMS, and ASD-related PMS.

**Methods:** Eighty-seven children participated, including 61 with iASD (51 males;  $M_{age}=X\ 6.42\pm2.96$  years), 8 with PMS without ASD (2 males;  $M_{age}=6.46\pm2.84$ ), and 17 with PMS and ASD (12 males;  $M_{age}=6.45\pm3.00$ ). All participants completed a full-length ADOS-2 assessment conducted by licensed clinicians. Between-group differences in ADOS-2 total and subscale scores were examined across iASD, PMS-only, and ASD+PMS groups. Sensitivity and Specificity of the ADOS-2 Assessment as a diagnostic tool was also calculated.

**Results:** Results yielded an overall sensitivity of 0.987 and specificity of 0.375 on the ADOS-2 assessment. Specifically, there were 5 false positives and 1 false negative (in the PMS+ASD group) among the 86 participants. Despite low specificity, there were significant differences among groups across all ADOS-2 subscales, total score, and comparison score ( $p<.01$ ), with the most marked contrasts in the Social Affect (SA) domain and on the Total Score. Within the SA domain, the PMS-only group ( $M=5.25\pm2.252$ ) scored significantly lower ( $p<.001$ ) than the iASD group ( $M=12.66\pm3.705$ ), while the PMS+ASD group ( $M=15.76$ ,  $SD=4.116$ ) scored significantly higher ( $p=.003$ ) than the iASD group. On the Total Score, the PMS+ASD group ( $M=20.12\pm5.278$ ) scored significantly higher ( $p=.043$ ) than the iASD group ( $M=17.52\pm4.603$ ), while the PMS-only ( $M=7.75\pm2.493$ ) scored significantly lower ( $p<.001$ ) than the iASD group.

**Conclusions:** These results suggest that while the ADOS-2 is a highly sensitive assessment, it poorly differentiates between non-ASD and ASD participants in a subset of individuals with PMS (specificity<0.8). The frequency of false positives reported in this sample suggest overdiagnosis of ASD in patients with other neurodevelopmental syndromes if ADOS-2 is used alone. The ADOS-2's low specificity rate may also explain such significant scoring differences between iASD and PMS+ASD groups. In trying to distinguish between ASD and other neurodevelopmental disorders, clinicians may perceive ASD symptom severity to be even higher in PMS patients who ultimately receive ASD diagnoses than in iASD individuals. This is most markedly the case with social behavior ratings. Overall, these results point towards the need for more precise diagnostic measures of ASD for use in complex behavioral syndromes such as PMS.

### **409.046 (Poster)** Diagnostic Discrepancies: Factors Associated with Unconfirmed/Inaccurate Community-Based ASD Diagnosis in a Research Referred Sample

S. W. Duvall<sup>1</sup>, **R. K. Greene<sup>1</sup>**, R. A. Phelps<sup>2</sup>, S. Markwardt<sup>2</sup>, T. M. Rutter<sup>3</sup>, J. Grieser Painter<sup>3</sup>, O. Doyle<sup>3</sup>, J. Nigg<sup>3</sup>, E. Fombonne<sup>4</sup>, D. Fair<sup>5</sup>, B. Calame<sup>3</sup> and M. Cordova<sup>6</sup>, (1)Oregon Health & Science University, Portland, OR, (2)Oregon Health & Science University - CDRC, Portland, OR, (3)OHSU, Portland, OR, (4)Department of Psychiatry, Oregon Health & Science University, Portland, OR, (5)Masonic Institute for the Developing Brain, Minneapolis, MN, (6)SDSU/UC San Diego Joint Doctoral Program in Clinical Psychology, San Diego, CA

**Background:** Despite increased awareness of autism spectrum disorder (ASD) heterogeneity and improvements in diagnostic reliability, there is concern for under-diagnosis (Zuckerman et al., 2013), over-diagnosis (Hill, Zuckerman, & Fombonne, 2015; Skellern, Schluter, & McDowell, 2005),

and misdiagnosis (Lucinao et al., 2014). Diagnostic accuracy is crucial for targeting intervention, and inaccurate ASD diagnoses hamper efforts to characterize the disorder at the population-level.

**Objectives:** We describe children with community-based diagnoses of ASD in a research referred sample with confirmed/included ASD diagnoses (ASD+) and unconfirmed/excluded/inaccurate diagnoses (ASD-) and explore the clinical characteristics that differentiated the groups.

**Methods:** Participants were 232 children (M<sub>Age</sub> = 10.71 years; 19% female) recruited for a study examining brain functioning in ASD. Families completed a phone screening confirming they met eligibility criteria (i.e., prior formal diagnosis of ASD, fluent in English, and no intellectual disability). Diagnostic confirmation was ascertained via team consensus of expert ADOS-2 reliable clinicians using DSM-IV and DSM-5 after review of intake paperwork and standardized assessments protocols and video recordings. Children's demographic characteristics, psychiatric history, developmental history, and medication use were ascertained via caregiver report. Measures included questionnaires (SRS-2, CCC-2) and assessments (WISC-V, ADOS-2, ADI-R). Group differences between unconfirmed/excluded (ASD-) and included (ASD+) children were examined via chi-square or Fisher's exact tests for categorical variables, and t-tests or Kruskal-Wallis tests for continuous variables.

**Results:** Nearly half ( $n = 109$ ) of children with a community-based ASD diagnosis did not meet ASD criteria by expert consensus. ASD+ and ASD- groups did not differ in age, gender, ethnicity, or racial make-up ( $p$ 's  $> .20$ ). The ASD+ group was more likely to have a history of early language delays (33%) compared to the ASD- group (14.9%,  $p < 0.01$ ); however, no group differences in current functional language use were observed on parent report ( $p$ 's  $> 0.05$ ). The ASD+ group scored significantly higher on the ADOS-2 Social Affect, Restricted and Repetitive Behaviors and Total scores ( $p$ 's  $< 0.01$ ) and on calibrated severity scores (CSS;  $M = 7.64$ ,  $SD = 1.45$ ) relative to the ASD- group ( $M = 2.50$ ,  $SD = 1.93$ ,  $p < 0.01$ ). Additionally, ASD+ had greater elevations on the ADI-R total scores (88.6%) compared to the ASD- group (56%). No group differences emerged for SRS-2 scores ( $p$ 's  $> 0.23$ ). The ASD- group attained higher full-scale IQ scores ( $M(SD) = 106.57(19.08)$ ) compared to the ASD+ group ( $M(SD) = 97.64(21.59)$ ,  $p < 0.01$ ). The ASD- group had more psychiatric disorders ( $p < .01$ ), with higher rates of anxiety disorder, conduct disorder, and mood disorder diagnoses ( $p$ 's  $< 0.04$ ). No differences were demonstrated in current medication use ( $p = 0.69$ ).

**Conclusions:** Parent questionnaires (SRS-2, CCC-2) did not differentiate the groups suggesting more limited clinical utility when ASD is the referring/central question. Clinician mediated tools (ADI-R and ADOS-2) demonstrated higher scores among the ASD+ group and were sensitive, even in this group with high concerns and previous (suspect) diagnoses, suggesting utility in ASD clinical referral settings. Increased reported psychiatric disorders in the ASD- group suggests psychiatric complexity may contribute to misdiagnosis.

#### **409.047 (Poster) Differences in Children at Risk for Autism Detected By Screening Vs. Surveillance**

**S. Y. Eldeeb<sup>1</sup>, A. T. Wieckowski<sup>1</sup>, R. K. Ramsey<sup>2</sup>, K. L. Coulter<sup>3</sup>, Y. Aljur<sup>4</sup>, V. Ryan<sup>4</sup> and D. L. Robins<sup>1</sup>, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Georgia State University, Atlanta, OH, (3)Psychological Sciences, University of Connecticut, Storrs, CT, (4)Epidemiology & Biostatistics, Drexel University, Philadelphia, PA**

#### **Background:**

Pediatric providers are often the first to identify whether a child is at risk for autism spectrum disorder (ASD) through the complementary processes of surveillance and screening. This project evaluates what factors in this process may relate to provider referrals and evaluation attendance.

#### **Objectives:**

This study 1) examined the likelihood of evaluation attendance after positive screen, provider concern (surveillance), or both, and 2) determined whether likelihood of endorsed provider concern for ASD is greater with more severe ASD symptomology or cognitive delays in children.

#### **Methods:**

7,040 toddlers (age 14.24–22.43 months) were screened at well-child visits across two multi-site studies examining early detection of ASD. During well-child visits, parents completed the Modified Checklist for Autism in Toddlers, Revised, with Follow-Up (M-CHAT-R/F) and providers had the opportunity to endorse ASD concerns. Children at risk for ASD ( $n=616$ ) from screen result, surveillance, or both were invited for an evaluation; 284 children attended the evaluation and were classified as ASD ( $n=141$ ) or non-ASD ( $n=143$ ). The Mullen Scales of Early Learning (MSEL) and the Autism Diagnostic Observation Schedule, 2<sup>nd</sup> Edition (ADOS-2) quantified cognitive abilities and ASD symptoms, respectively. ADOS-2 calibrated severity score (CSS) and MSEL early learning composite (ELC) scores were used.

#### **Results:**

There was a significant difference in evaluation attendance depending on referral source ( $X^2(2, n=616) = 39.79$ ,  $p < .001$ , *Cramer's V*=0.25). Pairwise comparisons indicated that attendance was significantly higher when both screen and concern indicated risk for ASD (65.97%) compared to when screen-only indicated risk (36.30%;  $X^2(1, n=549) = 39.95$ ,  $p < .001$ ,  $\phi=0.27$ ) or when provider-only indicated risk (35.82%;  $X^2(1, n=211) = 16.90$ ,  $p < .001$ ,  $\phi=0.28$ ). The difference in attendance based on screen-only and surveillance-only was not significant ( $p=.94$ ). The proportion of children with cognitive delay (i.e. MSEL ELC  $< 70$ ; see Figure 1) identified by provider concern (with or without at-risk screen) did not differ from screen-only ( $p=.18$ ). Providers were more likely to indicate concern for children with more severe ASD symptom severity whereas children in the screen-only group were more evenly divided among milder vs. more severe severity ( $X^2(1, n=272) = 6.70$ ,  $p=.01$ ,  $\phi=.16$ ); this was also true when examining ASD severity among the subgroup of children who received an ASD diagnosis ( $X^2(1, n=136) = 5.53$ ,  $p=.02$ ,  $\phi=.20$ ).

## Conclusions:

Our findings suggest that evaluation attendance increases when both screening and provider concern indicate risk compared to either modality alone. Providers may be more likely to encourage attendance and/or parents may be more aware of the need for evaluation when children are identified by both strategies. When examining symptom profiles in children identified by provider concern versus those detected by screen-only, cognitive impairment did not differ; however, providers were more likely to refer children with more severe ASD presentations, whereas screening identified cases across the spectrum of severity. These findings suggest providers may be missing milder presentations of ASD and, as a whole, highlights the importance of both providers and screening in the diagnostic process.

### **409.048 (Poster)** Differences in Reported and Observed Skills in Children with ASD from Multiplex and Simplex Families

**J. Anbar<sup>1</sup>, N. L. Matthews<sup>1</sup>, S. James<sup>1</sup>, C. J. Smith<sup>1</sup>, A. Ariff<sup>2</sup> and K. Pierce<sup>2</sup>, (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Neurosciences, University of California, San Diego, La Jolla, CA**

---

**Background:** Recent research suggests that children with Autism Spectrum Disorder (ASD) from multiplex families have greater cognitive functioning compared to children from simplex families (Berends et al., 2019). Other research indicates that similar differences may be detectable at evaluation with the Mullen Scales of Early Learning (MSEL; Dissanayake et al., 2019). Further research is needed to assess differences between multiplex and simplex children.

**Objectives:** (1) To replicate findings of previous research demonstrating cognitive advantages for multiplex children; and (2) to compare differences on screening and assessment tools in children from multiplex and simplex families.

**Methods:** Participants included 105 age and gender matched children who were screened and diagnosed with ASD as part of a parent study that investigated the effects of the Get SET Early Model (Pierce et al, 2021). Participants were split into three groups of 35: 1) multiplex; 2) simplex1 (i.e. ASD children without siblings); and 3) simplex2 (i.e. ASD children with siblings without ASD). The simplex families were split into two groups to examine the potential effects of siblings on development. Screenings were conducted between the ages of 9 and 36 months using the Communication and Symbolic Behavior Scales Developmental Profile Infant-Toddler Checklist (CSBS-ITC). While the upper age limit of the CSBS-ITC is 24 months, the parent study permitted the referral of children up to age 36 months; thus, CSBS-ITC data from children 24 to 36 months were included. Diagnoses were made by a licensed clinical psychologist and included the Autism Diagnostic Observation Schedule (ADOS), MSEL, and Vineland Adaptive Behavior Scales (VABS).

A Kruskal-Wallis test was used to compare ADOS calibrated severity scores among the three groups. Separate MANOVA models were used to examine the differences on the subscales (i.e. not global composite scores) of the CSBS-ITC, MSEL nonverbal and verbal developmental quotients (Stephens et al., 2018), and VABS.

**Results:** Statistically significant effects were not detected between the multiplex and simplex groups for the ADOS ( $\chi^2=0.57$ ,  $p=0.75$ ), MSEL developmental quotients (Pillai's Trace=0.04,  $p=0.410$ ), or VABS subscales ( $\lambda=0.93$ ,  $p=0.463$ ). A statistically significant global effect between mean CSBS-ITC subscale scores was identified among the three groups ( $\lambda=0.85$ ,  $p=0.014$ ). A post-hoc ANOVA revealed the effect to be associated with speech subscale ( $F(2, 99) = 3.11$ ,  $p=0.049$ ), with the multiplex group having significantly higher mean speech subscale scores than the simplex1 group ( $p=0.04$ , Cohen's  $d=0.545$ ; mean(SD) = 6.47(3.58) vs 4.56 (3.43), respectively).

**Conclusions:** In this sample there were no differences in MSEL developmental quotients, which differs from previous research. Findings suggest possible differences based on parent-reported speech skills among multiplex children compared to simplex1 children. These differences, however, were not found in a direct measurement of skills (i.e. MSEL developmental quotients). One possible explanation could be that parents from multiplex families have lower expectations for speech skills than simplex1 parents. Future research should examine discrepancies in parent reports of child language skills compared to direct assessments.

### **409.049 (Poster)** Differential Patterns of Response across Seven Dimensions of Risk on the First Years Inventory (FYIv3.1) Screening As Related to Autistic Traits at Age 3 in a Community Sample

**J. Sideris<sup>1</sup>, Y. J. Chen<sup>2</sup>, L. R. Watson<sup>3</sup>, E. Crais<sup>3</sup> and G. T. Baranek<sup>1</sup>, (1)USC Mrs. T.H. Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA, (2)Chan Division of Occupational Science and Occupational Therapy, McMaster University, Los Angeles, CA, Canada, (3)Department of Allied Health Sciences, University of North Carolina at Chapel Hill, Chapel Hill, NC, (4)Chan Division of Occupational Science and Occupational Therapy, University of Southern California, Los Angeles, CA**

---

**Background:** The First Year(s) Inventory (FYI; v2.0, Turner-Brown et al., 2013) has demonstrated promise as an ASD risk screener in a community sample of 12-month-olds, due in part to the inclusion of prodromal sensory-regulatory markers in addition to traditional social-communication markers. The FYI, version 3.1 (Baranek et al., 2013) was expanded to a broader age range (6-18 months) and seven dimensions to better capture heterogeneity. Dimensions include: Communication, Imitation & Play (CIP); Social Attention & Affective Engagement (SAE); Sensory Hyperresponsiveness (HYPER); Sensory Hyporesponsiveness (HYPO); Self-regulation in Daily Routines (SREG); Sensory Interests, Repetitions, Seeking Behaviors (SIRS); and Motor Coordination and Milestones (MCM). However, these factors haven't been tested in relation to diagnostic outcomes.

**Objectives:** We examined scores on the seven FYIv3.1 risk dimensions to assess group differences in diagnostic and/or autistic traits at age 3.

**Methods:** FYIv3.1 surveys were collected via mail and online from parents (N=6,427) of infants (6-16 months), recruited through birth records in North Carolina. At age 3, parents (n=2211) completed the Developmental Concerns Questionnaire (regarding medical/developmental history/diagnoses) and Social Responsiveness Scale (to quantify autistic traits). Coding of outcome groups was: Group 1=Diagnosis of ASD and/or high ASD traits, Group 2=Other Diagnosis/Developmental Concerns, and Group 3=No reported diagnosis/concerns. ANOVAs were used to test group differences across dimensions, and describe differential patterns. Follow-up analysis explored heterogeneity in Group 1 by comparing those with a confirmed ASD diagnosis to those without, but with SRS-T score $\geq$ 60.

**Results:** Results indicated significant differences between groups across all seven dimensions (see Table 1) (all  $p < .05$ ). For six risk dimensions: Group 1>Group2>Group3; CIP dimension showed Group 1=Group2>Group 3. Next, (Table 2) we parsed Group 1 into two subgroups – (Group 1A) with ASD diagnoses (n=15), and (Group 1B) with high SRS traits but without ASD diagnoses (n=55), per parent report at age 3. Group 1A tended to have higher risk scores on CIP, SAE and MCM dimensions, but lower risk scores on HYPER, HYPO, SIRS and SREG. In Group 1B, although they were not currently diagnosed with ASD, ~75% were reported to have various developmental problems, most notably developmental delay and language delay.

**Conclusions:** Our findings indicate important differences in both amount and pattern of FYIv3.1 risk scores across outcome groups in this community sample. Six of seven dimensions discriminated Group 1 (ASD Diagnosis/Traits) from both other groups, whereas, Group 1 and 2 were statistically similar on CIP. Further, the subgroup of children (Group 1A) with confirmed ASD diagnoses by age 3 differed from the subgroup with high autistic traits but no diagnosis (Group 1B) with respect to higher social communication and motor problems, whereas, the opposite was true for sensory-regulatory risk scores. These findings suggest that current ASD screening methods with the general population may be missing early expressions of sensory-regulatory risk of children who have high ASD traits by age 3. Longitudinal follow-up is needed to assess how many children in Group 1B “age-in” to an ASD diagnosis and determine whether the FYIv3.1 screener may help decrease barriers to early diagnosis.

**409.050 (Poster)** Discordance Among Parents and Teachers with Self-Reports on Internalizing Problems in Children and Youth with Autism Spectrum Disorders

**K. N. Dovgan<sup>1</sup>** and **K. Nowell<sup>2</sup>**, (1)Psychology, Marist College, Poughkeepsie, NY, (2)Health Psychology, Univ. of Missouri; Thompson Center for Autism & Neurodevelopmental Disorders, Columbia, MO

**Background:** Co-occurring internalizing disorders (i.e., anxiety and depression) are common in youth with Autism Spectrum Disorder (ASD) thus it is essential for clinicians to quickly identify and treat associated symptoms. However, measurement of internalizing symptoms is complicated by continued debate about differences in phenomenology of anxiety and depression in youth with and without ASD, and poor agreement on standardized measures across respondents. Understanding possible differences in ratings across respondents and how that compares to self-report is important as clinicians are often faced with reconciling discrepant data from multiple sources.

**Objectives:** This was an exploratory study that aimed to examine the agreement between parent and teacher ratings of internalizing problems in younger and older children with ASD, and how those ratings predict self-report measures of anxiety and depression in older children with ASD.

**Methods:** The sample included 1,386 participants (78.2% male) with ASD ranging in age from 1 to 21 years old ( $M=8.41$ ,  $S=4.33$ ), with an average IQ of 90.25 ( $S=17.41$ ; 13.2% with  $FSIQ \leq 70$  and 1.3% with  $FSIQ \geq 130$ ). Data were normal (skewness and kurtosis  $< \pm 1$ ), and extreme outliers (i.e.,  $> 2$  standard deviations) were removed. All analyses were conducted using standard scores, and separately for two age groups (1.5-5 and 6-18). We conducted paired sample  $t$ -tests to determine whether parent ratings (from the Child Behavior Checklist; CBCL) were significantly different from teacher ratings (from the Teacher Report Form; TRF) for internalizing problems. A subsample of participants ( $n=687$ ) completed self-report measures of anxiety (Multidimensional Anxiety Scale for Children; MASC) and/or depression (Children's Depression Inventory; CDI). We conducted logistic regressions to assess if parent report or teacher report predicted self-reports of anxiety or depression.

**Results:** In 1.5-5 year old children, parents reported significantly more somatic complaints ( $t=2.447$ ,  $p<.05$ ) than teachers; whereas, in 6-18 year old children, parents reported significantly higher levels of every subscale of internalizing problems ( $p's<.05$ ) than teachers (Table 1). In older children, levels of self-reported anxiety and depression did not differ by gender or IQ ( $p's>.05$ ). Of the sample who completed self-report measures, 45.9% were at-risk for anxiety on the MASC (22.9% reached clinical threshold), and 40.3% were at-risk for depression on the CDI (15.3% reached clinical threshold). Teacher-reported internalizing problems and stress problems significantly predicted the likelihood that the individual would report themselves at-risk for anxiety on the MASC; whereas, no CBCL or TRF scores significantly predicted at-risk levels of depression on the CDI (Table 2).

**Conclusions:** In this large, well-characterized sample of children with ASD, we found more discordance between parent and teacher ratings of older children than younger children, with parents endorsing greater levels of internalizing problems than teachers. Parent report and teacher report of internalizing problems were largely not predictive of self-reported at-risk levels of anxiety and depression in older children. Clinicians should continue to utilize multiple informants when assessing internalizing problems in children and youth with ASD until rater agreement can be improved and interpretation of discrepant data is clarified.

**409.051 (Poster)** Discrepancies between Parent and Clinician Report of Autism Spectrum Disorder Features: Associations with Demographics, Diagnosis, and Intervention

**M. A. Azu<sup>1</sup>**, **J. M. Wolf<sup>1</sup>**, **A. Naples<sup>1</sup>**, **K. Chawarska<sup>1</sup>**, **G. Dawson<sup>2</sup>**, **R. A. Bernier<sup>3</sup>**, **S. Jeste<sup>4</sup>**, **C. A. Nelson<sup>5</sup>**, **J. Dziura<sup>6</sup>**, **S. J. Webb<sup>3</sup>**, **C. Sugar<sup>4</sup>**, **F. Shic<sup>7</sup>** and **J. McPartland<sup>8</sup>**, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (3)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (4)University of California, Los Angeles, Los Angeles, CA, (5)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA,

**Background:** The autism spectrum disorder (ASD) diagnostic process incorporates parent report and clinician observation (Neuhaus et al., 2017). However, discrepancies may arise between parent and clinician perceptions of ASD (Neuhaus et al., 2017; Ventola et al., 2006). Understanding factors associated with clinician-parent disagreement is important because discrepancies may impede access to care.

**Objectives:** This study explored how discrepancies between clinician and parent reports of ASD symptoms related to children's demographic background (i.e., sex, family income, race), age at first diagnosis, and amount of intervention received.

**Methods:** As part of the Autism Biomarkers Consortium for Clinical Trials (ABC-CT), 280 children with ASD (76.8% male, 67.9% white), ages 6 to 11 ( $M=8.5\pm1.64$  years), were assessed via the Autism Diagnostic Observation Schedule (ADOS-2; Lord et al., 2012) and the Social Responsiveness Scale (SRS-2; Constantino, 2012). Parents also reported family income, child's age at initial diagnosis, and number of hours of intervention their child received in the past six weeks. Clinician-parent discrepancy scores were calculated by subtracting SRS z-scores (parent report) from ADOS z-scores (clinician report). Mann Whitney U and Kruskal Wallis Tests were used to explore how discrepancies between parent and clinician ratings of ASD symptoms differed by race, sex, and family income. Relationships between clinician-parent symptom rating discrepancies and the child's age at first diagnosis, as well as the number of hours of intervention received, were examined using Spearman's correlations.

**Results:** Discrepancies between parent and clinician ratings of ASD symptoms did not differ by race or family income; however, they did differ by child sex ( $U=553.00$ ,  $p=.028$ ) such that, relative to clinicians, parents reported higher symptom levels for males ( $M=.10$ ) and lower symptom levels for females ( $M=-.38$ ). Discrepancies between the SRS Social Communication and Interaction domain and the ADOS Social Affect domain revealed a similar pattern ( $U=5408.50$ ,  $p=.014$ ;  $M=.12$  for males and  $M=-.40$  for females). Additionally, higher clinician ratings of overall ( $r(264)=-.20$ ,  $p=.001$ ) and social symptoms ( $r(264)=-.19$ ,  $p=.002$ ), relative to parent ratings, were associated with an earlier diagnosis. This pattern was also observed for intervention hours (overall [ $r(254)=-.19$ ,  $p=.003$ ], social [ $r(254)=-.20$ ,  $p=.001$ ]).

**Conclusions:** Findings suggest that agreement between clinician and parent ratings of ASD symptoms differs by child sex, with parent ratings lower than clinician ratings for boys and higher than clinician ratings for girls. This study cannot differentiate whether these findings reflect parental under-report in boys and over-report in girls or clinicians overlooking female symptoms, potentially due to 'social camouflaging' (Dean et al., 2017). Both clinicians and parents may benefit from a deeper understanding of how ASD presents differently in boys and girls. Another major finding was that higher clinician ratings of ASD symptoms, relative to parent ratings, was correlated with an earlier diagnosis age and a greater number of intervention hours. These results emphasize the importance of clinician evaluation in facilitating support for children with ASD. The lack of other demographic differences may reflect the homogeneity of the present sample and should be revisited in more diverse samples.

#### 409.052 (Poster) Do Behavioral and Parent-Reported Measures of Sensory Filtering in Autism Match?

A. Seif<sup>1</sup>, R. Phillips<sup>1</sup>, S. E. Schulz<sup>2</sup>, K. R. Henderson<sup>3</sup>, S. Schmid<sup>3</sup> and R. A. Stevenson<sup>1</sup>, (1)University of Western Ontario, London, ON, Canada, (2)Western University, London, ON, Canada, (3)Anatomy and Cell Biology, University of Western Ontario, London, ON, Canada

---

**Background:** Sensory responsivity and filtering differences are commonly associated with autism. Sensory issues have been hypothesized to influence many other aspects of autism, such as social communication skills, restricted and repeated behaviors and interests, and motor stereotypies (Sinclair et al., 2017). Clinically, sensory issues are usually evaluated through parent questionnaires, though behavioural measures of sensory processing are available in laboratory settings. Specifically, the acoustic startle response is used to measure acoustic reactivity, pre-pulse inhibition, and habituation, all of which are measures of sensory filtering. The startle response is a reflexive muscular reactivity to an acoustic stimulus measured by the strength of an eyeblink (Takahashi et al., 2014). To date, however, it is unknown how sensory responsivity and sensory filtering measured through parental reports and through the startle response relate.

**Objectives:** The objective of this study is to use both parent report and the acoustic startle paradigm to examine sensory gating differences in autism, and to directly compare behavioral and parent-reported measures.

**Methods:** Autistic ( $n=14$ ) and neurotypical ( $n=13$ ) school-aged children completed an auditory startle task to assess the acoustic startle response, habituation, and pre-pulse inhibition (Figure 1). Participants listened passively to a series of pulses ranging from 65db to 105db while watching a silent video. The startle response is measured through the eyeblink by electromyogram (EMG) of the muscles under the eye. An increase in EMG magnitude reflects an increase in startle response. Parents completed the Short Sensory Profile questionnaire. The startle magnitude was correlated with the auditory filtering and auditory/visual sensitivity sections of the short sensory profile.

**Results:** The sample included autistic ( $n=14$ ) and neurotypical children ( $n=13$ ). The autistic children displayed significantly increased startle ( $M_{ASD}=290\pm21.57$ ,  $M_{NT}=172.69\pm30.23$ ,  $p=0.005$ ) compared to neurotypicals (Figure 2), but there were no significant differences in habituation and pre-pulse inhibition. Moreover, the autistic children scored lower in the total short sensory profile ( $M_{ASD}=124\pm5.89$ ,  $M_{NT}=145.25\pm6.66$ ,  $p<0.001$ ) and the auditory filtering section specifically ( $M_{ASD}=18.38\pm1.43$ ,  $M_{NT}=25.38\pm1.03$ ,  $p<0.001$ ). Moreover, individuals showing stronger startle responses were also rated as having significantly more sensory issues by their parents overall ( $n=15$ ,  $r=-0.634$ ,  $p=0.011$ ), and a trend towards showing difficulties in auditory filtering based on parent reports ( $n=26$ ,  $r=-0.363$ ,  $p=0.069$ ).

**Conclusions:** It is important to ensure that behavioral, lab-based measures of sensory filtering map onto existing clinical measures. Here, both parent reports and the startle task confirmed the presence of sensory processing alterations in autism. Importantly, the negative correlation between SSP score and startle indicate that children whose parent reports indicated more sensory issues also had increased startle response. The lab-based startle measures thus confirm the subjective parent-reports and provide guidance for future research into the startle pathway. Previous research indicates

auditory filtering issues may relate to alterations in the brainstem (Seif et al., 2021), which overlaps the sensorimotor interface of the startle pathway. Future research should investigate the startle pathway for mechanism of disruptions which could inform us about the neurobiological underpinnings of autism, which could inform the development of targeted supports.

**409.053 (Poster)** Early Autism Adaptive Behavior Subtypes Differ in Verbal, Non-Verbal, and Motor Developmental Trajectories over the First 6 Years of Life

*V. Mandelli<sup>1,2</sup>, I. Landi<sup>2</sup>, E. M. Busuoli<sup>2,3</sup>, E. Courchesne<sup>4</sup>, K. Pierce<sup>5</sup> and M. V. Lombardo<sup>6</sup>, (1)Center for mind/brain sciences - CIMEC, Centre for Mind Brain Sciences (CIMEC), University of Trento, Italy, Trento, Italy, (2)Center for Neuroscience and Cognitive Systems, Laboratory for Autism and Neurodevelopmental Disorders, Istituto Italiano di Tecnologia, Rovereto, Italy, (3)University of Trento, Center for mind/brain sciences - CIMEC, Trento, Italy, (4)Neuroscience, UC San Diego Autism Center of Excellence, San Diego, CA, (5)Neurosciences, University of California, San Diego, La Jolla, CA, (6)Center for Neuroscience and Cognitive Systems, Istituto Italiano di Tecnologia, Rovereto, Italy*

---

**Background:** One of the major goals of precision medicine in psychiatry is to develop clinically meaningful stratification tools for more individualized intervention strategies. Adaptive behavior, measured by the Vineland Adaptive Behaviors Scales (VABS), is considered a key treatment target in interventions for autism. Stratification tools applied on the VABS may help facilitate intervention work to understand variability in treatment response in clinical trials.

**Objectives:** We developed a highly generalizable developmentally meaningful stratification model of autism using one snapshot of the VABS at early ages (<72 months) to make accurate out-of-sample predictions. Next, we tested whether the subtypes identified by our model differ from each other in terms of developmental trajectories through the first 5 years of life.

**Methods:** We developed a stratification model of adaptive behavior using a large dataset of VABS identified in 1098 autistic individuals aged 0-72 months within the National Database for Autism Research (NDAR). Standardized scores from the four subscales of VABS (Communication, Daily Living Skills, Socialization, Motor) were used as input features for our model. We applied an unsupervised clustering algorithm (k-means) within a context of relative clustering validation to ensure reproducibility of the clustering solution (Landi et al., 2021). Subsequently, we tested the newly discovered clusters for differences in developmental trajectories. With a k-nearest neighbor classifier trained on NDAR data we applied subtype labels to a new dataset of 1216 autistic children aged 0-72 months who participated in a longitudinal study at University of California San Diego (UCSD). These children were administered with VABS at T1, together with Mullen Scales of Early Learning (MSEL) collected at multiple time points after T1 within the first 5 years of life. Longitudinal trajectories of MSEL domains (Visual Receptive -VR, Fine motor -FM, Receptive Language -RL, Expressive Language -EL) were modeled with linear mixed effect models with random intercepts and slopes for the effect of age grouped by participant and fixed effects of age and subtype, along with their interaction.

**Results:** Our stratification model, trained on the NDAR dataset identified 3 clusters of autism adaptive functioning with high out-of-sample prediction accuracy (97%). Applying this model to UCSD dataset, we find age\*subtype interactions for every MSEL domain (VR:  $F=23$ ,  $p<0.001$ ; FM:  $F=14$ ,  $p<0.001$ ; RL:  $F=13$ ,  $p<0.001$ ; EL:  $F=31$ ,  $p<0.001$ ), indicating that VABS subtypes differ significantly in their longitudinal trajectories. Combining our subtype model with VABS norm cutoffs, we were able to significantly improve prediction models of developmental trajectories over and above a range of other comparison models (e.g.,  $\Delta AIC>80$ ).

**Conclusions:** Unsupervised clustering of adaptive behavior in autism yields consistent and reproducible subtypes that highly differ in their developmental trajectories across verbal, non-verbal and motor domains. This subtyping model can be utilized for out-of-sample predictions in new data and will be applicable via a web application for facilitating future research on adaptive behavior subtyping in autism.

**409.054 (Poster)** Early Reading and Linguistic Indicators for Daughters with Delayed or Missed Diagnosis of Autism Spectrum Disorder  
*D. F. Stovall<sup>1</sup>, M. Gillies<sup>2</sup>, E. A. Cutrer-Parraga<sup>3</sup>, C. Yaccarino<sup>3</sup> and R. A. Lundwall<sup>4</sup>, (1)Psychology, Brigham Young University Psychology Department, Provo, UT, (2)Brigham Young University, Provo, UT, (3)Counseling Psychology and Special Education, Brigham Young University, Provo, UT, (4)Psychology & Neuroscience, Brigham Young University, Provo, UT*

---

**Background:** The ratio of male to female diagnosis in autism spectrum disorder (ASD) is 3 to 1, indicating a possible gender bias in assessment protocol. This disparity has led researchers to propose that females are misdiagnosed or underdiagnosed due to their natural propensity to “camouflage” autistic traits. These females need early, accurate detection to improve quality of life.

**Objectives:** This study attempts to find common early reading and linguistic traits among females with autism (and possible delayed or missed ASD diagnosis) to help pave the way for female-specific identifiers of ASD.

**Methods:** Our sample consisted of 21 parents whose daughters participated in a larger study investigating life experiences of females (aged 14+) with autism or autistic traits. The Broad Autism Phenotype Score (BAP-Q) was administered to potential participants, and parents were contacted to schedule 30–60-minute recorded interviews. Semi-structured interviews followed a guided protocol allowing for reflection and probing to ascertain pertinent developmental background information. The interviewer maintained deliberate naivete to diminish presumptions and preserve openness for unforeseen findings. Recordings of interviews were transcribed verbatim. Interpretative Phenomenological Analysis (IPA) was employed as a qualitative measure to analyze responses for interpretation of data. In phase one, transcriptions were reviewed by the research team to identify patterns. Data were compiled into two a priori codes: (a) early language development progression, and (b) early language development skills. Further organization of data was aided through process-coding to catalogue recurrent actions. Following within-case analyses, cross-case analyses were conducted in phase 2. Multiple rounds of revision led to the emergence of themes embodied in the data.

**Results:** Two overarching themes captured the data: (a) parents reported early reading development, and (b) parents reported advanced fluency in word level reading while acknowledging lagging comprehension skills (especially regarding the emotions and motivations of story characters). All participants, except one, reported literacy developing early (the remaining participant reported typical reading development). Most parents perceived their daughters to be voracious readers, demonstrating advanced and/or above grade-level ability. This finding was coupled with sleep issues and missed social opportunities. Despite a perceived hyper focus on reading, many parents indicated a concern for lack of comprehension, a need for speech therapy, and a distaste for conversation in general. Reading comprehension dominated as the most challenging domain of early literacy development. This was apparent in a struggle to identify emotions and connect with characters, a tendency to take language and characters literally, lack of general comprehension, and an obsessive propensity for one singular genre.

**Conclusions:** This exploratory study was successful in identifying common literacy and linguistic traits among daughters with delayed or missed ASD diagnosis. Our findings are consistent with previous findings of less coherent narrative production in story recall (Diehl, 2006) and overall lower reading comprehension amongst children with autism (McIntyre et.al., 2107). Early identification of autism in females may benefit from prompt detection of early, voracious readers who lack associated advanced level comprehension.

**409.055 (Poster)** Autism Observation Scale for Infants: Systematic Review and Meta-Analysis in Samples at Increased Likelihood of Autism Spectrum Disorders

**K. Reid<sup>1</sup>**, L. A. Sacrey<sup>2</sup>, L. Zwaigenbaum<sup>1</sup>, J. A. Brian<sup>3</sup> and I. M. Smith<sup>4</sup>, (1)University of Alberta, Edmonton, AB, Canada, (2)Autism Research Centre, Glenrose Rehabilitation Hospital, Edmonton, AB, CANADA, (3)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA

---

**Background:** The Autism Observation Scale for Infants (AOSI) has been used in many studies to investigate early features of children with an increased likelihood (IL) of a later diagnosis of autism spectrum disorder (ASD). Studies from independent research groups have evaluated its use in IL infant siblings (younger siblings of the children with ASD), with more recent studies examining its use in other IL populations.

**Objectives:** To assess the discriminative and predictive utility of the AOSI across different IL populations.

**Methods:** A systematic review and meta-analysis was conducted to provide an in-depth examination of current research investigating the use of the AOSI in IL infants. A search for relevant articles was conducted across four databases: CINAHL, PubMed, JSTOR, and Web of Science, with articles independently reviewed for inclusion and exclusion criteria by two reviewers.

**Results:** Searches resulted in a total of 276 articles, with 11 articles meeting inclusion criteria. Four IL infant populations were assessed across these studies: younger siblings of children diagnosed with ASD, as well as infants with Fragile X Syndrome (FXS), Tuberous Sclerosis Complex (TSC), and Down Syndrome. There were three main findings. First, five studies reported individual classification properties, yet they were not analyzed using a consistent approach. Second, across studies, stable group differences emerged between IL non-ASD, IL-ASD, and typically developing (control) samples beginning at 12 months of age. Third, meta-analyses resulted in a large effect size for comparisons between typically developing control and IL-ASD samples and a moderate effect size for comparisons of IL non-ASD and IL-ASD samples.

**Conclusions:** Utility of the AOSI to identify early signs of ASD was demonstrated in IL populations, including infant siblings of children diagnosed with ASD, FXS, TSC, and Down Syndrome.

**409.056 (Poster)** Gaze-Based Features Extracted Via Computer Vision Are Differentially Correlated with Parent-Report Measures of Autism-Related Behaviors and Internalizing and Externalizing Behaviors

---

**Background:**

Digital phenotyping via computer vision analysis (CVA) has potential to provide objective, scalable, and reproducible measures of autism-related behaviors. The *SenseToKnow* (S2K) application was developed to capture and quantify digital phenotypes associated with child behavior and engagement with movies and games displayed on a tablet. S2K was designed to strategically assess social, cognitive, and motor behaviors associated with autism, including patterns of eye gaze. Elucidating gaze patterns is a promising approach to autism screening, outcome monitoring, and differentiation from common comorbidities. However, measuring eye gaze has previously been limited to laboratory settings, requiring costly equipment and trained personnel. Understanding whether measures of eye gaze quantified via CVA are correlated with well-established caregiver report and clinician measures of autism-related behaviors is an essential next step in establishing the validity of a digital phenotyping approach.

**Objectives:**

The present project extended prior work by examining the relation between parent-report measures of autism-related behaviors and internalizing and externalizing behaviors and gaze features quantified via CVA.

## Methods:

Toddlers 17-36 months old (N=426) were invited to participate in the study during their well-child visit. 43 toddlers were diagnosed with autism based on the ADOS-2 and ADI-R and 20 toddlers were diagnosed with developmental and/or language delay (DDLD). In standard clinical settings, children watched S2K while their upper body and face were recorded using the tablet embedded camera (Chang, Z. *et al.* 2021). Three gaze-based features were extracted while the toddlers watched three stimuli (see Figure 1). We estimated the proportion of time children looked at the right side of the screen (which, depending on the stimuli, corresponds to attention to the social or non-social part of the stimuli, referred to as social/non-social gaze). The third stimulus consisted of two women conversing, from which we derived a feature representing the correlation between participant gaze and pattern of speech over time (gaze-speech correlation). We analyzed these digital phenotypes based on CVA features and compared their distribution with clinical measures of autism and internalizing and externalizing behaviors based on parent-report measures, namely, the Modified Checklist for Autism-Revised with Follow Up (M-CHAT-R/F), Social Responsiveness Scale – 2 (SRS-2) and the Child Behavior Checklist (CBCL).

## Results:

Significant correlations were observed between the SRS total score and S2K digital phenotypes of non-social gaze, social gaze and gaze-speech correlation. On the CBCL, significant correlations were observed between internalizing behaviors and nonsocial gaze, social gaze, and gaze-speech correlation and between externalizing behaviors on the CBCL and non-social gaze and gaze-speech correlations (Table 1). Figure 1 illustrates the distribution of participants for three CVA features: social gaze, non-social gaze, and gaze-speech correlation (horizontal axis), and the SRS/CBCL total score.

## Conclusions:

Parent-report measures of autism-related behaviors and internalizing behaviors were positively associated with gaze towards the non-social side of the stimuli whereas externalizing behaviors negatively associated with the gaze correlation with speech. Notably, correlations between gaze patterns and behavior were stronger for autism-related behaviors, as compared to behaviors related to internalizing and externalizing symptoms, providing suggestive evidence of convergent validity.

### 409.057 (Poster) Test-Retest Reliability of Social Attention Measures from a Digital Phenotyping Application

**K. L. Carpenter<sup>1</sup>**, C. Sullivan<sup>2</sup>, J. M. Di Martino<sup>3</sup>, Z. Chang<sup>3</sup>, S. Perochon<sup>3</sup>, P. R. Krishnappa Babu<sup>3</sup>, D. Y. Isaev<sup>4</sup>, J. A. Summers<sup>2</sup>, K. Washington<sup>1</sup>, M. Sabatos-DeVito<sup>5</sup>, G. Sapiro<sup>3</sup> and G. Dawson<sup>1</sup>, (1)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (2)Duke University, Durham, NC, (3)Department of Electrical and Computer Engineering, Duke University, Durham, NC, (4)Duke Center for Autism and Brain Development, Durham, NC, (5)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC

**Background:** Behavioral assessments of young autistic children currently rely on subjective clinical ratings and caregiver reports. These measures are influenced by expectancy, often lack granularity and sensitivity to change, and require labor-intensive coding. There is a need for objective, scalable, and quantitative behavioral assessments that can be used to complement clinician ratings and caregiver report. We developed the *SenseToKnow-Toddler-Preschool* (S2K-TP) application that can be administered on a smartphone or tablet. S2K-TP consists of brief, developmentally appropriate, engaging movies that contain naturalistic, dynamic social and nonsocial stimuli and take less than 10 minutes to deliver. The child's responses are recorded via the frontal camera embedded in the device and computer vision analysis (CVA) is used to quantify the child's behavioral responses automatically. In previous studies, we have demonstrated that S2K-TP can quantify several digital phenotypes, including those based on gaze, facial expressions, responding to name, and postural patterns.

**Objectives:** To assess the test-retest reliability of gaze features derived from the S2K-TP app.

**Methods:** We assessed test-retest reliability of two types of gaze features measure by the S2K-TP app, one feature related to the amount of gaze directed toward the social elements in the movie and a second feature related to the coordination between gaze and the speech patterns of actors in the movie (see Chang *et al.*, 2021).<sup>1</sup> The sample was 102 children ages 40.8-98.7 months, 62 of which were diagnosed with autism spectrum disorder via ADOS and ADI-R. Children received a second S2K-TP administration between 1 and 55 days after their first administration. Test-retest reliability was computed with the *psych* package in RStudio with the "testRetest" and "ICC" functions. Impact of time and multiple visits were inspected with the *lme4* package "lmer" function.

**Results:** Within-subject test-retest reliability of response patterns over items (rrq) was high (mean = .99 [SD = .03]; range = .80-.99). The ICC between visits for individual CVA features was .60-.80. Days between visits in the tested range did not affect outcomes. Preliminary analyses suggest there's not a difference between autistic and non-autistic children. Figure 1 illustrates the distribution of three gaze-based features during the first and second visit in the subset of autistic children.

**Conclusions:** These results describe the stability of the digital phenotypes captured by our novel S2K-TP application and suggest that gaze-based features can be extracted reliably across multiple administrations. Taken together, the objective nature of the digital features, the scalability of eliciting such behaviors using just an iPad or an iPhone, and the stability of the CVA signal as demonstrated by these results, suggest that the S2K-TP

may be a useful tool for evaluating the efficacy of interventions for young autistic children.

**409.058** (Poster) Validity Evidence of Cultural Adaptation of the English Original Version of Emotional Outburst Questionnaire to Brazilian Portuguese.

**C. S. Paula<sup>1</sup>, M. C. Teixeira<sup>1</sup>, C. Mevorach<sup>2</sup>, R. Lowenthal<sup>3</sup>, B. Balbueno<sup>1</sup>, J. Chung<sup>4</sup> and K. Woodcock<sup>4</sup>,** (1)Developmental Disorder Program, Universidade Presbiteriana Mackenzie, São Paulo, Brazil, (2)School of Psychology, University of Birmingham, Birmingham, United Kingdom, (3)Santa Casa Hospital, Sao Paulo, Brazil, (4)University of Birmingham, Birmingham, United Kingdom

---

#### Background:

The emotional outbursts (EO) are brief episodes of challenging behaviors or meltdowns disproportionate to the situation or context in which they occur and frequent in people with severe neurodevelopmental disorders.

#### Objectives:

To verify psychometric properties of cultural adaptation of the English original version of the Emotional Outburst Questionnaire instrument to Brazilian Portuguese.

#### Methods:

The measure was the Portuguese version of Emotional Outburst Questionnaire - informant-report measure for outburst characteristics, including 55 items that assesses the frequency and duration of behavioral topographies indicative of EO, emotional patterns during EO, recovery time from EO, environmental and physiological factors EO triggers and effectiveness of control strategies to calm EO. The study was conducted in four stages: a) Translation, translation synthesis and cultural adaptation of the instrument to Brazilian Portuguese, b) evaluation of translation by a sample of the target group, c) Back-translation, d) Pilot Study on sample composed of 359 individuals with autism spectrum disorder (ASD), Down syndrome (DS) and intellectual disability (ID) between 6 and 25 years old, both genders with average age=10.41, standard deviation=0.42.

#### Results:

The main results of the first three stages were: changes made for cultural adaptation purposes based on idiomatic and conceptual equivalence criteria and, of 11 terms that required adjustments, only two were fully modified and the others partially modified. In the item's evaluation, instructions, and response scale by the seven participants of the target group there were no suggestion of changes. In the back-translation stage, the semantic and idiomatic type adjustments predominated in 38 words and phrases with adjustments of the final version in Portuguese. The results of the pilot study showed that the most severe EO topographies presented more frequently in the sample are "non-verbal vocalizations", "avoidance", "ignoring or not talking to certain people", "increased motor activity" and "increased physiological response", the occurrence being 4 to 6 times every 10 outbursts. The duration of more severe EO (58%) and less severe (20.89%) was short being less than 5 minutes, followed by 34.81% of the sample with more severe EO and 59.94% with less severe EO that lasted from 5 to 15 minutes. Statistical association was verified between the overall frequency of EO and the diagnostic (ASD, DS and ID). The chi-square test of independence showed an association between some types of frequency of EO and diagnostic ( $\chi^2$  (24) = 46.840;  $p=0.004$ ). Participants with ASD are more likely to have EO once a week and people with ID are more likely to have EO 2 to 3 times a month. Cramer's V Index showed an association of approximately 28% between age classification and EO (V of Cramer =0.280;  $p=0.00$ ). Children between 6 and 11 years old have a greater tendency to have EO one to three times a week and people over 17 years have them once a month ( $\chi^2$  (16) = 56.267;  $p=0.00$ ).

#### Conclusions:

Study results showed psychometric properties suitable for use in a research context and clinical context in Brazil.

**409.059** (Poster) Potential Relationships between Sleep and Daily Activity in Children with Autism

**G. Eylon<sup>1</sup>, G. Meiri<sup>2</sup>, I. Menashe<sup>3</sup>, L. Tikotzky<sup>4</sup> and I. Dinstein<sup>5</sup>,** (1)Cognitive and Brain Sciences, Ben Gurion University of the Negev, Beer Shev, Israel, (2)National Autism Research Center of Israel, Ben-Gurion University of the Negev, Beer Sheva, Israel, (3)Public Health Department, Ben-Gurion University of the Negev, Beer Sheva, Israel, (4)Psychology, Ben Gurion University of the Negev, Be'er Sheva, Israel, (5)Cognitive and Brain Sciences Department, Ben-Gurion University of the Negev, Beer Sheva, Israel

---

#### Background:

More than half of children with autism exhibit considerable sleep disturbances evident in late sleep onset, multiple wake periods during the night, and shorter sleep duration. Large scale studies have so far used parent questionnaires, sleep diaries, and/or actigraphy to measure these sleep disturbances in large populations. Recent development of wearable sensors may offer more accurate identification of sleep parameters as well as additional measures, such as heart rate and activity levels throughout the day, that may yield further mechanistic insights regarding the causes of different sleep disturbances and ways of treating them (Figure 1).

#### Objectives:

To compare common sleep parameters as reported by the Fitbit Charge 3 sensor, parent questionnaire and sleep diary while relating them to daily activity measures.

#### Methods:

A total of 56 children with ASD (11 females), mean age 4.1 (range 1.9–7.6) were recruited to this ongoing study. Sleep variables, heart rate, and activity levels were measured in each child using a Fitbit Charge 3 sensor that was taped to the upper arm over 1-5 consecutive days and nights (i.e., at least 24 hours). Sleep onset, awakenings during the night, and awakening in the morning were identified by the Fitbit sleep staging algorithm. All parents completed the Child Sleep Habit Questionnaire (CSHQ) within six months of the recorded period. Parents of 36 children also completed a sleep diary in parallel with the Fitbit recordings (i.e., same nights). We computed total sleep time (TST), wake after sleep onset (WASO), sleep onset and final awakening across the three data sources. We then compared these measures using t-tests, and assessed their relationship with activity levels using Pearson's correlation coefficients.

#### Results:

The Fitbit Charge 3 sensor reported significantly lower estimates of TST in comparison to both parent report with the CSHQ ( $t(39) = -2.4, p < .05$ ) and the sleep diaries ( $t(35) = -13.5, p < .001$ ). Conversely, the sensor reported significantly higher estimates of WASO in comparison to parent report with the CSHQ ( $t(39) = 4.5, p < .001$ ) and the sleep diaries ( $t(35) = 17.1, p < .001$ ). Nevertheless, TST and WASO measures from the sensory and sleep diary were significantly correlated when compared across nights ( $r(34) = .57, p < .05$  and  $r(34) = .58, p < .05$  respectively, figure 2). Initial analyses did not reveal a significant correlation between the amount of activity during the day and the amount of sleep during the following night ( $r(210) = -.01, p = 0.16$ ).

#### Conclusions:

Initial results suggest that parents over-estimate their children's sleep likely because they are not aware of the child's precise sleep onset time and some of the child's awakenings during the night. Nevertheless, Fitbit and sleep diaries were significantly correlated, demonstrating the utility of Fitbit in quantifying sleep disturbances along with additional measures such as activity for further studying sleep disturbance in large cohorts of children with ASD.

## POSTER SESSION — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

### 418 - Diagnostic, Behavioral & Intellectual Assessment II

**418.083** (Poster) Echo Autism: Developing Clinical Expertise for Autism Spectrum Disorder Assessment and Diagnosis in Primary Care Clinicians K. Schieltz<sup>1</sup>, R. Brown<sup>2</sup>, V. Nanclares-Nogues<sup>3</sup>, M. Odum<sup>4</sup> and K. Sohl<sup>5</sup>, (1)University of Iowa, Iowa City, IA, (2)KUMC, Wichita, KS, (3)ECHO Autism Communities, University of Missouri, Columbia, MO, (4)ECHO Autism Communities, University of Missouri, School of Medicine, Columbia, MO, (5)ECHO Autism Communities, Child Health, Columbia, MO

#### Background:

Diagnosis of autism spectrum disorder (ASD) currently relies on highly specialized standardized instruments administered by subspecialist providers, making wait times for diagnostic assessments often very long. Project ECHO models provide an established platform to disseminate expert knowledge from specialist to community generalist. Implementing the ECHO Autism model has the potential to dramatically increase access to autism diagnosis, especially in rural and underserved communities.

#### Objectives:

The project aims to describe the process for determining a primary care clinician's (PCC) readiness to independently evaluate, discriminate differentials, and diagnose a child with unambiguous symptoms of ASD between ages 14-48 months, as well as assess the accuracy and level of entrustable professional activity (EPA) concordance in the development of clinical expertise in PCCs.

#### Methods:

ECHO Autism is an innovative approach that leverages videoconferencing technology to amplify scarce specialist knowledge to mentor generalist clinicians through de-identified, case-based learning. ECHO Autism sessions occur twice a month for 90 minutes. Between 2017-2020, 20 PCCs successfully achieved reliability with experienced diagnosticians. Each completed ECHO Autism: STAT training, including a 1.5-day training on the STAT (Screening Tool for Autism in Toddlers and Young Children) and elements of diagnostic best practices. Additionally, the PCCs completed a 12-module curriculum and presented cases to the ECHO Autism team for diagnostic process feedback and recommendations.

The PCCs completed case presentation forms that included comprehensive developmental/behavioral and medical history, screening results, and direct behavioral observation scores. Each PCC then synthesized this information to indicate their impression of the symptoms as absent, subthreshold, or present in each of the seven DSM-5 ASD criteria and provided a summative diagnostic impression rating of yes, maybe, or no.

Accuracy was defined as the level of agreement between ECHO Autism panel experts (who also rated the symptom presentation and diagnostic impression) and the PCC presenting the case. Accuracy was rated using a 4-point Likert scale ranging from *definitely disagree* (1) to *definitely agree* (4).

#### Results:

256 diagnostic cases were presented during teleECHO sessions across the 20 participants. Of the cases determined to meet unambiguous ASD diagnostic criteria, 90% met the average 3.5 accuracy criterion for DSM-5 symptom impressions and 94% met the impression score of 4 for the unambiguous diagnostic criterion. Similarly, of the cases determined to be not-autism or ambiguous, 73% met the average 3.5 accuracy criterion for DSM-5 symptom accuracy and 84% met the impression score of 4 for diagnostic impression. Thirteen of the 20 participants met criteria to independently evaluate children for ASD ( $M = 11.5$  case presentations; range, 9-20). The remaining participants continue to present cases for diagnostic discussion and verification.

#### Conclusions:

PCCs can develop clinical expertise in the evaluation and diagnosis of young children with ASD that is accurate and reliable. Their ability to discriminate symptoms within the DSM5 criteria as well as the overall diagnostic impression is promising as a means to reduce diagnostic bottlenecks in tertiary specialty centers. Expanding access for community-based diagnosis is critical to detect ASD symptoms and guide individualized intervention to support a child's development.

#### **418.084** (Poster) Examining the Cultural Sensitivity of a Social Communication Screening Tool for Toddlers ("My Toddler's Social Communication"): A Mixed-Methods Study

**K. Duffy-Greslo<sup>1</sup>**, S. M. Attar<sup>2</sup>, L. V. Ibanez<sup>3</sup> and W. L. Stone<sup>4</sup>, (1)Psychology, University of Washington - Seattle, Seattle, WA, (2)University of Washington, Seattle, WA, (3)UW READi Lab, Seattle, WA, (4)Psychology, University of Washington, Seattle, WA

---

#### Background:

Inequities in healthcare have led to disparities for many populations, particularly people belonging to linguistic, cultural, and racial minorities. One area where this is prevalent is in the diagnosis and treatment of Autism Spectrum Disorder (ASD). Among other causes for these existing disparities, the tools used for assessing children for ASD have been shown not to work equitably with all populations due to a lack of cultural sensitivity. This study assesses the cultural sensitivity of "My Toddler's Social Communication" (MTSC), a screening tool currently being developed by the UW Read Lab to assess for social communication deficits in toddlers. Unlike existing screening tools, MTSC employs photographs of toddlers engaging in a variety of common social communication behaviors, along with brief behavioral descriptions. Caregivers are asked to identify the extent to which their toddlers display behaviors such as requesting desired objects and directing someone's attention to items or events of interest. Photos were added to support accurate interpretation of our target behaviors through visual illustrations, and we included a diverse representation of children to allow a range of caregivers to feel that their child is visually represented in our tool.

#### Objectives:

This pilot study aims to assess the cultural sensitivity of the MTSC. Specifically, we aim to: (1) investigate whether caregivers of toddlers find the MTSC to be feasible for use with families from diverse backgrounds and (2) find the photos and target behaviors culturally relevant. We hope that our process will contribute toward elucidating a methodology for developing culturally sensitive and relevant assessment tools.

#### Methods:

The proposed study uses a sequential explanatory mixed-methods design. For the first phase, caregivers of children aged 16-30 months filled out the MTSC and a feedback survey that included two questions regarding the usability and feasibility of the MTSC. For the second phase which will take place between November 2021 – February 2022, 15 caregivers belonging to a culturally or linguistically diverse group will participate in semi-structured interviews about the MTSC. The survey data will be analyzed using descriptive statistics and the semi-structured interviews will be analyzed with a content analysis.

#### Results:

The preliminary results of this study found that 80% of the caregivers found the photos used in the MTSC to be representative of a broad range of cultures. The respondents who disagreed noted that the pictures chosen should show more gender and racial diversity. However, only 30% of the caregivers stated that they agreed with the statement that caregivers from various backgrounds could easily complete the MTSC. The additional comments provided suggest that this tool would need to be translated into multiple languages and that some target behaviors are not used the same in all cultures.

#### Conclusions:

These preliminary results suggest that the MTSC is largely representative in the photos chosen to depict social communication behaviors but can be revised to improve its feasibility and relevance of target behaviors. We hope the results from our planned second phase will gather more specific information and suggestions for improvement.

**418.085 (Poster)** Extending the Usefulness of the Brief Observation of Social Communication Change (BOSCC): Development of the Phrase Speech and Young Fluent Version

**K. Byrne<sup>1</sup>, K. Sterrett<sup>1</sup>, A. Holbrook<sup>1</sup> and C. Lord<sup>2</sup>,** (1)University of California, Los Angeles, Los Angeles, CA, (2)UCLA Semel Institute for Neuroscience and Human Behavior, Los Angeles, CA

---

**Background:** Individuals with autism spectrum disorder (ASD) are involved in numerous treatments and interventions throughout their lifespan, the most common of which are those aimed at improving communication or other social communicative behaviors. The ability to quantify and measure the effectiveness of these interventions is a critical component to the development of skills for the individuals involved. However, the field of ASD intervention research faces a number of significant limitations in its current practices of measuring treatment effectiveness, such as the lack of a uniform measurement approach or a reliance on parent or clinician report. Due to these limitations, measuring social communication changes in individuals with ASD in response to treatment and comparing the effects of various interventions has proven to be especially difficult. There is a critical need for the development of outcome measures that adequately address the limitations of the measures historically used in intervention research, and that can reliably detect changes in the social communicative behaviors of individuals with ASD, especially in a short period of time. The Brief Observation of Social Communication Change (BOSCC) has been validated with minimally verbal children (called the BOSCC-MV) but has not yet been validated for use with older or more verbal individuals.

**Objectives:** The aim of the present study is to determine the utility of the BOSCC-Phrase Speech Young Fluent (PSYF) as an outcome measure of treatment response. More specifically, this study will analyze the factor structure of the measure by exploring the relationship between items, examine the initial psychometric properties, including inter-rater and test-retest reliability, and provide evidence of its utility as a measure of change by examining changes in scores over time in autistic individuals receiving various interventions.

**Methods:** The present study applies the BOSCC coding scheme to 345 video administrations over 160 participants diagnosed with ASD. Participants include individuals of any age with consistent and flexible phrase speech (defined as a two-word noun verb combination), or individuals under age 8 with fluent, complex sentences.

**Results:** Initial analyses have concluded that the BOSCC-PSYF has an underlying three-factor structure. Additionally, preliminary analyses have shown changes in various social communication items. We anticipate that the BOSCC will have high inter-rater and test-retest reliability.

**Conclusions:** If validated, the BOSCC would provide a standardized, flexible, and minimally biased assessment of social communication changes in response to treatment. The validation of such measure would have important implications for ASD intervention research, including the possibility of a low-cost measure that reliably measures changes in a short period of time, can be conducted and coded by individuals of various skill levels, and is flexible enough to be used across various sites/studies.

**418.086 (Poster)** Feasibility of Actigraphy for Evaluating Sleep and Daytime Physical Activity in Children with Autism Spectrum Disorder

**M. L. Alder<sup>1</sup>, C. R. Johnson<sup>2</sup>, B. A. Malow<sup>3</sup>, L. Scatell<sup>4</sup> and J. A. Zauszniewski<sup>5</sup>,** (1)Department of Pediatrics/Marcus Autism Center, Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (2)Center for Autism, Department of Pediatrics, Cleveland Clinic Children's, Case Western Reserve University School of Medicine, Cleveland, OH, (3)Neurology Sleep, Vanderbilt University, Nashville, TN, (4)Marcus Autism Center, Atlanta, GA, (5)Frances Payne Bolton School of Nursing, Case Western Reserve University, Cleveland, OH

---

**Background:** Sleep disturbances are common in children with autism spectrum disorder (ASD). Daytime physical activity (PA) improves sleep in some children but not others. Little is known about the effect of PA on sleep in children with ASD. Although actigraphy has been used to measure sleep in pediatrics, few studies have used actigraphy in children with ASD.

**Objectives:** The study aimed to evaluate the feasibility of using actigraphy to measure sleep and daytime PA in children with ASD and to gather preliminary data on the association of sleep and parent-reported disruptive behavior.

**Methods:** A sample of 32 children 2 to 8 years (mean = 5.50 ± 1.68, 75% male, 78.1% White) with a community diagnosis of ASD from Midwestern United States participated. Parents were 96.9% female, 90.6% White. Children were recruited through Facebook support groups, autism schools, and centers. To be included, children were screened for an ASD diagnosis with the Modified Checklist for Autism in Toddlers, Revised score ≥ 8 or Social Communication Questionnaire score ≥ 15. Of the 38 children screened, four did not meet the age criteria, one had suspected obstructive sleep apnea, and one did not meet ASD screening and were excluded. Parents completed the Modified Children's Sleep Habits Questionnaire (CSHQ-autism) and Aberrant Behavior Checklist-Irritability subscale (ABC-I) to measure disruptive behavior. The lead investigator (MA) conducted a Zoom session with parents and children on placement of the ActiGraph™ wGT3X-BT on the child's non-dominant wrist for 5 consecutive days and nights to measure sleep total sleep time (TST), sleep efficiency (SE%), and steps per day for PA. Parents completed a sleep diary to report the child's sleep and wake times. The Sadeh (1994) algorithm was used to analyze sleep data. To explore the effect of PA on sleep, children ≥ median steps per day (12,129.40) were compared to those < median on TST and SE%, CSHQ-autism total, and ABC-I total scores.

**Results:** Of the 32 children, 27 (84.4%) had complete actigraphy data. Mean values: TST = 475.31 ± 41.69 minutes, SE% = 75.20 ± 6.88; steps per day = 12,335.24 ± 2,971.98; CSHQ-autism = 39.03 ± 8.58, ABC-I = 16.69 ± 9.80. Based on validated thresholds, 25 children had *poor* SE% (< 85%), 21 had *significant* sleep disturbances (CSHQ-autism ≥ 35), and 17 had *moderate or greater* level of disruptive behaviors (ABC-I ≥ 15). Pearson correlations were -.33 (*p*=.049) and -.38 (*p*=.026) between the CSHQ-autism and SE% and TST, respectively. Children ≥ median on PA had

significantly lower mean TST minutes  $458.44 \pm 25.31$ , compared to  $493.48 \pm 48.81$  in those  $<$  median ( $p=.026$ ). There were no group differences on SE% ( $p=.169$ ) or CSHQ-autism ( $p=.085$ ). Children  $\geq$  median had higher mean ABC-I scores  $20.21 \pm 10.91$ , compared to  $12.23 \pm 8.11$  for those  $<$  median ( $p=.042$ ).

**Conclusions:** Actigraphy is a feasible measure of sleep and PA in children with ASD. Future research could examine the association of daytime behavior and sleep in larger, well-characterized samples of children with ASD.

**418.087 (Poster)** Gender Differences in Autistic Phenomenon and Adaptive Behaviors in the Indian Setting

**S. M. Kaku<sup>1</sup>, A. Joseph<sup>2</sup>, R. Nagaraj<sup>3</sup>, V. Raman<sup>3</sup> and A. Mysore<sup>1</sup>,** (1)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India, (2)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bengaluru, India

---

**Background:**

Studies that have investigated gender differences in Autism Spectrum Disorders have demonstrated differences in abilities and symptoms. The trend of prevalence of ASD in males and females in India is similar to that reported in the West [1]. Our ASD database shows a 5:1 male to female ratio. Gender differences however have not much been reported from India.

**Objectives:**

We explored gender differences in the clinical profiles of children with ASD in our database, focusing on identifying differences in the autistic phenomenon and adaptive behaviors.

**Methods:**

We had data from 653 children with ASD (530 males and 123 females) in our database for whom clinical and adaptive behavior measures were available. For this analysis, we randomized the male sample to get 123 males (male: female = 1:1). We investigated differences in subdomain and total scores of Social Responsiveness Scale (SRS), Indian Sale for Assessment of Autism (ISAA) and Vineland Adaptive Behavior Scale II (VABS). Statistical analysis was done using SPSS version 26. Frequency analysis, Mann Whitney U test, chi-square test and Fisher's exact test helped comparison across genders and to explore associations.

**Results:**

There were no significant differences seen in age and socio-demographic variables. Mann Whitney U test was carried. On ISAA (48 males and 86 females) there was significant difference in social relationship and reciprocity domain (median- males=34, females=27;  $p<0.001$ ), speech language and communication domain (median- males=27, females=24,  $p<0.001$ ) and ISAA total scores (median- males = 106, females=96,  $p=0.027$ ) with males having higher scores indicating greater severity. VABS scores were available for 108 males and 109 females. There were significant differences in coping scaled score (median – males=11, females=10.50,  $p=0.022$ ), socialization domain (median – males=66, females=63.50,  $p=0.05$ ), with males having higher severity while females had higher severity in the motor skills domain (median – males=77, females=72,  $p=0.043$ ). SRS scores did not show significant difference in total or sub domain scores.

**Conclusions:**

We have reported gender differences in autistic phenomenon and adaptive behaviors in our population. These are not vastly different from international reports[2,3]. The data does not support the notion that only more severely ill females are brought for help in the Indian context. Understanding gender differences can help refine our understanding of the biology of autism.

**418.088 (Poster)** Identifying Features of Minimally-Structured Interaction Activities That Facilitate or Impede Social Opportunities for Autistic Youth

**M. L. McNair, K. M. Hauschild and M. D. Lerner,** Psychology, Stony Brook University, Stony Brook, NY

---

**Background:** Autism spectrum disorder (ASD) is characterized by pathognomonic difficulties in social interaction (Hobson, 2014). During interactions with familiar or unfamiliar peers, autistic youth participate less in social interactions (Anderson et al., 2004), engage in less cooperative social interactions (Corbett et al., 2016), and display fewer positive (i.e., prosocial) and low-level interaction behaviors (Bauminger et al., 2003). Numerous observational studies have evaluated interaction behaviors of autistic children in structured and unstructured settings (e.g., recess/lunchtime; Humphrey & Symes, 2011; Lock et al., 2016). However, no work to date has directly compared peer interaction behaviors during naturalistic interactions that systematically vary based on the degree of structure and social demands in which those behaviors occur (e.g., unstructured, minimally-structured with a physical/non-physical interaction component). Such an evaluation is crucial for determining which social and environmental contingencies create the most challenge – and opportunity – for autistic youth.

**Objectives:** To 1) assess peer interaction behaviors in autistic youth across peer interactions activities with differing structure and social demands; 2) evaluate the relationship between ASD symptomatology and peer interaction behaviors in specific contexts.

**Methods:** 179 children ( $N_{\text{male}}=127$ ; 11-17 years,  $M_{\text{age}}=13.81$ ,  $SD_{\text{age}}=1.96$ ) with and without ASD (89 autistic, 90 non-autistic; confirmed via ADOS-2) and  $IQ \geq 70$  ( $M_{IQ}=103.53$ ,  $SD_{IQ}=16.08$ ) completed an observed peer interaction assessment comprised of three activities: an unstructured activity, a minimally-structured activity with a physical interaction component, and a minimally-structured activity with a non-physical, but verbal, interaction component (Figure 1). To evaluate differences in peer interaction behaviors (positive, negative, low-level) by activity and diagnostic group, a repeated measures ANOVA was conducted. A follow-up hierarchical multiple regression was performed to assess the relationship between interaction behavior and ASD symptomatology (Table 1).

**Results:** Autistic and non-autistic youth did not differ in amount of positive interaction behaviors during the unstructured activity and minimally-structured activity with a physical interaction component ( $p's > .05$ ). There was an activity by diagnostic group interaction, such that, in the minimally-structured activity with a non-physical, verbal interaction component, fewer positive interactions were observed in autistic than non-autistic youth (Figure 1;  $F_{1,146}=6.97$ ,  $p < .01$ ). Within this activity only, positive interactions predicted ASD symptomatology severity ( $R^2=.177$ ,  $F_{5,142}=6.10$ ,  $p < .001$ ), such that youth who displayed more positive peer interactions were more likely to have fewer ASD symptoms, even after accounting for amount of peer interaction during the task, verbal abilities, IQ, and parent-reported theory of mind skills (Table 1).

**Conclusions:** While autistic and non-autistic youth showed comparable positive interaction behaviors during the unstructured and minimally-structured, physical activities, autistic youth displayed fewer positive interaction behaviors than non-autistic peers when in a minimally-structured activity with a non-physical, but verbal, interaction component. Even among otherwise minimally-structured peer interactions, and after controlling for amount of peer interaction and perspective-taking skills, autistic youth still displayed fewer positive peer-related behaviors in a social context demanding verbal interaction. Present findings highlight important details and nuance to types of social situations that may be especially challenging – and those that may not – for autistic youth to implement positive interaction behaviors and have implications for intervention targets and development.

#### **418.089 (Poster)** Identifying Gender Differences on the Autism Diagnostic Observation Scale: Preliminary Results

C. Savard<sup>1</sup>, C. Dorval<sup>2</sup>, J. Cadorette<sup>3</sup>, E. Gilbert<sup>4</sup> and I. Abi-Zeid<sup>4</sup>, (1)Health Sciences, Université Du Québec à Rimouski, Lévis, QC, Canada, (2)Université Du Québec à Rimouski, Lévis, QC, Canada, (3)School of Psychology, Université Laval, Quebec, QC, Canada, (4)Operations and Decision Systems, Université Laval, Quebec, QC, Canada

**Background:** The prevalence of autism spectrum disorder (ASD) in Canada is 1 in 66 children and 1 in 54 in the U.S. This prevalence also differs considerably according to genders as males are 4 times more likely to be diagnosed with autism than females. This prevalence is even higher in individuals with higher IQs. Gender differences in the manifestation of autistic traits have been investigated in a range of studies over the past few decades. Some studies (Schuck et al., 2019) indicated that gender-related distinctions in behavioural phenotypes of ASD may be detected differently depending on the type of diagnostic assessments. Currently, the diagnosis of ASD is primarily based on standardized assessment instruments such as the ADOS. Nonetheless, there are several inconsistencies between studies regarding the existence of real differences between women and men on the ADOS. These discrepancies may be attributable to several factors including sample sizes, unequal proportion of male/female, diagnostic heterogeneity, bias in the assessment tool per se, or most likely, a combination of these factors.

**Objectives:** The aim of this project is to clarify whether there are gender differences on the ADOS scoring algorithm using an extensive clinical dataset from the National Institute for Mental Health (NIMH).

**Methods:** Algorithm scores of the ADOS Module 3 were analysed for a total of 1214 participants with a confirmed ASD diagnosis from the National Data Autism Research and the NIMH Autism Genetic Resource Exchange datasets. Reflecting the existing gender ratio discrepancy, the sample consisted of 923 males and 291 females. Descriptive statistics, such as frequency analyses and contingency tables were conducted for each of the ADOS Module 3 criteria by gender.

**Results:** Preliminary results highlight gender differences in scores for some ADOS-Module 3 criteria. The domain of language and social interaction stand out particularly for female subjects. This group recorded lower scores on these two domains compared to males. Due to the unequal group size, these results should be interpreted cautiously.

**Conclusions:** These preliminary results suggest that some subtleties of female autistic expression may not be captured by some of the ADOS criteria. This could partially contribute to the under-diagnosis of women with ASD.

#### **418.090 (Poster)** Infant Effortful Control Predicts Childhood Emotion Dysregulation in Autism-Enriched Cohort.

T. Bazelmans<sup>1</sup>, E. Shephard<sup>1,2</sup>, R. Arthur<sup>1</sup>, B. Milosavljevic<sup>3</sup>, M. W. Wan<sup>4</sup>, M. H. Johnson<sup>5</sup>, E. J. Jones<sup>5</sup> and T. Charman<sup>1</sup>, (1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Faculdade de Medicina, Universidade de São Paulo, São Paulo, Brazil, (3)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (4)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (5)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom

**Background:**

Many autistic children experience difficulties with emotion regulation, which may derive from difficulties with self-regulation. In infancy, effortful control (EC), the ability to exert top-down control over behaviour, can be used as an early indicator of later self-regulation. Children learn to self-regulate their behaviours through interaction with the environment and thus, early parenting behaviours may help counter later difficulties with regulation. This may particularly be the case for those children who show lower EC in infancy.

#### Objectives:

We compared children with typical and elevated familial likelihood for autism on a measure of emotion dysregulation at mid-childhood. We examined whether EC at 8 and 14 months predicted emotion dysregulation and if this association was moderated by parenting behaviour measured at 14 months.

#### Methods:

43 children with typical likelihood (TL) and 75 children with elevated autism likelihood (EL) due to having an older sibling with a diagnosis were assessed in mid-childhood (7-11 years) as part of a longitudinal follow-up study. Children had been allocated to diagnostic outcome groups (EL-TD, EL-atypical or EL-autism) based on all available diagnostic data at age 3 years. The parent-rated Strengths and Difficulties Questionnaire Dysregulation Profile (SDQ-DP) was used to index emotional dysregulation in mid-childhood. EC was assessed at age 8 and 14 months by the parent-report Infant Behavior Questionnaire-Revised (IBQ-R). Parenting was indexed at 14 months by parental sensitivity and responsivity coded using the Manchester Assessment of Caregiver-Infant Interaction (MACI) during a 6-min parent-child free-play interaction. 92 children at 8 months and 91 at 14 months had data available on all measures. T-test and ANOVA were used to compare likelihood and 3-year outcome groups on SDQ-DP. Linear regression was used to examine the effect of autism likelihood, EC (at 8 and 14 months, separately), likelihood\*EC, parenting (at 14 months) and parenting\*EC on emotion dysregulation in mid-childhood. Predictors were entered one-by-one and nested regressions were compared using the likelihood-ratio test. For the regression, the SDQ-DP was transformed using zero-skewness log to normalise the data distribution.

#### Results:

Children in the EL group had higher scores on the SDQ-DP compared to the TL group ( $t(116)=-3.52, p<.001$ ). By 3-year outcome ( $F(3,113)=6.85, p<.001$ ), the EL-autism group had higher scores on the SDQ-DP compared to the TL ( $p<.001$ ) and EL-TD ( $p=.031$ ) groups. None of the other differences were significant.

At 8 months, autism likelihood predicted SDQ-DP scores ( $B=.37, p=.001$ ). Adding EC, likelihood\*EC, parenting and parenting\*EC to the regression did not improve the model fit (all  $ps>.125$ ). At 14 months, autism likelihood ( $B=.27, p=.028$ ) and EC ( $B=-.26, p=.039$ ) were significant predictors of SDQ-DP. Adding likelihood\*EC, parenting or parenting\*EC (all  $ps>.075$ ) did not make a significant difference.

#### Conclusions:

Children with elevated likelihood of autism, specifically those who received a diagnosis at 3, showed higher levels of emotional dysregulation in mid-childhood. EC at 14, but not 8, months predicted emotion dysregulation, however parenting did not predict dysregulation, nor did it impact the effect of EC on emotion dysregulation. Future studies should look at the impact of interventions targeting early EC on later emotion dysregulation.

#### 418.091 (Poster) Influence of Gender Differences in Clinical Presentation on ASD Diagnosis

K. N. Drapalik, E. Wilkinson, M. Rinaldi and K. V. Christodulu, Center for Autism and Related Disabilities, Albany, NY

**Background:** There is a 4.3:1 male-to-female ratio among those who are diagnosed with autism spectrum disorder (ASD) (Maenner et al., 2020). Recent research has suggested that females with ASD may employ social “camouflaging” skills to compensate for deficits caused by core ASD symptomatology which may delay or fully elude clinical ASD diagnosis (Lai et al., 2015; Ratto et al., 2017; Tubío-Fungueirino et al., 2021). Moreover, females who are diagnosed with ASD are thought to present with more severe symptoms and comorbidities when compared to their male counterparts (Ratto et al., 2017).

**Objectives:** The present study aimed to identify gender-based differences in ASD that elucidate the differential rates of ASD diagnoses in males and females by investigating ASD presentation and age at diagnosis from individuals evaluated at a community-based clinic.

**Methods:** Comprehensive psychological evaluations of 116 males aged 3-59 years old (Median = 12.25) and 46 females aged 3-39 years old (Median = 11.83) with presenting concerns of ASD were analyzed. Evaluations were conducted at a university affiliated diagnostic clinic in Albany, NY and included a detailed developmental and psychosocial history review, and formal assessments of intellectual, adaptive, and behavioral functioning. The present study extracted male and female scores for analysis from the following assessments: *Autism Diagnostic Observation Schedule (ADOS-2)*; *Stanford-Binet Intelligence Scales (SB-5)*; *Vineland Adaptive Behavior Scales (Vineland-3)*; *Social Skills Improvement System (SSIS) Rating Scales*.

**Results:** 64.7% males (75 of 116) and 56.5% females (26 of 46) presenting with concerns of ASD received an official ASD diagnosis. Within the subset of ASD diagnoses, males and females were diagnosed at similar ages ( $M_M=13.56, SD=8.09$ ;  $M_F=14.22, SD=8.96$ ). Independent samples t-tests revealed significant differences in male and female *SSIS-Parent Social Skills* ( $M_M=78.56, SD=14.94$ ;  $M_F=65.32, SD=9.57$ ;  $p < .05$ ) and *SSIS-Parent Problem Behaviors* ( $M_M=124.26, SD=15.43$ ;  $M_F=135.41, SD=18.97$ ;  $p < .05$ ). On all other measures, no significant differences were found: *SB-5*

Full Scale IQ ( $M_M=90.52$ ,  $M_F=90.00$ ), *SB-5* Nonverbal IQ ( $M_M=92.43$ ,  $M_F=92.30$ ), *SB-5* Verbal IQ ( $M_M=89.78$ ,  $M_F=88.78$ ), *Vineland-3* Adaptive Behavior Composite (ABC) ( $M_M=65.19$ ,  $M_F=64.00$ ), *ADOS-2* Comparison Scores ( $M_M=6.96$ ,  $M_F=6.32$ ).

**Conclusions:** There were no significant differences in age or clinician rated cognitive, language, adaptive, or behavioral functioning scores in males and females diagnosed with ASD. However, in parent-rated measures of social skills and problem behaviors, females were rated as significantly more impaired than males in each domain. These findings point to the potential influence of gender-norms on ASD diagnosis such that parents may perceive the same ASD symptoms as more distressing in females due to differential social and emotional expectations and tolerance for problematic behaviors.

**418.092 (Poster)** Investigating the Accuracy of People's Judgements about Social Dyads' Autistic Diagnostic Status from Videos of Social Interaction

**H. Sutherland<sup>1</sup>**, D. Ropar<sup>2</sup>, S. Fletcher-Watson<sup>3</sup> and C. J. Crompton<sup>1</sup>, (1)University of Edinburgh, Edinburgh, United Kingdom, (2)University of Nottingham, Nottingham, United Kingdom of Great Britain and Northern Ireland, (3)Salvesen Mindroom Research Centre, University of Edinburgh, Edinburgh, United Kingdom

---

Background:

Autism is defined in diagnostic criteria by the presence of "social and communication impairments". However, research has shown that interactions between autistic dyads entail successful communication (in the form of information transfer) and social interaction. Autistic people rate their own rapport with a partner as higher when that social partner is also autistic. In addition, autistic dyads are rated as having equivalent rapport to non-autistic dyads (with mixed autistic and non-autistic dyads having worse rapport ratings), when scored by independent raters.

This suggests that evidence of social and communication atypicalities are dependent on the diagnostic status of the social partner. As a result, it may be more difficult for observers to accurately identify diagnostic status when two autistic people are interacting.

Objectives:

To examine a) whether it is possible to correctly identify people's neurotype based on a video clip and/or photograph of an interaction, b) whether participants are more accurate at identifying people of their own neurotype, and c) whether participants are more accurate at identifying autistic people in mixed dyads and less accurate at identifying autistic people in matched autistic-autistic dyads.

Methods:

78 raters (39 autistic, 39 non-autistic; 28M, 2NB; age mean = 34, range 18-64) watched clips from three of nine total videos showing autistic dyads, non-autistic dyads, and mixed dyads in conversation, and were asked to identify whether each member of the dyad was autistic or non-autistic. A subset of 54 participants repeated the procedure with photographs taken from the six videos they had not viewed clips from.

Results:

Raters correctly identified the neurotype of dyad members at a rate better than chance for videos (0.58,  $p<0.001$ ) and photographs (0.55,  $p<0.001$ ) – though identification of autistic participants within autistic dyads was significantly below chance (videos 0.34,  $p<0.001$ ; photographs 0.27,  $p<0.001$ ). Raters on average were significantly less accurate at identifying neurotype from photos compared with videos.

For videos, both autistic and non-autistic raters showed an own-neurotype accuracy effect across all pair types (autistic raters outperformed non-autistic raters for autistic and mixed pairs; the opposite for non-autistic pairs). Ratings of mixed pairs had the highest accuracy (non-autistic raters 0.71  $p<0.001$ ; autistic raters 0.88  $p<0.001$ ). For photographs, raters performed only slightly above chance overall (0.55,  $p=0.015$ ). Ratings of non-autistic pairs had the highest accuracy rate overall (0.71,  $p<0.006$ ).

GLMM analysis is ongoing to examine the details of the interaction between rater neurotype, pair type, and guess accuracy.

Conclusions:

Mixed dyads appear to make autistic traits more 'visible' in comparison to autistic dyads, which meant that raters were more able to identify autistic people within mixed pairs. This supports the double empathy problem, which suggests communicative differences arise as a result of mismatched neurotypes rather than due to an autistic deficit. Autistic and non-autistic raters also differ in how they guess a person's neurotype, including by data type; more research is needed to determine whether this is an own-group prediction bias, or whether autistic and non-autistic people deploy different strategies to determine a person's neurotype.

**418.093 (Poster)** Limited Specificity across Psychological Domains of Parent Rating Forms in ASD

**M. A. Levine<sup>1</sup>**, H. Chen<sup>2</sup>, E. Wodka<sup>3</sup>, B. Caffo<sup>2</sup> and J. B. Ewen<sup>4</sup>, (1)Developmental Neurology, Kennedy Krieger Institute, Baltimore, MD, (2)Department of Biostatistics, Johns Hopkins University, Baltimore, MD, (3)Center for Autism and Related Disorder, Kennedy Krieger Institute, Baltimore, MD, (4)School of Medicine, Johns Hopkins University, Baltimore, MD

---

**Background:** In psychometrics, there has long been concern that performance-based measures and rater-based measures allegedly of the same psychological construct often do not agree. Such disagreement may be based on the biases within the rater method (e.g., systematic rater subjectivity), within the performance method (e.g., individuals' ability to participate in any sort of testing), or, most concerning, lack of validity of the construct being studied. In particular, poor correlation between performance and rater measures of core autism symptoms (Autism Diagnostic Observation Schedule [ADOS] and Social Responsiveness Scale, second edition [SRS-2]) in some datasets have raised questions as to whether the ASD diagnosis itself is a meaningful construct.

**Objectives:** We examined the degree to which parent-rating forms and clinician-administered performance measures correlate across psychological domains, to determine the relative contribution of method-associated biases by instrument type.

**Methods:** From 83 pediatric participants with ASD, we collected information from specific subtests of motor, attention, inhibition, working memory, and social communication performance and rater instruments. We attempted to match psychological constructs across instrument type with as great a precision as possible. We ran Principal Components Analysis (PCA) independently on data from the rater instruments and from the performance instruments.

**Results:** Across rater instruments, 56% of variance loaded on the first principal component. The second through fifth components all had loadings of less than 16% total. In the group of performance measures, 40% of the variance loaded on the first component, with 25% loading on the second component, and loadings of less than 17% on the remaining three components.

**Conclusions:** These findings demonstrate a greater amount of shared variance across psychological domains in parent rating forms than in clinician-administered assessments of the same abilities. While some covariance across domains is very likely attributable to true, within-subject covariation of performance, the fact that rater scales show greater across-domain covariance than do performance instruments suggests an additional rater-associated biasing factor. Furthermore, with almost 60% of the rater variance being shared across psychological domains, additional work is critical to understand the degree to which domain-specific instruments are truly and validly measuring nuanced psychological constructs.

#### **418.094 (Poster) Objective Measures to Quantify Homophily in the Inclusion Classroom**

**C. Banarjee<sup>1</sup>, R. M. Fasano<sup>2</sup>, Y. Tao<sup>3</sup>, C. Song<sup>4</sup>, J. Wang<sup>5</sup>, M. L. Shyu<sup>6</sup>, L. K. Perry<sup>2</sup> and D. S. Messinger<sup>1</sup>,** (1)Child Study Center, Child Study Center, Yale School of Medicine, New Haven, CT, (2)Psychology, University of Miami, Coral Gables, FL, (3)University of Miami, Miami, FL, (4)University of Miami, Coral Gables, FL, (5)Educational and Psychological Studies, University of Miami, Coral Gables, FL, (6)Electrical and Computer Engineering, University of Miami, Coral Gables, FL

**Background:** Homophily is a tendency for individuals to preferentially interact with others similar to themselves. In classrooms, homophily is evident across a range of ages in a variety of dimensions, including child sex, disability, and academic performance. While teacher-report provides insights into homophilic peer preference, human measurement limits the collection large-scale datasets that characterize children with autism spectrum disorder (ASD), other developmental disabilities (DD) and typical development (TD) in naturalistic settings.

**Objectives:** In the current study, we utilize automated measurements of velocity and proximity to quantify homophily in the classroom through the following dyadic measures: (1) social approach, quantified as a weighted measure of movement toward each peer and (2) shared time in social contact with each peer.

**Methods:** 77 children ( $M=48.26$  months,  $SD=7.47$ ), including 24 children with ASD, 23 children with DD, and 30 TD children were observed in 8 inclusion preschool classrooms. Each child was observed on 3.52 mean occasions ( $SD=1.32$ ) for a duration of mean 138.2 minutes ( $SD=63.6$ ). Objective measurements of position and orientation were collected using ultra-wide radio frequency identification (Ubisense) sensors, which tracked a right and left tag worn by each child in a specially designed vest. Social approach was computed as the distance each child moved toward (or away from) the initial position of each peer, weighted by distance, orientation, and angle of movement. Social contact was defined as proximity between 0.2 and 2 meters and relative orientation (within 45°) and computed as a proportion of available time with each peer. Social approach and shared time in social contact were analyzed using linear mixed effect models, with a term for the type of one child in the pair (ASD, DD, TD) and the homophily status of the pair (concordant vs discordant).

**Results:** Children in concordant dyads (e.g., ASD-ASD) both approached and withdrew from one another at higher velocities than discordant dyads (e.g., TD-ASD) ( $ps < 0.001$ ). Children with ASD and DD did not differ from TD children in the velocities with which they approached other children. Similarly, concordant dyads spent a greater proportion of time in social contact than discordant dyads ( $p<0.001$ ). In addition, concordant pairs including children with ASD and DD (ASD-ASD, DD-DD) were in social contact less than TD-TD dyads, as revealed by significant interaction terms ( $p_{ASD-ASD}=0.014$ ,  $p_{DD-DD}<0.001$ ).

**Conclusions:**

ASD-specific deficits might be expected in both social approach and social contact during naturalistic interaction. However, we did not find evidence of differential social approach by group. Instead, overall, concordant dyads interacted with one another at higher velocities than discordant dyads, indicating early homophilic patterns of social movement in all three groups. We also found strong patterns of homophily in social contact. Here, children with ASD were in social contact with other children with ASD less than TD-TD dyads, and DD dyads showed a corresponding pattern. The results suggest the potential of a new generation of objective measures to quantify the dynamics of social approach and social contact for children with ASD in preschool inclusion classrooms.

**418.095 (Poster)** Output Metrics for Prototype and Reference Standard Hand-Held Pupillometers: Comparison of Pupillary Measures for ASD and Typical Development in Children between 2-4 Years

**L. E. Neuenschwander<sup>1</sup>, S. Buckley<sup>2</sup>, D. Sidell<sup>3</sup>, K. Morales<sup>4</sup>, G. Brundage<sup>5</sup>, O. Vargas<sup>6</sup>, M. A. Minjarez<sup>3</sup> and G. T. Lynch<sup>6</sup>,** (1)Elson S. Floyd College of Medicine, Washington State University Health Sciences Spokane, Spokane, WA, (2)Northwest Autism Center, Spokane, WA, (3)Seattle Children's Hospital Autism Center, Seattle, WA, (4)Elson S Floyd College of Medicine, Washington State University, Spokane, WA, (5)Seattle Children's Autism Center/University of WA, Seattle, WA, (6)Elson S. Floyd College of Medicine, Washington State University Health Sciences, Spokane, WA

---

**Background:** Recent attention has been given to emerging research investigating the pupillary light reflex (PLR) as a potential biomarker for autism spectrum disorder (ASD) to support first line screening. Studies have demonstrated differences for ASD in comparison to typical development (TD) on measures of constriction latency, constriction amplitude, and return to baseline metrics, indicating accelerated constriction in infants and toddlers, and decreased time for return to baseline measured across developmental levels. These findings were demonstrated using binocular eye tracking systems and handheld pupillometry technology. Hand-held technology may support clinical application more readily, given its mobility, ease of calibration, and ease of use. To determine potential utility of this technology in clinical practice, there is a need to examine validity of hand-held technology tools in relation to the reference standard hand-held pupillometer, as well as to identify PLR metrics presenting differences in young children with and without ASD measured using hand-held technology.

**Objectives:** This exploratory study involved collection of pupillary data to a) analyze output metrics of a hand-held prototype pupillometer made to capture PLR measurements associated with ASD in comparison to output metrics of the reference standard research-based hand-held monocular pupillometer, and b) compare a pediatric comparative PLR dataset obtained using hand-held technology to PLR metrics obtained from those with ASD using the same reference standard tool (N = 28 ASD; 28 TD, 2-4 years of age).

**Methods:** Analyses were conducted by a researcher blinded to group diagnostic status and comparative PLR data were collected by an independent clinical research team trained in monocular PLR data capture. Pearson product-moment correlation was used to determine the relationship between output metrics obtained with the prototype pupillometer and the current reference standard hand-held pupillometer, the Neuroptics PLR 3000. Bland-Altman analysis, a robust statistical method for comparing medical screening and diagnostic measurements, was used to determine limits of agreement within 95% confidence intervals between the two devices for each parameter. PLR data from the comparison sample were then analyzed for differences between ASD and TD for PLR metrics across six parameters.

**Results:** Results indicated agreement between the pupillometer prototype and the Neuroptics PLR3000. Analysis of PLR datasets indicated group differences for mean constriction latency and constriction time for children under three, and differences for constriction latency, constriction time and return to baseline for children beginning at age four. Trends related to age effects reveal accelerated constriction time in ASD and increased return to baseline for children with ASD four and older. Return to baseline measures were not consistent in children under three years of age.

**Conclusions:** These findings support previous studies using binocular systems and PLR parameters associated with ASD. Validation of hand-held pupillometry for PLR data capture have implications for developing technology to support ASD screening. However, further research is still needed to develop PLR metrics for specific age effects by diagnostic status. These results are explained in the context of studies relating pupillometry to ASD biomarkers and translation of these findings to potentially bolster ASD screening within pediatric clinical practice.

**418.096 (Poster)** Patterns of Peer Relations in Youths with Autism Spectrum Disorder: An Analysis of Gender and Age

**S. Finkelstein and C. Brown, Pacific University, Hillsboro, OR**

---

**Background:** Autistic youths often experience difficulties in their relations with peers (Sterrett et al., 2017). Indeed, common areas of concern for autistic youth include having few or no friends, being victimized by peers, and having friendships that are characterized as relatively brief and of low quality (Petrina et al., 2014; Storch et al., 2012). Extant research has demonstrated that peer relation concerns are linked with symptoms inherent to ASD, such as impairment in social communication and reciprocity. However, there has been relatively little focus on developmental and gender considerations with regard to peer relations in autistic youths. Identifying potential differences may have implications for intervention for this clinical population.

**Objectives:** The primary aim of this study was to examine the differences in key domains of peer relations in children and adolescents with Autism Spectrum Disorder (ASD) based on age and gender.

**Methods:** Participants were 2,142 caregivers of children and adolescents (ages 6-17) with ASD. Autism symptoms were measured using the Social Communication Questionnaire (SCQ; Rutter et al., 2003). The Missouri Peer Relations Inventory (MPRI; Borduin et al., 1989) was used to assess domains of peer relations: number of friends, emotional bonding, social aggression, and social maturity. The sample was divided into four groups based on gender (younger girls  $n=275$ , younger boys  $n=854$ , older girls  $n=280$ , older boys  $n=733$ ) and mean age ( $M=11.07$  years;  $SD=3.17$ ). Analysis of variance (ANOVA) and post-hoc comparisons (LSD) were used to examine the differences in SCQ scores and the peer relations domains.

**Results:** A one-way ANOVA did not show a significant main effect for gender and age groups on SCQ scores,  $F(3, 2138) = 1.78, p = .149$ . A main effect for gender and age was found for number of friends,  $F(3, 2138) = 3.05, p = 0.28$ , with older girls having more friends than younger boys ( $p = .004$ ). A main effect was also found for social maturity,  $F(3, 2129) = 7.44, p < .001$ , with younger girls having greater social maturity than younger boys and older boys ( $p < .001$ ) and older girls ( $p = .051$ ). No main effects on gender and age were found for emotional bonding,  $F(3, 2138) = 1.65, p = .175$ , or social aggression,  $F(3, 2128) = .33, p = .804$ .

**Conclusions:** The findings suggest that there are differences in peer relations between gender and age in autistic youths, regardless of autism symptoms as assessed by the SCQ. Older girls had the most friends relative to other groups, with younger girls having more social maturity. Girls having more robust peer relations than boys may be consistent with the notion that autistic girls engage in compensatory behaviors (i.e., “masking” or “camouflaging” ASD symptoms) to gain acceptance with peers. The findings may also reflect social and parental expectations of girls, which is notable given the caregiver-report methodology. Future research should examine the contribution of compensatory behaviors in peer relations for autistic youth, as well as other age- and/or gender- specific mechanisms that may affect peer relations.

**418.097 (Poster)** Peer Stress in Adolescence: Differential Coping Strategies Reported By Individuals with Autism Spectrum Disorder and Typical Development

**M. E. Klemencic and B. A. Corbett, Psychiatry and Behavioral Sciences, Vanderbilt University Medical Center, Nashville, TN**

---

**Background:** Adolescence is often distinguished by a unique set of interpersonal challenges, including stress related to peers. The Responses to Stress Questionnaire (RSQ; Connor-Smith et al., 2000; Compas et al., 2001), a well-validated and widely used measure of stress-related coping strategies, categorizes the ways in which individuals interact and cope with a particular stressor. Each of these categories (Primary Control Engagement Coping, Secondary Control Engagement Coping, Disengagement Coping, Involuntary Engagement, and Involuntary Disengagement) is distinguished by the degree to which it is cognitively and psychologically adaptive for an individual dealing with stress.

**Objectives:** This study aimed to investigate potential differences between youth with Autism Spectrum Disorder (ASD) and Typical Development (TD) in terms of strategies utilized to cope with stress explicitly related to problems with peers in the past six months.

**Methods:** Participants were enrolled in an ongoing longitudinal study examining stress, pubertal development, and physiological arousal during adolescence. First-year self-report RSQ (Peer Stress Version) data was analyzed from 238 youth with ASD ( $n = 137$ ; 102 males, 35 females) or TD ( $n = 101$ ; 58 males, 43 females).

**Results:** Compared to the TD sample, youth with ASD reported significantly higher Involuntary Engagement ( $M = 0.25$ ,  $SD = 0.043$ ,  $t(215) = -3.76$ ,  $p < .001$ ) and Involuntary Disengagement ( $M = 0.19$ ,  $SD = 0.036$ ,  $t(214.87) = -4.61$ ,  $p < .001$ ). Youth with TD reported significantly higher use of Primary Control Engagement Coping ( $M = 0.19$ ,  $SD = 0.036$ ,  $t(214) = 3.51$ ,  $p = .001$ ) and Secondary Control Engagement Coping ( $M = 0.26$ ,  $SD = 0.048$ ,  $t(215) = 3.99$ ,  $p < .001$ ).

**Conclusions:** Key stress-related coping differences were observed between diagnostic groups. While youth with TD utilized more Primary and Secondary Control Engagement Coping strategies, those with ASD reported more involuntary, maladaptive reactions to peer stress. These findings substantiate the potential clinical utility of evaluating stress-related coping in adolescent populations. A longitudinal approach to future research in this area can potentially elucidate changes in coping strategies as individuals—particularly those with ASD—transition to adulthood.

**418.098 (Poster)** Preliminary Factor Analysis of the Autism Parent Screen for Infants

**T. Djiko<sup>1</sup>, S. Sung<sup>2</sup>, J. J. Wolff<sup>3</sup>, L. Zwaigenbaum<sup>4</sup>, J. A. Brian<sup>5</sup>, L. A. Sacrey<sup>6</sup>, I. M. Smith<sup>7</sup>, S. Jacob<sup>7</sup> and J. T. Ellison<sup>2</sup>, (1)University of South Carolina, Columbia, SC, (2)University of Minnesota, Minneapolis, MN, (3)University of Alberta, Edmonton, AB, Canada, (4)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (5)Autism Research Centre, Glenrose Rehabilitation Hospital, Edmonton, AB, CANADA, (6)Dalhousie University / IWK Health Centre, Halifax, NS, CANADA, (7)Department of Psychiatry, University of Minnesota - Twin Cities, Minneapolis, MN**

---

**Background:** Early identification of ASD remains an enduring challenge, as the median age of diagnosis remains around four years (Maenner et al., 2020). Level 1 screening with parent report plays a vital role in detecting early emerging signs of ASD. The *Autism Parent Screen for Infants* (APSI) is a 26-item parent-report measure designed to screen for ASD in infants and toddlers (Sacrey et al., 2016). Research has demonstrated the clinical utility of APSI screening in infant siblings of autistic children (Sacrey et al., 2018; 2020). The full psychometric properties of the instrument, including the factor structure and invariance of that structure across key moderators, have yet to be fully elucidated.

**Objectives:** This study aims to characterize the latent factor structure and measurement invariance of the APSI across two samples from different ascertainment strategies.

**Methods:** Parental ratings on the APSI were gathered from participants at the University of Minnesota (UMN;  $n=955$ , 463 females) and a Canadian collaborative including the University of Alberta, Holland-Bloorview, and Dalhousie University (CDN;  $n=463$ , 181 females). The UMN sample included community-ascertained toddlers aged between 17-36 months ( $M=23.29$  months,  $SD=4.20$  months). The CDN sample included younger siblings of autistic children ascertained before age 12 months, with APSI data gathered between 16-32 months ( $M=20.23$  months,  $SD=2.88$  months). The combined sample was stratified by age, sex, and ascertainment group and randomly assigned to either the exploratory factor analysis (EFA) group ( $n=701$ ) or the confirmatory factor analysis (CFA) group ( $n=701$ ). EFA using polychoric correlations, principal axis factoring extraction, and oblique rotation were performed to determine the number of factors. The fit of the factor structure yielded by the EFA was assessed in the CFA group. Finally, preliminary examination of measurement invariance across age, sex, and cohort was conducted using the moderated nonlinear factor analysis (MNLFA) method.

**Results:** One- to five-factor solutions were examined; a two-factor solution best characterized emerging autistic traits as measured by the APSI (see Table 1). Factor 1 was interpreted as Social Communication Behaviors and Factor 2 was interpreted as Restricted and Repetitive Behaviors, Interests, and Activities. Item 18, which didn't load clearly on either factor, was excluded from the model. The subsequent CFA analyses further supported the two-factor solution as the model fit the data well in the other half of the sample (see Table 2). Finally, the preliminary MNLFA analyses showed

differential item functioning (DIF) across the two ascertainment groups on both factor loadings (Q2,Q11,Q20,Q23) and item intercepts (Q2,Q17,Q20,Q25). Age did not affect factor loadings. Sex effects on factor loadings were observed on only one item (Q15).

**Conclusions:** These findings provide preliminary evidence for a two-factor structure of the APSI within both elevated-familial-likelihood and community-derived toddler populations. This two-factor structure is consistent with DSM-5 criteria for ASD – Factor 1 represents atypical social communication, while Factor 2 maps to restricted and repetitive behaviors, interests, and activities. Deriving factor scores that account for differential item functioning may be warranted for future research.

**418.099 (Poster)** Psychometric Properties of the Spanish Version of the Autism Quotient Questionnaire for Children (AQ-Child)

**C. J. Fernandez Alvarez<sup>1</sup>, M. Magan Maganto<sup>2</sup>, J. A. Yon-Hernández<sup>3</sup>, A. N. Mota Rodriguez<sup>3</sup>, D. Z. Wojcik<sup>3</sup>, Á. Bejarano<sup>3</sup>, E. Díez Villoria<sup>3</sup>, A. Huete-García<sup>4</sup> and R. Canal-Bedia<sup>3</sup>,** (1)Univeristy of Salamanca, Salamanca, Spain, (2)University of Salamanca, Salamanca, Spain, (3)InFoAutismo-Instituto Universitario de Integración a la Comunidad (INICO), Salamanca, Spain, (4)Sociology and Communication Department, University of Salamanca, Salamanca, Spain

---

**Background:** Autism Spectrum Disorder (ASD) is a lifelong heterogenous neurodevelopmental condition characterized by difficulties in social communication and stereotyped patterns of behaviors and interests. Individuals with an ASD are often at a higher risk of experiencing other associated cognitive disorders and adaptive difficulties. The Broader Autism Phenotype (BAP) refers to mild manifestations of autistic-like behaviors present in the general population. The Autism Spectrum Quotient, Child version (AQ-Child), is a report questionnaire for parents that aims to identify the characteristic features of autism in children aged 4 to 11 years. The scores in the AQ-Child range from 0 to 150, where higher scores correspond to behaviors more characteristic of ASD.

**Objectives:** The purpose of this study was to perform an analysis of the psychometric properties of the Spanish version of the AQ-Child.

**Methods:** AQ-Child data was collected from a sample of school-age children aged 4 to 11 years from the general population (n = 635). Diagnostic assessments were completed on a sample of children who scored positive on the AQ-Child. The internal consistency of the Spanish version of the AQ-Child was assessed by calculating Cronbach's Alpha coefficients for the entire measure. The factor model structure of the AQ-Child was evaluated through a Confirmatory Factor Analysis (CFA) of the proposed factor structure model for the AQ-Child.

**Results:** The preliminary results indicate that for the measure as a whole Cronbach's  $\mu$  coefficient was good ( $\mu = .86$ ). Furthermore, the internal consistency of the four-factor model structure was also satisfactory (mind reading = .83; attention to detail = .76; social skills = .80; and imagination = .72). In general, the proposed four-factor model fits well with all the measures ( $p < 0.001$ ) and captures important associations between the variables (SRMR = 0.072). The preliminary results indicate a good model fit (RMSEA = 0.066).

**Conclusions:** As this is an on-going study, the data from the preliminary analyses seem to indicate that the Spanish version of the AQ-Child could be a reliable instrument for evaluating behaviors associated to an ASD. Our preliminary findings suggest that the Spanish version of AQ-Child may be a useful tool to be used in the education system to aid and improve the identification of ASD-related behaviors in children aged 4 to 11 years, who may have gone unidentified by early detection programs and could be at a greater risk of suffering social exclusion and academic failure due to their behavioral difficulties.

**418.100 (Poster)** Psychopathological Correlates of Autism Symptom Severity Change during Middle Childhood

**E. Waizbard-Bartov<sup>1</sup>, E. Ferrer<sup>2</sup>, B. Heath<sup>3</sup>, D. S. Andrews<sup>4</sup>, S. J. Rogers<sup>5</sup>, C. W. Nordahl<sup>1</sup>, M. Solomon<sup>3</sup> and D. G. Amaral<sup>1</sup>,** (1)UC Davis M.I.N.D. Institute, Davis, CA, (2)UC Davis, Davis, CA, (3)Department of Psychiatry and Behavioral Sciences, The Medical Investigation of Neurodevelopmental Disorders (MIND) Institute, UC Davis School of Medicine, University of California Davis, Sacramento, CA, (4)Department of Psychiatry and Behavioral Sciences, MIND Institute, UC Davis Medical Center, Sacramento, CA, (5)Department of Psychiatry and Behavioral Sciences, University of California at Davis, Sacramento, CA

---

**Background:** By school age, many children with autism experience a change in the severity of their autism symptoms. It is also during middle childhood when some types of psychopathology begin to emerge at approximately the same time.

**Objectives:** The current study evaluated the hypothesis that change in autism symptom severity across middle childhood (from 6 to age 11), is associated with an increase in co-occurring psychopathology.

**Methods:** A group of 75 autistic children were followed longitudinally and evaluated at three occasions: at approximately 3, 6 and 11 years of age. Autism symptom severity was evaluated using the Autism Diagnostic Observation Schedule-2 (ADOS-2). Co-occurring psychopathology was evaluated using the Child Behavior Checklist (CBCL) and the Anxiety Disorders Interview Schedule/Autism Spectrum Addendum (ADIS/ASA). Change in autism severity was evaluated using the ADOS Calibrated Severity Scores (CSS) across middle childhood (from age 6 to age 11); significant change was determined using the Reliable Change Index. Change in severity was examined separately for social-communication symptoms (SA CSS) and restricted, repetitive behaviors (RRB CSS). Based on their change patterns (decrease, increase or stable severity), children were classified into different groups.

**Results:** Using change in social-communication symptoms, we identified a group of 16 children (21.3% of the sample; SA-I group) that decreased in the severity of social-communication symptoms during early childhood, from age 3 (SA CSS 6.2(1.4)) to age 6 (SA CSS 4.7(1.5)). Across middle childhood, however, children in this group increased substantially in the severity of their social-communication symptoms resulting in a higher mean

severity level compared to other children at age 11 (SA CSS 8.4(1.4)) (Figure 1, Panel A). Based on the CBCL, this group also had elevated psychopathology levels, mainly for ADHD symptoms and externalizing behaviors, across childhood and predominantly at age 11. This group also showed significantly higher mean IQ scores across childhood compared to other children in the sample. Analysis of change in restricted, repetitive behaviors identified a group of 17 children (22.7%; RRB-D group) that did not significantly change in RRB severity across early childhood, from age 3 (RRB CSS 7.9(1.6)) to age 6 (RRB CSS 8.5(1.2)) and their RRB severity was similar to those of the other children in the study. Across middle childhood, however, children in this group significantly decreased in RRB severity, to have a lower severity level at age 11 (RRB CSS 5.8(2.1)) than other children (Figure 1, Panel B). Based on the ADIS/ASA, this group also had a higher anxiety level compared to other children in the study at age 11, with 94% of the children in this group meeting clinical criteria for having an anxiety disorder (compared to 65% of other children).

**Conclusions:** Increase in the severity of social-communication symptoms across middle childhood is associated with co-occurring psychopathology such as ADHD symptoms and externalizing behaviors. Decreases in the severity of RRB may be associated with the emergence of clinically meaningful anxiety later in childhood.

#### **418.101 (Poster)** Remote Assessment of ASD Symptoms in Clinical Trials: Automated Analysis of Repetitive Speech Behaviours in Natural Conversations

Hoffmann-La Roche AG, Basel, Switzerland

#### **Background:**

Outcome measures currently used in clinical trials for autism spectrum disorder (ASD) have limitations in terms of reliability, validity, burden and ecological validity (Anagonostou et al., 2014). To address this unmet measurement need we have developed novel digital tools for the remote measurement of ASD signs and symptoms and deployed these into an observational study. By measuring symptoms objectively in the home environment, digital health technology tools could reduce participant burden, improve ecological validity and be administered more frequently, which may increase sensitivity to change compared to clinical scales.

Social communication impairments and restricted and repetitive behaviors (RRBs) are the core symptoms of ASD. In natural conversations, these can manifest through low-level features such as the duration which a person talks, acoustic features such as prosody and pitch, and high-level features such as repetitive speech; including focusing on a restricted interest and repetition of another person's speech (echolalia). These features can be quantified by recording natural conversations in the home environment of a participant. We have previously reported differences in expressive communication between low- and high-functioning individuals with ASD (O'Sullivan, 2020). Here we report on differences in repetitive speech during natural conversations. To this end, audio recordings must be segmented according to when each speaker is talking. Whilst segmentation can be done manually, this is labor intensive when applied to large datasets. Instead algorithms can be used for automated segmentation (speaker diarization; SD) followed by machine learning algorithms to perform automatic speech recognition (ASR) to identify repeated words.

**Objectives:** To automatically assess repetitive speech behaviours in ASD via a combination of SD and ASR.

**Methods:** 90 individuals with ASD and 45 typically developing (TD) controls (5-45yrs) were asked to record a conversation with a conversation partner once per week during the 12-week observational period of a non-drug observational study. Individuals with ASD were categorized as low-functioning (IQ<70) or high-functioning (IQ>70). For automated segmentation, a deep-learning based SD pipeline (Profant I.J., 2019) was applied to the conversation recordings, and validated via manual segmentation of a subset of conversations. This was followed by ASR to measure how many times a participant repeated the same words.

#### **Results:**

Task adherence was observed to be between 40-50% throughout the study leading to conversation recordings every 2-3 weeks on average. We found that both low- and high-functioning ASD participants had significantly more repetitive speech than TD controls (Mann-Whitney *U*,  $p < 0.005$ ). In particular, we found that content words (which convey semantic meaning) were repeated significantly more than function words (which connect speech but do not have semantic information).

#### **Conclusions:**

Our results show that the repetitive speech of individuals with ASD can be assessed in the home environment using natural conversation recordings. Analyses of conversational features can demonstrate known-group differences through automated segmentation and speech recognition, which will allow the use of this approach in large clinical trials. Future work will focus on additional repetitive speech behaviours such as preoccupations with certain topics over multiple days, and echolalia.

#### **418.102 (Poster)** School-Based Universal Screening for Autism: Feasibility and Initial Findings

**Background:** Efforts aimed at early identification of autism spectrum disorders (ASD) have focused largely on detecting toddlers with relatively clear behavioral symptoms (e.g., absence of pointing). For children who have less overt signs and symptoms (previously associated with Asperger's disorder or high functioning autism), functional impairment may not be realized until school-age, adolescence, or adulthood. Identifying these children before functional impairments emerge may mitigate potential negative events, including bullying, truancy, and social exclusion. One approach to identifying undiagnosed children with ASD is to conduct universal screenings. Most research on universal screenings, however, has been conducted in younger children, typically at pediatrician offices (e.g., Pierce et al., 2021). No research, to our knowledge, has examined the feasibility, acceptability, and efficacy of school-based universal screening programs for detecting ASD.

**Objectives:** The objective of the current study was to examine the feasibility and efficacy of a school-based universal screening program for identifying undiagnosed school-aged children with ASD.

**Methods:** Teachers from 12 public charter schools in the Phoenix metropolitan area were recruited in 2018 to screen all students in second, fourth, and eighth grades for social challenges using the Social Challenges Screening Questionnaire (SCSQ) (Smith et al., 2015). Students who flagged the SCSQ were eligible to receive a free diagnostic evaluation at the study center. Licensed psychologists evaluated students with the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2; Gotham et al., 2007; Lord et al., 2009; 2012), Kaufman Brief Intelligence Test, Second Edition (KBIT-2; Kaufman & Kaufman, 2006), and Vineland Adaptive Behavior Scales, Third Edition (VABS-3; Sparrow et al., 2016). Initial indices of program feasibility and efficacy such as rates of screening and diagnostic outcomes were tracked.

**Results:** Over the course of two school years (2018-2019 and 2019-2020), 103 teachers screened 2,521 students. Of the students screened, 110 (4%) scored in the concern range, and parents of 42 students agreed to be contacted by the research team. Out of the 42 families who agreed to be contacted, parents of 17 students declined an evaluation; developmental evaluations were completed for 25 students. Of the students who were evaluated, 88% ( $n = 22$ ) met full diagnostic criteria for ASD.

**Conclusions:** Results provide preliminary evidence that school-based universal screening for social challenges is both feasible and a promising approach for identifying previously unidentified cases of ASD.

#### **418.103 (Poster)** Sensitivity and Specificity of the Autism Diagnostic Interview, Revised (ADI-R) in an Ethnically and Racially Diverse Clinical Sample

*E. F. Geib, K. G. Stephenson, C. Murphy and E. Butter, Nationwide Children's Hospital, Columbus, OH*

---

**Background:** Standardized instruments such as the Autism Diagnostic Interview, Revised (ADI-R; Rutter et al. 2003) are routinely used to assess symptoms of Autism Spectrum Disorder (ASD). While rates of clinical ASD diagnosis vary between families from some racial and ethnic minorities (Mandell et al. 2009), other ASD prevalence data indicate no significant differences between ASD diagnostics between White and Black 8-year-olds (Baio et al. 2018). Researchers must validate diagnostic instruments in minority populations to assist clinicians in best understanding the needs of families and making accurate diagnoses. Several factors lead to disparities of diagnosis including ASD awareness, general prejudice, family differences regarding developmental concerns, specialty healthcare accessibility and acceptability, provider responsiveness to caregiver concerns, and performance of standardized diagnostic tools and algorithms (Institute of Medicine, 2002; Mandell et al., 2009). This study focuses on the latter and assesses the sensitivity and specificity of the ADI-R in a clinical sample of children from White and Black households.

**Objectives:** Accurate clinical diagnosis is necessary for many children with ASD to access appropriate interventions and services. Our research seeks to compare the diagnostic accuracy of the ADI-R between families from two different racial backgrounds.

**Methods:** ADI-R data was obtained from a retrospective chart review. Subjects included 441 children ages 2-17 ( $M=5.4$ ,  $SD=3.5$ ) who participated in autism evaluations at a large children's hospital in the Midwestern United States between March 2020 and January 2021. Eighty-four children identified as Black (19%) and 357 (81%) identified as White. The sample was primarily male (73%). A large portion lived in rural areas (40%) and the majority qualified for state insurance (Medicaid; 58%). Families were administered the algorithm items of either the standard ADI-R ( $n=231$ ; *older group*) or the Kim & Lord (2012) updated algorithms for toddlers and young preschoolers ( $n=210$ ; *younger group*). Receiver Operating Characteristic (ROC) analyses were completed, including Area Under the Curve (AUC), for each racial group. DeLong's test was used to test for group differences in AUC.

**Results:** There were no group differences in diagnosis rate for the older group [ $\chi^2(1)=0.03$ ;  $p=.85$ ]. The rate of ASD diagnosis was significantly higher for Black children (95.5%) vs. White children (74.7%) in the younger group [ $\chi^2(1)=7.84$ ;  $p=.005$ ]. See Table 1 for ROC analysis results. The ADI-R Standard has 82% sensitivity and 56% specificity among Black children and 69% sensitivity and 75% specificity among White children. There were no significant differences in AUC values between groups. ADI-R Toddler research cutoffs indicated the Black group had a significantly higher AUC compared to the White group, largely driven by 100% specificity. The ADI-R Toddler Clinical Cutoffs had high sensitivity but low specificity.

**Conclusions:** The ADI-R Standard yielded no significant group differences in diagnosis of ASD for both groups. The ADI-R Toddler Research Cutoffs were more accurate for Black children and indicated 100% diagnosis confirmation rate. Future research should assess how the ADI-R performs among other ethnic, racial, and linguistic, minority groups, differences between referrals, the role of parental concerns, and the influence of ASD symptom severity in rates of diagnosis.

**418.104 (Poster)** Sensitivity and Specificity of the Modified Checklist for Autism in Toddlers: A Systematic Review

**L. Williams<sup>1</sup>**, A. T. Wieckowski<sup>1</sup>, D. L. Robins<sup>1</sup>, K. Lyall<sup>1</sup> and A. Resnikoff<sup>2</sup>, (1)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (2)Drexel University, Philadelphia, PA

---

**Background:**

Despite recommendations from The American Academy of Pediatrics that all children receive autism-specific screening, adherence to this recommendation is inconsistent, as is implementation of the most commonly used screening tool, the Modified Checklist for Autism in Toddlers (M-CHAT) and its revision, M-CHAT Revised, with Follow-Up (M-CHAT-R/F). Variation in implementation contributes to equivocal findings regarding the screening tools' properties.

**Objectives:**

The current systematic literature review assessed variations in sensitivity and specificity in studies reporting psychometric properties of the M-CHAT(-R/F) across multiple factors, including false negative detection strategies, sample risk level for autism, screening age, and single vs. repeat screenings.

**Methods:**

Included articles (n=43) 1) were published in English language peer-review journals from 2000-2020, 2) used M-CHAT(-R/F) to identify new cases of autism in children <=48 months, 3) identified at least 10 ASD cases, and 4) reported procedures for identifying false negative cases. Psychometric data was extracted independently by the authors and compared for accuracy, or data was calculated from raw values provided in included studies. In the case of discrepancies, coauthors reviewed papers and reached resolution. Authors used the Quality Assessment of Diagnostic Accuracy Studies – 2 (QUADAS-2 Tool) with adapted signaling questions to evaluate bias in sample selection, implementation, and diagnostic procedures.

**Results:**

M-CHAT(-R/F) sensitivity and specificity varied across studies (sensitivity: 0.33-1.00,  $M = 0.78$ ; specificity: 0.27-1.00,  $M = 0.81$ ). Sensitivity estimates were higher with use of concurrent (0.59-1.00,  $M = 0.84$ ) compared to prospective strategies (0.33-0.91,  $M = 0.55$ ). The lowest sensitivity estimates were found for studies utilizing medical record reviews (n = 5; 0.33-0.70,  $M = 0.45$ ), though specificity was high (0.93-1.00,  $M = 0.97$ ). Most studies that reported data for older and younger samples (n=5) found differences in sensitivity for >30 months (0.69-0.82,  $M = 0.74$ ) compared to <30 months (0.78-0.90,  $M = 0.87$ ). Sensitivity was slightly higher in studies using high-risk samples (0.52-0.94,  $M = 0.80$ ), compared to low-risk (0.33-1.00;  $M = 0.71$ ). In studies which utilized single and repeat screening (n=2), 18-30% higher sensitivity was demonstrated across repeat screens compared to a single screening, without a meaningful decrease in specificity. Studies generally demonstrated low risk of bias across domains, with the exception of flow and timing, for which 30 studies (68%) showed high risk of bias. Regarding applicability, all studies showed low concern for patient selection and reference standard, with only one rated to be of high risk for concern of applicability for the index test domain.

**Conclusions:**

Across studies, sensitivity and specificity of the M-CHAT(-R/F) were generally strong, though variability in sensitivity related to concurrent or prospective study design, as well as age of participants. Repeat screening was found to maximize sensitivity, but was under-utilized. Specificity was impacted by the ASD risk level of samples. Results highlight utility of the M-CHAT(-R/F) and reiterate that screening early and at multiple timepoints is critical to optimal identification of children at risk for ASD.

**418.105 (Poster)** Social Communication and Repetitive Behavior and Interests in Girls with High-Functioning Autism Spectrum Disorder

**J. M. Burton<sup>1,2</sup>**, N. A. Creaghead<sup>3</sup>, A. Duncan<sup>4</sup> and N. Silbert<sup>5</sup>, (1)Communication Sciences and Disorders, Western Kentucky University, Bowling Green, KY, (2)Communication Sciences and Disorders, University of Cincinnati, Cincinnati, OH, (3)University of Cincinnati, Cincinnati, OH, (4)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (5)Tubi, Cincinnati, OH

---

**Background:**

Sex may influence symptoms of ASD (Kreiser & White, 2014). Males are four times more likely to be diagnosed with ASD than females (Maenner et al., 2020). However, this ratio is inconsistent when intellectual functioning is considered, and ranges from 2:1 for individuals with intellectual disability (Mattila et al., 2011) to 6:1 (Baird et al., 2006) to 16:1 (Scott et al., 2002) for individuals without intellectual disability. Lower rates of ASD in females with average IQ may suggest that this group has symptoms that are distinctly different from males which may lead to underdiagnosis (Halladay et al., 2015). Examination of ASD symptoms in this group may have implications for assessment and treatment services as well as establishment of diagnostic criteria for females.

**Objectives:**

To investigate deficits in autism symptoms in girls with ASD and average IQ (i.e., high-functioning ASD; HF-ASD) compared to girls who are typically developing (TD), we examined the following:

1. What are the symptoms of social communication and repetitive behavior and interests in girls with HF-ASD compared to girls who are TD based on structured observation and parent report?

## Methods:

Thirty-seven girls between 7;5—15;2 years participated (HF-ASD,  $n=18$ ; TD,  $n=19$ ).  $T$  test confirmed that the groups did not differ in age, verbal IQ, nonverbal IQ, and IQ composite on the Kaufman Brief Intelligence Test-2<sup>nd</sup> Edition (KBIT-2; Kaufman & Kaufman, 2004). The Autism Diagnostic Observation Schedule-2<sup>nd</sup> Edition (ADOS-2; Lord et al., 2012) was administered to confirm symptoms of ASD by a research reliable examiner. All TD participants demonstrated absence of ASD symptoms. The Social Communication Questionnaire—Lifetime Form (SCQ; Rutter et al., 2003) was completed to obtain a parent report of symptoms.

## Results:

Mann-Whitney  $U$  tests were used to examine differences. False Discovery Rate was applied (Benjamini-Hochberg, 1994).

The groups differed in regard to Total scores on the ADOS-2 ( $p=0.000$ ) and SCQ ( $p=0.000$ ).

### Item-Analysis on the ADOS-2 and SCQ

Girls with HF-ASD earned significantly higher scores on 3 of 11 items (27%) from the subdomain of reciprocal social interaction, 2 of 9 items (22%) from the subdomain of communication, and 0 of 5 items (0%) from the subdomain of repetitive behavior and interests.

Girls with HF-ASD earned significantly higher scores on 5 of 15 items (33%) from the subdomain of reciprocal social interaction, 3 of 13 items (23%) from the subdomains of communication, and 7 of 8 items (88%) from the subdomain of repetitive behavior and interests.

## Conclusions:

No significant differences were observed on most items from the subdomains of reciprocal social interaction and communication on the ADOS-2 and SCQ. Girls with HF-ASD were less likely to demonstrate repetitive behavior and interests on the ADOS-2, but presence of these symptoms were noted on the SCQ. Current measures frequently used for assessing ASD may not consider females' relative strengths or advantages over males in social communication or differences in expression of repetitive behaviors and interests. Future studies should aim to include larger samples of females who are TD and females with HF-ASD in the standardization process for such measures.

### 418.106 (Poster) Stability of ASD Outcomes: Expected Change of Commonly Used Social Communication Measures

**K. Sterrett**, University of California, Los Angeles, Los Angeles, CA

**Background:** There is no agreed upon set of measures to track social communication change within the early intervention literature for children with ASD and many measures have not undergone rigorous psychometric evaluation, despite their frequent use (McConnachie et al., 2015). One area of psychometric evaluation of particular relevance to the early intervention literature is the lack information on the sensitivity of measures of social communication to change (Grzadzinski et al., 2020). Further, recent syntheses of intervention studies have combined outcome data based on constructs, such as language, without accounting for the potential error introduced when different measures of the same construct are combined (e.g. Sandbank et al., 2020). Information is needed on whether there is significant heterogeneity in social communication outcomes purported to measure the same constructs.

**Objectives:** The aims of this study were: (1) to examine and compare the expected change of social communication measures used in ASD longitudinal research and (2) to determine whether the presence of treatment, age of children, cognitive ability and type of measure (e.g. standardized versus age equivalent) moderates the expected change.

**Methods:** A systematic search and review of manuscripts from three online databases was conducted to identify any longitudinal study of children with ASD that included a social communication measure at two or more timepoints and that included children between 2 and 8 years old. Effect sizes were generated, representing the standardized mean difference between the two timepoints, and the effect sizes were pooled within each identified outcome measure using a meta-analytic approach. Meta regression was used to determine whether the length of the measurement period was related to the magnitude of change and the moderating influence of the presence of treatment, children's age, cognitive ability and type of measure on the expected change of each measure. Inter-rater reliability was collected at each stage of the search and data extraction process.

**Results:** 7098 articles were culled for review and 203 articles met full inclusion criteria. From those studies, 119 unique social communication measures were identified of which 55 measures were only used in a single study. A total of 1232 effect sizes were generated and pooled across measures.

75% of measures had expected change over time that was considered a small to medium effect, though there was considerable variability across measures of the same construct. Most outcomes were not sensitive to change; there was a positive relationship between change and the length of the study in only 9 of the 42 analyzed measures. Some measures were influenced by cognitive ability, chronological age, and intervention, though no consistent pattern was noted. Age-equivalent scores had approximately twice the expected change as standard scores of the same measure.

Conclusions: These data suggest that careful consideration is needed when selecting an outcome measures, tests of similar constructs can vary considerably in their expected change over time. Some recommendations based on these data include using caution when reporting standard scores to measure change over time and using caution when combining different outcome measures to synthesize intervention data.

**418.107 (Poster)** The Autism-Spectrum Quotient - Hebrew Version (AQ-Heb): A Full and a Short Form, Adapted for DSM-5

**O. Golan<sup>1,2</sup>, M. Terner<sup>3</sup>, S. Israel Yaacov<sup>1,2</sup>, C. Allison<sup>4</sup> and S. Baron-Cohen<sup>4</sup>,** (1)Department of Psychology, Bar-Ilan University, Ramat-Gan, Israel, (2)Association for Children at Risk, Givat-Shmuel, Israel, (3)Bar-Ilan University, Ramat-Gan, Israel, (4)Autism Research Centre, Department of Psychiatry, University of Cambridge, Cambridge, United Kingdom

---

Background: The Autism Spectrum Quotient (AQ) is a self-report scale used to assess autistic traits. It was tested cross-culturally, and a short version was recommended to help identify adults who should be referred for an autism assessment.

Objectives: The current study aimed to examine the psychometric properties of the Hebrew version of the AQ (AQ-50-Heb), and to create a short version based on items which map on to DSM-5 criteria.

Methods: Seventy autistic adults, clinically diagnosed according to DSM-5 (15 female), aged 18-51, and 147 comparable controls (34 female), filled out the AQ-50-Heb. Ten clinicians who specialize in diagnosing autism in adults classified the AQ's items according to DSM-5 criteria.

Results: The AQ-50-Heb showed good internal consistency (.89). At a cut-off of 23 it shows good sensitivity (.84) and specificity (.85). The AQ-10-Heb comprised 5 of the most discriminating items representing each of the DSM-5 diagnostic domains (see Table 1 below). Representing two Social Communication and two Restricted, Repetitive Behaviors criteria of DSM-5, the AQ-10-Heb yielded good internal consistency (.84) and optimal sensitivity (.87) and specificity (.82) at a cut-off of 5.

Conclusions: The AQ-50-Heb, and its short DSM-5 adapted AQ-10-Heb version are reliable and sensitive instruments that can help referring adults for autism assessment.

**418.108 (Poster)** The Consequences of Using Different 10-Item Autism Spectrum Quotient (AQ10) Cut-Offs in Psychological Research

**L. H. Waldren<sup>1</sup>, L. A. Livingston<sup>2</sup>, R. A. Clutterbuck<sup>1</sup>, E. Walton<sup>1</sup> and P. Shah<sup>3</sup>,** (1)Department of Psychology, University of Bath, Bath, United Kingdom, (2)Wales Autism Research Centre, School of Psychology, Cardiff University, Cardiff, United Kingdom, (3)University of Bath, Bath, United Kingdom

---

Background: The 10-item Autism Spectrum Quotient (AQ10, Allison et al., 2012), as recommended by the National Institute for Health and Care Excellence (NICE), is widely used to quantify autistic traits and screen for autism both in the UK and internationally. A worrying discrepancy has recently been found in the screening guidelines for the AQ10, in which NICE has erroneously recommended an incorrect  $\geq 7$  cut-off value, instead of the correct  $\geq 6$  value specified in the original research on the AQ10 (Waldren et al., 2021). A review of the literature shows this discrepancy has proliferated across research, generating confusion and misuse of the AQ10 cut-off over the past decade, with 56% of the research identified using the incorrect  $\geq 7$  or an ambiguous cut-off value.

Objectives: We aimed to quantify how the misuse of the AQ10 cut-off, specifically use of the incorrect  $\geq 7$  value instead of the correct  $\geq 6$  value, has affected autism research over the past decade.

Methods: Open-access data from three published studies in high-ranking journals using the AQ10 (Gollwitzer et al., 2019; Clutterbuck et al., 2021; Livingston et al., 2020; Total  $N = 6997$ ) were reanalysed, using both the correct  $\geq 6$  and incorrect  $\geq 7$  AQ10 cut-offs to classify participants with high and low autistic traits. These high and low autistic trait classifications were then used to re-test the main hypotheses from each of the three studies. The effect sizes produced using the correct  $\geq 6$  and incorrect  $\geq 7$  cut-off values were then statistically compared using the COCOR package (Diedenhofen & Much, 2015), to quantify how a 1-point difference in the AQ10 cut-off affects empirical results.

Results: Using the incorrect  $\geq 7$  AQ10 cut-off value reduced the number of participants who met the screening threshold for autism across all three datasets by up to 56%. The correct  $\geq 6$  cut-off value was also more accurate in classifying participants who had a clinical diagnosis of autism. Most critically, our analyses showed that the one-point difference in the AQ10 cut-off significantly changed effect sizes in two of three datasets by up to 47.62% (Gollwitzer et al., 2019:  $p < .001$ ; Clutterbuck et al., 2021:  $p = .004$ ), demonstrating that the misuse of the AQ10 cut-off has serious consequences for research.

Conclusions: Misuse of the AQ10 cut-off is commonplace in the literature, likely due to NICE recommending an incorrect screening value. Our results demonstrate the consequences of AQ10 cut-off misuse for international autism research, both in terms of sample composition and effect sizes of autism-related associations. We discuss the wider implications of these results for autism research and call for an appropriate AQ10 cut-off value to be established and used consistently in research and clinical practice.

**418.109 (Poster)** The Importance of Language Delays for Early ASD Diagnosis

**T. Nitzan<sup>1,2</sup>, J. Koller<sup>3</sup>, M. Ilan<sup>2,4,5</sup>, M. Faroy<sup>2,5</sup>, A. Michaelovski<sup>2,6</sup>, I. Menashe<sup>2,7</sup>, G. Meiri<sup>2,5</sup> and I. Dinstein<sup>2,4,8</sup>,** (1)Psychology Department, Ben Gurion University in the Negev, Beer Sheva, Israel, (2)National Autism Research Center of Israel, Ben-Gurion University of the Negev, Beer Sheva, Israel, (3)Seymour Fox School of Education, Hebrew University of Jerusalem, Jerusalem, Israel, (4)Psychology Department, Ben-Gurion University of the

**Background:** Early diagnosis of autism spectrum disorder (ASD) enables early access to treatment and better outcome (Hyman et al., 2020; Zwaigenbaum, Bauman, Choueiri, et al., 2015; Zwaigenbaum, Bauman, Stone, et al., 2015). Previous studies have reported that children with more severe ASD symptomatology tend to be diagnosed earlier (De Giacomo & Fombonne, 1998; Mandell et al., 2005; Mishaal et al., 2014; Rhoades et al., 2007; Salomone et al., 2016; Vanegas, 2021). However, it is not clear whether some of these variables affect the age of diagnosis more than others.

Recent studies have demonstrated that the majority of children with ASD (>85%) exhibit language delays that include delays in word learning and the use of phrases (Adamson et al., 2019; Pickles et al., 2014). Hence, while most children with language delay do not have ASD, language delay may still be an important, highly visible, early sign that justifies assessment of ASD symptoms.

**Objectives:** To determine the relative strength of language delay as a predictor of early ASD diagnosis, particularly prior to the age of 30 months, which is the upper age limit of many ASD screening tools (Zwaigenbaum, Bauman, Fein, et al., 2015).

**Methods:** We examined data from 97 Hebrew speaking children with ASD (mean age: 31.6 months old) who completed the Preschool Language Scale, fourth edition (PLS-4) and the Autism Diagnostic Observation Schedule, 2<sup>nd</sup> edition (ADOS-2) during their diagnosis. In addition, 80 of the children (~82.5%) also completed standardized cognitive assessments. We compared children diagnosed with ASD before 30 months of age with children diagnosed at older ages.

**Results:** Our results revealed that the age of diagnosis was positively correlated with PLS-4 scores ( $r(95)=0.61$ ,  $p<0.001$ ) and cognitive scores ( $r(78)=0.27$ ,  $p=0.021$ ), and negatively correlated with ADOS-2 Social Affect (SA) calibrated severity scores (CSS) ( $r(95)=-0.38$ ,  $p=0.0001$ ). A stepwise regression analysis demonstrated that PLS-4 scores were the strongest predictor of the age of diagnosis, explaining >37% of the variability across children. All the children diagnosed before 30 months of age in our sample exhibited moderate to severe language delays. Despite these strong relationships, approximately half of the children diagnosed after the age of 30 months also exhibited moderate to severe language delays that should have been noticeable during the second year of life.

**Conclusions:** While ASD is not defined as a language disorder, clear language delays are apparent in the vast majority of children diagnosed with the disorder. These results suggest that streamlined referral of children with language delays to ASD assessments may help further reduce the age of ASD diagnosis and identify children with ASD who are otherwise diagnosed late.

#### **418.110 (Poster) Trends in Intellectual Ability Among Children with Autism Spectrum Disorder from 2000 to 2016 in a Large Diverse Metropolitan Area**

**J. Shenouda<sup>1,2,3</sup>, W. Zahorodny<sup>4</sup>, K. Sidwell<sup>5</sup>, C. Lescott<sup>6</sup>, M. Jackson<sup>7</sup> and L. Kam<sup>7</sup>, (1)Department of Pediatrics, Rutgers University, Newark, NJ, (2)Pediatrics, Rutgers University - NJ Medical School, Newark, NJ, (3)Biostatistics and Epidemiology, Rutgers University, Piscataway, NJ, (4)Department of Pediatrics, Rutgers-New Jersey Medical School, Newark, NJ, (5)Department of Pediatrics, Rutgers New Jersey Medical School, Newark, NJ, (6)Rutgers New Jersey Medical School, Newark, NJ, (7)Rutgers University, Newark, NJ**

---

**Background:** Early studies found 40-75% of children with ASD had Intellectual Disability (ID). More recently, this trend has shifted, and now multiple epidemiological investigations show 40-60% of children with ASD have borderline to average intellectual ability. Intellectual ability is a strong predictor of functional outcomes, level of impairment, and support needed. Causal pathways for ID and ASD are known to be related.

**Objectives:** In this study, we describe intellectual ability across multiple populations of 8-year-olds between 2000 and 2016. Additionally, we examine sociodemographic shifts over the period.

**Methods:** ASD cases were identified through a population-based active ASD surveillance system. The Autism and Developmental Disability Monitoring (ADDMM) surveillance system utilizes a two-phase process. Data collected by the surveillance includes demographic and clinical information obtained from professional evaluations. ID status was obtained from surveillance data and categorized based on most recent IQ score for each case. A case was classified to have ID if IQ score  $\leq 70$ . ASD cases with missing IQ data were re-reviewed and classified as ID or no ID if they further met specific criteria. Data from seven surveillance cycles (2000, 2002, 2006, 2010, 2012, 2014 and 2016) were used. ASD prevalence estimates overall and by ASD with ID and ASD without ID were determined. ASD prevalence estimates were determined overall, and by sex, race/ethnicity and socioeconomic status (SES). Wilson score method was used to calculate 95% confidence intervals (CI).

#### **Results:**

Across all surveillance cycles, 4,661 cases met the surveillance standard case definition for ASD, and among those 2,760 (59%) ASD cases were classified as ASD without ID, 1,503 (32%) classified as ASD with ID and 398 remained with unknown ID status. While overall ASD prevalence estimates increased 3-fold in the 16-year period, ASD without intellectual disability increased approximately 5-fold (PR = 5.4; 95%CI: 4.4-6.5), and ASD with ID increased 2-fold (PR = 2.0; 95%CI: 1.6-2.5) in the same period. Comparing sex differences among children with ASD and ID, we observed that overall the prevalence ratio by sex was lower among ASD cases with ID compared to the prevalence ratio by sex among ASD cases without ID, which increased steadily over time. Across surveillance cycles, prevalence of ASD without ID was highest in Non-Hispanic White (NHW) children and lowest in Non-Hispanic Black (NHB) children. By 2016, the most recent surveillance cycle, across all race/ethnicities,

prevalence estimates of ASD without ID were higher than estimates for ASD and ID. Multivariate regression showed when we control for time trends, race/ethnicity, sex, and SES, children with ASD were two times more likely to have ASD without ID than ASD with ID (Figure 2).

Conclusions: ASD prevalence estimates among children with ASD with borderline to average intellectual ability has increased 540% between 2000 and 2016. Steeper increases in ASD estimates were seen among children with ASD without ID than children with ASD and ID. Our findings reveal possible disparities in identification of ASD without ID among Black and Hispanic children and children from low SES areas.

#### **418.111** (Poster) Validating a Swedish Measure of Social Camouflaging in Autism

**K. Lundin**<sup>1</sup> and **S. Bolte**<sup>2</sup>, (1)Karolinska Institutet, Stockholm, Sweden, (2)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, & Stockholm Health Care Services, Region Stockholm, Stockholm, Sweden

---

##### Background:

Research suggests that camouflaging, i.e. the use of behavioral strategies to appear less autistic in social interactions, is associated with increased mental health problems and even suicidality among autistic individuals. While the original English version of the Camouflaging Autistic Traits Questionnaire (CAT-Q) has been validated, previous research reports intercultural differences in autism assessment instruments also between countries often presumed to be similar, underlining the need for language- and culture specific validation of assessment instruments.

##### Objectives:

The aim of this study was to psychometrically evaluate and validate a translated Swedish version of the CAT-Q (CAT-Q/SE) in Swedish settings, in order to provide a valid measurement of camouflaging for research and clinical use. Also, we aimed to evaluate the utility of the CAT-Q/SE among adolescents.

##### Methods:

A sample aged between 10 and 83 years was recruited (N = 652, 59% female), comprising a general population group (n = 549) and a group of autistic individuals (n = 103). Participants completed a web survey including the CAT-Q/SE, as well as self-report questionnaires of autistic traits, stress, depression symptoms, anxiety symptoms, functioning and disability, and quality of life. The CAT-Q/SE will be psychometrically evaluated regarding validity (convergent, discriminant, factor structure), and reliability (test-retest, internal consistency). In addition, Swedish norm scores for the CAT-Q/SE will be developed.

##### Results:

Total scores on the CAT-Q/SE were positively correlated with theoretically linked measures of symptoms of anxiety and depression, and negatively correlated with quality of life, replicating findings in previous studies. The autistic participants scored significantly higher on the CAT-Q/SE total score than participants in the general population group. A subgroup (n = 138) completed the CAT-Q/SE a second time approximately four to eight weeks after the first, and the total scores from the two time points were strongly correlated, suggesting good test-retest reliability.

##### Conclusions:

The preliminary analyses suggest that the CAT-Q/SE demonstrates convergent and discriminant validity as well as test-retest reliability. The additional psychometric analyses described under methods will be conducted before INSAR 2022.

#### **418.112** (Poster) Pediatrician Accuracies in the Early Identification of Autism and Other Developmental Disorders and Delays

**J. Mahmalji**<sup>1</sup>, **C. Andreason**<sup>2</sup>, **T. Wen**<sup>2</sup>, **A. Grzybowski**<sup>2</sup>, **S. Nalabolu**<sup>2</sup>, **C. Carter**<sup>2</sup>, **S. Arias**<sup>3</sup> and **K. Pierce**<sup>2</sup>, (1)Neuroscience, Autism Center of Excellence, UCSD, La Jolla, CA, (2)UCSD Autism Center of Excellence, La Jolla, CA, (3)Autism Center of Excellence, UCSD, San Diego, CA

---

Background: Pediatricians are essential for early ASD detection through timely referrals of children showing early warning signs. With limited time during well-child checkups, research has shown that pediatricians prefer to use their clinical judgment over lengthy developmental screening tools (Gabrielsen et al., 2015). Within this context, it is not surprising that pediatrician clinical impressions are sometimes incorrect (Gabrielsen et al., 2015), resulting in missed referral and evaluation opportunities for children showing delays consistent with ASD.

Objectives: To explore the accuracy of pediatrician clinical judgments concerning early child development, and how factors such as toddler age and sex may impact accuracy.

Methods: Parents filled out a broadband screening tool, the Communication and Symbolic Behavior Scales, Developmental Profile Infant-Toddler Checklist during 12, 18 & 24 month well-baby visits on an iPad. Pediatricians then referred 341 toddlers for a developmental evaluation by a licensed psychologist at UC San Diego's Autism Center of Excellence, and also denoted their clinical impression as ASD, delay (language delay, global developmental delay, or other delay) or typical on the iPad. Pediatrician clinical impressions were compared to diagnoses given by psychologists at the center. Factors that might influence accuracy such as sex and age were examined using logistic regression.

Results: Of 341 pediatrician impressions, 42.82% accurately identified whether a patient was at risk for ASD, typically developing, or had another development delay. However, when toddler classification was simplified as a typically developing versus an atypically developing group, accuracy increased to 70.40%. A binary logistic regression suggests that while sex is not a significant factor ( $p = .762$ ), age significantly influenced the accuracy of pediatrician impressions, (Wald  $\chi^2 = 6.51$ ,  $p < .011$ , Nagelkerke  $R^2 = .029$ ).

Conclusions: During well-child checkups, the majority of pediatricians were able to discern between young children who are typically developing and those that are not. However, accuracy in pediatrician clinical judgment decreased in regard to children at risk for ASD. This demonstrates a need to adapt and possibly change current developmental screening protocols and medical training to enhance the accuracy of pediatrician clinical impressions of ASD.

**418.113 (Poster)** Test-Retest Reliability of Automated Social Communication Algorithms to Support Autism Characterization

C. W. Brune<sup>1</sup>, E. V. Ocampo<sup>2</sup>, L. V. Soorya<sup>2</sup>, S. Licon<sup>3</sup>, Z. Tóšér<sup>4</sup>, K. Kamal<sup>5</sup>, **L. Hermle<sup>2</sup>** and A. Hirshman<sup>1</sup>, (1)Department of Psychiatry, AARTS Center, Rush University Medical Center, Chicago, IL, (2)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (3)University of California, Santa Barbara, Santa Barbara, CA, (4)Argus Cognitive, Inc., Lebanon, NH, (5)Argus Cognitive, Inc., Budapest, Hungary

---

**Background:**

The effort to improve existing measurement paradigms within the autism spectrum disorder (ASD) & neurodevelopmental disorders (NDD) clinical research communities has included several digital health approaches even prior to COVID. These approaches include telehealth and remote assessments as were widely adopted during COVID, as well as automated video and audio analysis and sought to address several challenges with existing measures including limited applications at extreme ends of standard distribution (Tager-Flusberg & Kasari, 2013), poor operationalization of behavior and minimal sensitivity to change over short time frames (Leonard, Cobb, & Downs, 2017).

**Objectives:**

This project utilized ARGUS-MDS, a non-intrusive, digital package utilizing machine learning, automated speech analysis, computer vision analysis (CVA), and computational models to support social communication phenotyping in children (2-11 years). Project goals included evaluating: 1) quality control metrics for machine learning (ML) algorithms, 2) test-retest reliability of biometric output, and 3) communication protocols between computer and clinical science teams.

**Methods:**

17 families with a history of ASD or suspected ASD were recruited from June 2020 to August 2020. We collected demographic information, NIH medical history, ACE family medical history, IQ (Mullen, WISC, WASI-II, Stanford Binet, or DAS-Early Years), ADOS-2 (toddler module or modules 1, 2, 3). We also collected caregiver ratings on the Social Responsiveness Scale-2 (SRS-2), Pervasive Developmental Disorders Behavior Inventory-Screening Version (PDDBI-SV), and the Vineland-3. Families were brought in for an initial screening and testing visit for the full battery, and a second a retest visit 1-4 weeks later for the ADOS-2 with biometric protocol to assess test-retest reliability. A software program was tested using sample videos to facilitate communication between software developers at Argus Cognitive, Inc. and clinician raters in house.

**Results:**

After screening, 15 participants with confirmed diagnoses of ASD met eligibility criteria (3 female, 12 male), between the ages of 1.5 to 12 years ( $M=4.27$ ,  $SD=3.20$ ). Quality control (QC) metrics were evaluated through hand-coding of biometric data by trained computer scientists. Several key social communication behaviors exceeded both quality control, test-retest reliability, and ICC targets including eye gaze (% of time patient looking at clinician), facial emotions (% of time action units 4, 9, 10), prosody (number of pauses), conversational exchanges (average duration), synchronized gaze, facial emotions, gestures (% of time), and initiation. Metrics that did not reach reliability thresholds included gesture analysis and word repetitions. Clinician feedback on coding interface and output suggested a need for the system to capture several subtle behaviors (e.g. ambiguous facial expressions), low frequency but atypical behaviors (e.g., unusual laughing), and more refined gesture analysis.

**Conclusions:**

Argus-MDS produces high quality and reliable data during naturalistic observations taken during routine clinical evaluations on several key social-communication behaviors including eye contact, responsive gaze, facial action units associated with speech and emotions, integration of eye gaze and emotions, nonverbal social initiation bids. Test-retest data for individual variables are commensurate with global reliability scores on the conventional measure (e.g., ADOS-2). Areas for development include speech recognition and gestural analysis.

**418.114 (Poster)** A Systematic Review of the Use of Telehealth to Facilitate a Diagnosis for Children with Developmental Concerns

C. La Valle<sup>1</sup>, E. Johnston<sup>2</sup> and H. Tager-Flusberg<sup>1</sup>, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Boston University, Boston, MA

---

**Background:**

Telehealth holds the potential to reduce the gap between time of first developmental concern and diagnosis (McSwain et al., 2017), especially for families residing in rural locations with limited access to specialty input (Vitrikas et al., 2017). However, there is a critical need to evaluate the use of telehealth methods for facilitating a diagnosis for children with developmental concerns to provide evidence for providers to make informed decisions about using telediagnostic assessments in practice.

#### Objectives:

Although prior systematic reviews (SR) examined telehealth in the diagnosis of ASD (Alfuraydan et al., 2020), this SR evaluates telehealth to facilitate a diagnosis in children with other developmental concerns including suspected genetic syndromes (e.g., FXS). This SR lends insights into whether multidisciplinary evaluations are conducted and identifies the range of developmental domains assessed using telediagnostic services. Research questions included 1) what specific populations of children with developmental concerns received a diagnosis via telehealth methods and what type of diagnostic evaluation was conducted? 2) What telehealth technologies were used to facilitate a diagnosis and how did they compare with face-to-face diagnostic methods? 3) Where the telehealth technologies feasible and acceptable to use?

#### Methods:

Following PRISMA guidelines for SR, we searched for empirical peer-reviewed studies indexed in PsycINFO, CINAHL, Web of Science, PubMed, Embase, Cochrane, and relevant journals (*Pediatrics; Telemedicine and e-Health; Telemedicine and Telecare*) published from January 2000 to July 2021 using a combination of keywords: “telehealth” AND “developmental concern” AND “diagnosis”. Data extraction was conducted for type of population, type of diagnostic evaluation, telehealth technology, and specific outcomes: diagnostic accuracy, feasibility, and acceptability. The NHLBI Quality Assessment tool was used to assess the methodological quality of the included articles.

#### Results:

A total of nine studies were identified for inclusion in the SR (Figure 1). 1) Children with suspected fetal alcohol syndrome (FAS), newborns who failed their hearing screen, children with mental health/social-emotional concerns, and children with a suspected genetic condition(s) associated with developmental concerns received a diagnosis via telehealth methods. Children with suspected FAS received a multidisciplinary diagnostic evaluation (physical/dysmorphology, feeding, neurological, and developmental assessments), newborns who failed their hearing screen received a comprehensive tele-audiology diagnostic hearing evaluation, children with mental health concerns received psychiatric assessments, and children with suspected genetic conditions associated with developmental concerns received a neurological exam and dysmorphology assessment. 2) Seven studies used videoconferencing technology and two studies used Store-and-Forward telehealth methods. Overall high agreement was found when comparing face-to-face and telehealth-based diagnostic methods. 3) Families and providers reported high levels of satisfaction and feasibility in the use of telehealth methods to facilitate a diagnosis.

#### Conclusions:

Findings underscore the importance of collaborative partnership models between local providers and remote specialists. Telehealth holds the potential in facilitating a timely diagnosis for families of children with developmental concerns residing in remote locations with limited access to specialty care. However, more rigorous study designs with larger samples covering a wider range of developmental domains and including multidisciplinary assessments are needed to provide a stronger empirical base for providers using telediagnostic services.

## VIRTUAL POSTER SESSION — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

### 509 - Diagnostic, Behavioral & Intellectual Assessment I --- (V)

**509.028** (Virtual Poster) A Training Needs Analysis to Determine Professionals' Needs for Asdetectpro: An Early Autism Training Program and Early Identification Tool

**M. Gilbert<sup>1</sup>**, R. Nair<sup>2</sup> and J. Barbaro<sup>2</sup>, (1)Olga Tennison Autism Research Centre, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

Background: Medical and primary health (MPH), allied health (AH), and early childhood education (ECE) professionals play an essential role in identifying children with developmental conditions, including autism. Previous research indicates they often have limited knowledge about autism and early identification; furthermore, there is no known research comparing the needs of these groups.

ASDetectPRO is an online autism training program and early identification tool for such professionals, based on the award-winning parent/caregiver mobile app, ASDetect (Barbaro & Yaari, 2020) and using the highly accurate SACS-R tool (Barbaro et al., under review). Currently under development, ASDetectPRO aims to address the need for autism knowledge training and an accurate early autism identification tool in a more accessible format, increasing access for professionals who cannot attend in-person training. While lockdown restrictions due to the COVID-19 pandemic have highlighted this need, professionals based rurally, regionally, and internationally, have long had this barrier.

Objectives: The objective of this study was to investigate MPH, AH, and ECE professionals' autism knowledge and training needs, to inform the development of ASDetectPRO. Differences in knowledge and training needs between the professional groups were examined.

**Methods:** MPH, AH, and ECE professionals who regularly work with children aged 11-36 months were invited to complete an online survey regarding their early autism knowledge, current use of early autism screening tools, and their autism training needs. Participants were recruited by sharing the study information and link through various means, including Facebook and Twitter posts, newsletters, and email. A total of 81 participants (25 MPH, 38 AH, 18 ECE) completed the survey. Mean participant age was 40.8 years (SD=10.8); most were female (96.3%) and based in Australia (74.1%), though participants were based in other countries such as New Zealand (16.0%) and the US (2.5%).

**Results:** MPH and AH professionals had significantly greater knowledge of the early signs of autism in comparison to ECE professionals, though no significant differences were found between MPH and AH professionals. While most (88%) of MPH professionals reported currently using an early autism screening tool, only 34.2% of AH and 5.6% of ECE professionals reported doing so.

All groups ranked “*information on the early signs and symptoms of autism*” as their top training need to be addressed in an autism training program. However, the importance of subsequent autism training needs differed. MPH professionals ranked “*training on effective communication strategies with children suspected of having autism*” as their second highest training need. AH professionals selected “*training on how to effectively communicate results with parent/caregivers*”, with ECE professionals’ preference being “*training on how to use and access an autism screening tool*”.

**Conclusions:** These findings highlight the need for access to training on the early signs of autism for ECE professionals, while also emphasising the need and desire for all professional groups to increase their knowledge of autism and use of autism screening tools. The study also emphasises the similarities and differences in these professionals’ autism training needs, which will ensure ASDetectPRO can be developed to meet the needs of its target users.

#### **509.029 (Virtual Poster) Early Autism Identification Training for Maternal and Child Health Nurses**

K. E. Gore<sup>1</sup>, M. Gilbert<sup>2</sup>, R. Nair<sup>3</sup> and J. Barbaro<sup>3</sup>, (1)Olga Tennison Autism Research Centre, La Trobe University, Bundoora, VIC, Australia, (2)Olga Tennison Autism Research Centre, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (3)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia

---

**Background:** Early identification of children on the autism spectrum is an important precursor to accessing diagnosis, services, and supports, which can enhance development and wellbeing. Previous research has demonstrated that maternal and child health (MCH) nurses can be trained to accurately identify infants and toddlers who have a ‘high likelihood’ of autism. This study was part of a Victorian Government (Australia) funded autism surveillance training program for all MCH nurses.

**Objectives:** The overall objectives of this study were to identify areas of training need in the early detection of young children with autism and ‘pain points’ for MCH nurses when assisting these children and their families, and to address these as part of a training program that included the Social Attention and Communication-Revised (SACS-R, Barbaro et al, under review) tool. Additionally, the early autism knowledge, self-efficacy, and confidence of MCH nurses pre- and post-training, to determine predictors of these outcome variables pre-training, as well as a follow up to establish the impact of the training were examined.

#### **Methods:**

**Training Needs Analysis (TNA):** 303 MCH nurses completed a pre-training questionnaire, covering aspects such as current autism knowledge, self-efficacy in identifying children with a ‘high likelihood’ of autism, and their self-identified training needs. A referral pathway session with 43 MCH co-ordinators uncovered current referral pathways, barriers for families and nurses in accessing the pathways, and perspectives on an ideal pathway. Focus groups with parents/caregivers and autistic adults were conducted to understand their needs and preferences for the training program.

**Training:** A full-day in-person workshop with online pre- and post-training modules were developed. From May-June 2019, 29 workshops were held, training 1700 MCH nurses to use the SACS-R tool. Additional resources were developed based on the needs identified in the TNA, including a referral form and pathway, and parent/caregiver poster and booklet resources.

**Follow-up questionnaires:** Attendees were asked to complete online questionnaires establishing their training feedback (n = 344), and SACS-R implementation and follow-up of the TNA variables (n = 113), with 36 participants completing both pre- and post- questionnaires.

**Results:** Findings of the pre-training questionnaire indicated completing previous autism training and knowledge of autism community services were positively related to MCH nurse self-efficacy and confidence in speaking with parents/caregivers about autism. Working in a metropolitan location was also correlated with higher confidence levels, while nurse age and tenure were inversely related with both self-efficacy and confidence.

Responses to the training feedback questionnaire indicated nurses were satisfied with the training and resources and felt confident in implementing the learnings in their practice. The implementation questionnaire responses revealed 91.1% of nurses were using the tool, with over three-quarters indicating the tool was easy to implement, had a positive impact on their practice, and was adaptable for families.

The results of the pre-/post-training questionnaire comparison found a statistically significant increase in mean levels of autism knowledge, self-efficacy, and confidence post-training.

**Conclusions:** These results have implications for future autism surveillance training and present opportunities to better support mature nurses and those in rural and regional locations.

**509.030 (Virtual Poster)** An Update on the TAP: Diagnostic Agreement, Diagnostic Certainty, and Analysis of Scoring Procedures

**L. Corona<sup>1</sup>, L. Wagner<sup>2</sup>, M. Hooper<sup>3</sup>, J. Hine<sup>3</sup>, A. S. Weitlauf<sup>3</sup> and Z. Warren<sup>1</sup>,** (1)Vanderbilt University Medical Center - Treatment and Research Institute for Autism Spectrum Disorder, Nashville, TN, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Vanderbilt University, Nashville, TN, (4)Vanderbilt Kennedy Center, Vanderbilt University Medical Center, Nashville, TN

---

**Background:** The COVID-19 pandemic has accelerated the use of telemedicine for evaluation of toddlers at risk for ASD. The TAP (formerly TELE-ASD-PEDS) is one of the first instruments designed explicitly for parent-led, clinician-guided assessment of characteristics of ASD in young children. The TAP is comprised of a series of brief activities designed to allow a trained clinician to observe a child's social interactions, communication, and play, including observation of potential behaviors indicative of ASD. The TAP was disseminated broadly during the COVID-19 pandemic and has been used widely both within the United States and internationally. In 2021, our team presented interim results of a clinical trial (ClinicalTrials.gov: NCT03847337) comparing use of the TAP and another tool for ASD tele-assessment (the TELE-STAT).

**Objectives:** This presentation will share the results of our completed clinical trial, with a focus specifically on the diagnostic accuracy of the TAP, as well as an analysis of two options for scoring the TAP.

**Methods:** Seventy-two children (mean age = 2.54, range 18-36 months, 64% male) received telemedicine evaluation using the TAP. Tele-assessment was completed in a clinic setting (i.e., family located in a clinic room with clinician interacting remotely) and immediately followed by in-person ASD evaluation with a clinician blind to tele-assessment results. Following tele-assessment, clinicians assigned scores on seven behavioral domains (e.g., socially directed speech and sounds; unusual or repetitive play) using two distinct scoring options. Clinicians first assigned Likert ratings for each item (1 = the behavior characteristic of ASD is not present; 2 = the behavior is present but at subclinical levels; 3 = the behavior is present and clearly consistent with ASD). Next, clinicians provided dichotomous ratings for each domain, indicating simply whether the behavior was present or not present. Current research and scoring recommendations rely on Likert ratings. The present study will analyze and compare Likert and dichotomous ratings.

**Results:** Comparison of diagnostic impressions following tele-assessment versus blinded clinicians' diagnoses following in-person evaluation indicated diagnostic agreement of 93%. Four children diagnosed with ASD after in-person evaluation were not identified as having ASD via telemedicine. One child was inaccurately identified as having ASD following tele-assessment. One-way ANOVA indicated that clinician diagnostic certainty via telemedicine ( $F(2, 67) = 12.17, p < .01$ ) differed as a function of diagnostic agreement, with clinicians reporting greater certainty when assigning ASD diagnoses than when ruling out ASD. The included table displays mean scores on the TAP using Likert vs. dichotomous ratings. We will present results of analysis utilizing an IRT approach to investigate whether and to what degree the scoring method used predicts whether a child received a diagnosis following in-person assessment.

**Conclusions:** Parent-mediated, telemedicine-based ASD assessment using the TAP yields a high level of diagnostic agreement with blinded in-person evaluation. As new work on the TAP investigates in-home use in a community sample, and as clinicians continue to use the TAP as part of ongoing tele-practice, this work intends to inform and further refine our understanding and use of this instrument.

**509.031 (Virtual Poster)** Comparison of Telehealth & Adapted Protocols Vs. Standard-of-Care Evaluations for the Diagnostic Assessment of Autism Spectrum Disorder Due to the COVID-19 Pandemic

**G. Binion<sup>1</sup>, H. Tokish<sup>2</sup>, E. McQueen<sup>3</sup>, A. Rudrabhatla<sup>2</sup>, J. Pincus<sup>4</sup>, J. Ferguson<sup>5</sup>, S. P. White<sup>1</sup>, C. Klaiman<sup>6</sup> and S. Sivathanan<sup>7</sup>,** (1)Marcus Autism Center, Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (3)Department of Allied Health Sciences, Marcus Autism Center, Children's Healthcare of Atlanta & Emory School of Medicine, Chapel Hill, NC, (4)Department of Pediatrics, Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (5)Clinical Assessment and Diagnostics, Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (6)Marcus Autism Center, Emory University, Atlanta, GA, (7)Educational & Counseling Psychology, McGill University, Montreal, QC, Canada

---

**Background:** Guidelines and restrictions surrounding the current global COVID-19 pandemic have necessitated significant changes to supporting children and families seeking diagnostic evaluation for autism spectrum disorder (ASD). Through this pilot study, we aimed to explore the feasibility and efficacy of using remote telehealth options, as well as adaptations to in-person assessment methods.

**Objectives:** To assess the diagnostic accuracy/concordance and convergent validity between traditional ASD assessment batteries with telehealth and adapted in-person protocols.

**Methods:** Children were recruited to participate if they had received an ASD diagnosis following a standard diagnostic evaluation (i.e., Mullen Scales of Early Learning [MSEL] or Differential Ability Scales-2 [DAS-2], and an Autism Diagnostic Observation Schedule-2 [ADOS-2]) by a licensed psychologist and/or supervised trainee, between January and March 2020, prior to assessment modifications due to the COVID-19 pandemic (original evaluation). The study evaluation comprised of either a Telehealth or an In-Person protocol. The Telehealth protocol included the Childhood Autism Rating Scale, 2nd Ed. Zoom Observation (CARS-OBS; an 8-item, 15-minute observation) and the full CARS-2 protocol completed with the AutismEYES Interview Guide (CARS-EYES), or ADOS-2 Module 3 adapted for telehealth (ADOS-Mod3-Tel). The In-Person protocol included an adapted ADOS-Mod1 or ADOS-Mod2 during which clinical administrators wore face masks and certain activities were modified to accommodate COVID-19 safety protocols. All families then completed the Developmental Profile-4 Parent/Caregiver Interview (DP-4). To compare scores across differing measures, standardized nonverbal and verbal IQ scores were calculated from the MSEL and DAS-2. Study protocols were administered by trained clinical/research staff. Interrater reliability via video coding (for ADOS-Mod3-Tel, CARS-OBS & CARS-EYES) was  $\geq 75\%$ .

**Results:** Twenty-five families completed this pilot study ( $n=19$  completed the Telehealth protocol,  $n=6$  completed the In-Person protocol). Participant ages ranged from 3.75-14.67 years. Mean time between original evaluation and the study evaluation was 15.24 months ( $SD=1.67$  months). Concordance of ASD diagnostic classification (i.e., participant met total score cutoffs) was 100% on the In-Person ADOS and 83% on the ADOS-Mod3-Tel. Concordance was 62% on the CARS-OBS, which improved to 91% with the addition of the CARS-EYES interview. Correlations between original and study evaluation ADOS scores varied by protocol. For In-Person ADOS' ( $n=6$ ) correlations ranged from  $r=.48-.91$  across Social Affect, RRB, Total, and Comparison scores, whereas for ADOS-Mod3-Tel ( $n=6$ ) they ranged from  $r=-.24-.52$ . Original ADOS Total Scores were correlated with CARS-OBS total scores ( $n=12$ ,  $r=.65$ ) but less so with CARS-EYES total scores ( $n=10$ ,  $r=.36$ ). Finally, original NVIQ and VIQ scores were significantly correlated with DP-4 Cognitive and Communication scores, respectively ( $n=24$ ;  $rs=.72-.74$ ).

**Conclusions:** Overall, diagnostic accuracy/concordance between pre-pandemic ASD evaluations and adapted protocols was high when completing an ADOS or a CARS observation with a follow-up caregiver interview. However, convergent validity was more variable; adapted in-person protocols were better able to capture the range of symptomatology observed in traditional assessments than did telehealth assessments. Adapted telehealth protocols may be particularly helpful in evaluating or confirming clearer cases, but may not capture more subtle symptom presentations that may be observed via traditional in-person assessment methods.

**509.032 (Virtual Poster)** Diagnosing Autism Spectrum Disorder during COVID-19 Pandemic: A Model Utilizing the Bosa  
T. Fried<sup>1</sup>, R. Battino<sup>2</sup>, M. Valicenti-McDermott<sup>2</sup> and L. Shulman<sup>2</sup>; (1)Department of Developmental Medicine, Rose F. Kennedy Children's Evaluation & Rehabilitation Center at Children's Hospital at Montefiore, Bronx, NY, (2)Rose F. Kennedy Center, Children's Evaluation and Rehabilitation Center; Montefiore Medical Center, Bronx, NY

---

**Background:** The arrival of the COVID-19 pandemic presented a challenge for diagnosing Autism Spectrum Disorder (ASD) in children. As professional staff transitioned to telehealth and/or utilizing significant personal protective equipment (PPE), diagnostic tools and clinical judgement were less reliable in accurately diagnosing ASD. The Brief Observation of Symptoms of Autism (BOSA) (Lord, 2020) was created to provide standardized observations in the context of social distancing and use of PPE. The BOSA incorporates parent/caregiver interaction without the use of PPE while clinicians observe from a separate location. Based on clinicians' experience with the ADOS-2, some supplemental assessment tasks from the appropriate ADOS-2 module were conducted using PPE following the BOSA

**Objectives:** 1)Describe the use of the BOSA in the diagnosis of ASD in an urban ethnically diverse multidisciplinary center 2) Determine clinical confidence in diagnosis of ASD using BOSA alone versus with supplemental assessments 3) Identify phenotypes of children associated with more/less confidence in the BOSA.

**Methods:** At our multidisciplinary center, children are typically referred for ADOS-2 assessment for the purpose of diagnostic clarification when other assessment tools (e.g. Childhood Autism Rating Scale-CARS, DSM-5 checklist, etc) and clinical judgment yield uncertainty. The BOSA was utilized during COVID-19 pandemic in place of the ADOS-2. Clinicians administering the BOSA rated their level of certainty of ASD/no ASD diagnoses based on the BOSA alone and after supplemental tasks. Reviewed Data included: demographics, clinical phenotype, CARS-2, BOSA algorithm score with/without supplemental tasks, and clinician confidence in ASD/ no ASD. Statistics included correlation, chi-square, and t-test.

**Results:** Since December 2020, 53 children were seen for BOSA: 43 boys (81%), 10 girls (19%), age  $6\pm 3$  years, 17(32%) Hispanic, 9(17%) bilingual English/Spanish, CARS-2 score  $28\pm 4$ , 11(21%) minimally verbal, 13(25%) with phrases/simple sentences, and 29(55%) with complex sentences. Of the 53, 36(68%) scored on the BOSA or on the supplemental assessments. Of the 36 children who scored, 32 were verbal (phrases or sentences) versus 4 minimally verbal (89% vs.11%  $p=0.02$ ). Children who were minimally verbal were less likely to score on the BOSA (27% vs. 73 %  $p=0.04$ ). There was a negative correlation between BOSA algorithm score and age of child ( $r=-.33$   $p=0.02$ ) and positive correlation between BOSA algorithm score with CARS ( $r=.37$   $p=0.01$ ). The evaluators' confidence rating scale in diagnosis of ASD/no ASD increased with supplemental materials (1 not confident to 5 very confident:  $3\pm 1$  to  $4\pm 0.8$   $p=0.001$ ). The level of evaluators' certainty of ASD/no ASD was optimal (Scores 4-5 in Likert scale) in 25 patients (47%) with BOSA alone versus 30 (56%) adding supplemental materials ( $p=0.06$ ).

**Conclusions:** The BOSA aided in ASD diagnostic clarification for children with milder social impairment. The addition of supplemental materials increased clinicians' ability to clarify ASD/no ASD. The BOSA was more likely to capture ASD diagnosis in younger children and those who had phrase speech/simple sentences. The BOSA, with supplemental ADOS-2 assessments tasks, may represent a useful tool for Autism diagnosis while PPE is necessary.

**509.033 (Virtual Poster)** Diagnostic Stability of Autism Spectrum Disorder in Preschool Children: A Systematic Review and Meta-Analysis  
A. Brignell<sup>1,2,3,4</sup>, R. Harwood<sup>5</sup>, T. May<sup>6</sup>, S. Woolfenden<sup>6,7</sup>, A. Montgomery<sup>7,8</sup>, A. Iorio<sup>9</sup> and K. Williams<sup>1,4</sup>; (1)Monash University, Clayton, VIC, Australia, (2)Murdoch Children's Research Institute, Parkville, VIC, Australia, (3)Speech Pathology, Australian Catholic University, Fitzroy, VIC, Australia, (4)Monash Children's Hospital, Clayton, VIC, Australia, (5)Western Health, Melton West, VIC, Australia, (6)Sydney Children's Hospital Network, Randwick, NSW, Australia, (7)University of New South Wales, Randwick, NSW, Australia, (8)Sydney Local Health District, Camperdown, NSW, Australia, (9)McMaster University, Hamilton, ON, Canada

---

**Background:**

The clinical pathway for children with autism spectrum disorder (autism) is varied and current research suggests some children may not retain their diagnosis over time.

**Objectives:**

The primary objective was to synthesise available evidence on the proportion of preschool children diagnosed with ASD who maintain a diagnosis at follow-up one or more years later.

#### Methods:

The search strategy (conducted up to end of 2017 and currently being updated) was sensitive and applied to eight databases. We included prospective and retrospective longitudinal studies that used the same measure and process to diagnose ASD at baseline and follow-up. Studies were required to have  $\geq 1$  year of follow-up and contain at  $\geq 10$  participants. Participants were  $<6$  years at baseline assessment and followed up  $< 19$  years of age. Two authors independently extracted data on study characteristics and assessed risk of bias. We conducted random effects meta-analysis as data allowed. We conducted subgroup analyses to explore factors that may predict diagnostic outcome. Planned sensitivity analyses of methodological differences was not completed because only two (6%) studies were rated low risk of bias.

#### Results:

In total, 40 studies met inclusion criteria (11350 participants). Of these, 28 (70%) were conducted in North America, nine (22%) in Europe/United Kingdom and three (8%) in Asia. Most (63%) studies were published before 2013. Mean age of participants at baseline was 3.10 years (range 1.13-5.0) and 5.6 years (range 3.0-11.6) at follow-up. Mean length of follow up was 2.6 years (range 1-7) and most children were male (79%). 53% of studies primarily included participants with intellectual disability ( $IQ < 70$ ). Mean sample size was 284 (range 10-8564). 55% of studies used one diagnostic assessment tool, 30% used two and 15% used three or more. Diagnosis was decided by a multidisciplinary team (MDT) in 53% of studies. Data was suitable for metaanalyses for 34 studies ( $n=11126$ ). In summary, 92% (95% confidence interval (CI): 89%-95%) of participants retained their ASD diagnosis one or more years later (Figure 1). The overall certainty of the evidence was judged as very low. Subgroup analyses did not identify any significant associations between diagnostic outcome and age at baseline diagnosis, age at follow-up diagnosis, duration of follow up, decade of publication, adaptive behaviour, language ability and mean IQ. A significantly higher proportion of children diagnosed by an MDT retained their diagnosis (98% [95% CI .94,1.0]) than those that did not have an MDT assessment (87% [95% CI .82,.92]). See Figure 2.

#### Conclusions:

Overall, most children (92%) who were diagnosed with ASD before six years of age retained their diagnosis a year or more later. A significant association was found between diagnosis by an MDT and a higher proportion of participants who retained their ASD diagnosis at follow-up. However, certainty of the evidence was rated very low due to high heterogeneity and risk of bias. Studies with low risk of bias that are relevant to the children seen in clinical diagnostic settings are needed to improve the utility of available evidence for families, clinicians and services.

**509.034** (Virtual Poster) Microanalysis of Daily Living Skills in Adolescents with Autism Spectrum Disorder without an Intellectual Disability  
**A. Duncan**<sup>1,2</sup>, **M. Liddle**<sup>3</sup>, **C. Fassler**<sup>1</sup> and **M. Glover**<sup>1</sup>, (1)Cincinnati Children's Hospital Medical Center, Cincinnati, OH, (2)College of Medicine, University of Cincinnati, Cincinnati, OH, (3)Behavioral Medicine and Clinical Psychology, Cincinnati Children's Hospital Medical Center, Cincinnati, OH

**Background:** Adolescents with autism spectrum disorder (ASD) without an intellectual disability (ID) have daily living skills (DLS) that often fall far below their chronological age and affect their ability to achieve successful outcomes in independent living, employment, and college. Research has shown that DLS deficits are linked to a more positive adult outcome, but we know less about the specific DLS that are challenging for adolescents with ASD and critical for interventions to target.

**Objectives:** The primary goals were to utilize the Vineland Adaptive Behavior Scales, 3<sup>rd</sup> Edition (VABS-3) in a sample of 151 adolescents with ASD without an ID to (1) explore the profile of the DLS subdomains of Personal, Domestic, and Community; (2) identify interview topics that were Mastered/Acquiring, Emerging, and Challenging; and (3) identify specific DLS items that were relative strengths and challenges.

**Methods:** All adolescents had confirmed diagnoses of ASD and IQs  $\geq 70$ . The VABS-3 computer-assisted parent/caregiver interview was administered. A total score for each interview topic within the DLS subdomains was first calculated and then a mean interview topic score was calculated by dividing the total score by number of items. Interview topic and item mean scores from 1.5 to 2 were classified as *Mastered/Acquiring*, scores from 1 to 1.5 were *Emerging*, and scores below 1 were *Challenging*. Descriptive statistics and t-tests were used to examine VABS-3 DLS domains, subdomains, interview topics, and item scores. One-way MANOVAs were conducted to examine the relationship between demographics and VABS-3.

**Results:** There were no significant relationships between VABS-3 DLS domain and subdomain raw scores and sex at birth ( $p$  values of 0.14-0.91), race ( $p$  values of 0.50-0.91), primary caregiver education ( $p$  values of 0.08-0.55), and annual income ( $p$ 's of .06-.23). The VABS-3 DLS Community subdomain v-scale score was the highest ( $M=10.2$ ,  $SD = 2.3$ ), followed by the Domestic subdomain v-scale ( $M=9.0$ ,  $SD=3.7$ ), and then followed by the Personal subdomain v-scale ( $M=8.8$ ,  $SD=3.5$ ). See Table 1 for VABS-3 Domestic subdomain means for each interview topic and item. In the Personal subdomain, the interview topics that were identified as *Challenging* included weather and health. In the Domestic subdomain, the interview topics that were identified as *Challenging* included basic household chores, cleaning up after meals, more complex food preparation, and advanced household chores. In the Community subdomain, the interview topics that were identified as *Challenging* included understanding rights, being on time, shopping skills, achieving goals, earning money, traveling, and managing money.

**Conclusions:** The emerging DLS profile found Community DLS as a relative strength, followed by Domestic DLS, and then Personal DLS. Adolescents with ASD demonstrated significant challenges in all interview topics on the DLS subdomains. The majority of these age-appropriate,

challenging areas are skills that could actually be taught and mastered much earlier in development (e.g., basic chores such as putting belongings away) using evidence-based strategies (e.g., task analysis, reinforcement, video modeling). Clearly, more intervention is needed to increase acquisition and mastery of age-appropriate DLS in order to facilitate the most successful transition possible for individuals with ASD.

**509.035 (Virtual Poster) ASD Symptomatology in Females: Data from a Community Clinic**

**M. Heyman<sup>1</sup>, K. K. Stavropoulos<sup>2</sup> and J. Blacher<sup>3</sup>,** (1)University of California, Riverside, Riverside, CA, (2)School of Education, University of California Riverside, Riverside, CA, (3)School of Education, University of California, Riverside, Riverside, CA

---

**Background:** Current literature suggests a 4:1 ratio of males: females with autism spectrum disorder (ASD). Although the level of impairment varies across the spectrum, females with ASD tend to have greater cognitive impairment and more behavioral problems than males (American Psychiatric Association, 2013; Centers for Disease Control and Prevention, 2020; Dworzynski et al., 2012). For those on the spectrum with average or above-average cognitive functioning, the sex ratio is more skewed towards males, reporting ten males for every female (Hiller et al., 2014; Loomes et al., 2017; Maenner et al., 2020). Among individuals with below-average cognitive abilities or more severe behavior problems, the ratio of males to females drops to about 2:1 (Halladay et al., 2015; Lai et al., 2015; Postorino et al., 2015).

**Objectives:** The study's objectives are: (1) Among individuals who met criteria for ASD on the ADOS-2, are there sex differences in scores on either the ADOS-2 or parent-reported variables (e.g., SSIS, SRS, CBCL)? (2) Are there differences between females who did versus did not meet criteria for ASD on the ADOS-2 on parent reported measures (e.g., SSIS, SRS, CBCL)?

**Methods:** Participants were screened at a free community autism center using the appropriate module of the Autism Diagnostic Observation Schedule, Second Edition (ADOS-2); module selection was based on child language ability. Caregivers completed the following questionnaires about their child's behaviors: Child Behavior Checklist (CBCL) to assess the child's behavioral and emotional difficulties; Social Skills Improvement System (SSIS) to describe the child's social skills, academic competence and problem behaviors; Social Responsiveness Scale, Second Edition (SRS-2) to provide information about the child's social abilities associated with ASD. One-way ANOVA and post-hoc Bonferroni tests were conducted to determine if there were sex differences across the described measures; these were conducted for each ADOS-2 module separately. For question 1, participants were included if they met ASD criteria on the ADOS-2 (Males = 144, Females = 51).

**Results:** There were sex differences for those who met ADOS-2 criteria. Children administered Module 1 significantly differed on the SSIS social skills total score, such that females with minimal language abilities demonstrated poorer social skills compared to males ( $p = 0.01$ ). Children administered the Module 2 significantly differed on the SSIS social skills total score and the SSIS problem behavior total score. Based on parent reports, females with phrase speech displayed poorer social skills ( $p = 0.048$ ) and more behavioral problems ( $p = 0.04$ ) compared to males. Children administered Module 3 did not significantly differ significantly on any diagnostic measure or parent questionnaire. There were no significant differences for parent report between females who did ( $N = 51$ ) versus did not meet criteria for ASD ( $N = 38$ ).

**Conclusions:** The results of this study suggest that females who were referred for an ASD evaluation displayed more severe social impairments and/or significant behavioral problems. Thus, caregivers or community professionals should recognize social impairments and behavioral concerns in females and provide referrals for an ASD specific evaluation.

**509.036 (Virtual Poster) Caregiver Concerns Predict Specific Areas of Adaptive Functioning in Infants and High- and Low-Risk for Autism**

**M. Fecher<sup>1</sup>, C. J. Zampella<sup>1</sup>, M. Drye<sup>1</sup>, R. Benecke<sup>1</sup>, L. S. Cubit<sup>1</sup>, G. Megginson<sup>1</sup>, L. K. Steinbeck<sup>1</sup>, L. A. Wang<sup>1,2</sup>, R. T. Schultz<sup>1,3</sup> and W. Guthrie<sup>1,3,4</sup>,** (1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Department of Psychology, University of Pennsylvania, Philadelphia, PA, (3)Departments of Psychiatry and Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, (4)Center for Pediatric Clinical Effectiveness, Children's Hospital of Philadelphia, Philadelphia, PA

---

**Background:** Caregiver concerns have been shown to be predictive of their child's developmental outcomes, including autism spectrum disorder (ASD). This literature demonstrates the importance of encouraging caregivers to raise concerns with providers, which may lead to earlier evaluation and intervention. However, these studies have used varying modalities to survey caregiver concerns (e.g., questionnaire, open-ended discussion), suggesting the need to identify an administration format that best captures caregivers' impressions of their child's development.

**Objectives:** (1) Characterize caregiver developmental concerns regarding their 12-month-old infants at high- and low-familial risk for ASD; (2) Examine whether caregiver concerns predict caregiver-reported adaptive behavior and whether concerns are specific to the domain of concern; (3) Test whether ASD risk status moderates this relationship.

**Methods:** Caregivers of infants ( $N=45$ ; 33 LR, 12 HR) completed an open-ended, semi-structured parent concerns interview (modeled from Ozonoff, et al., 2009), where clinicians asked about concerns in 11 developmental domains. Clinicians subsequently administered the Vineland-3 Comprehensive Interview. Fisher's Exact tests compared proportions of concerns across risk group and t-test compared concerns and Vineland-3 scores. For concern domains measured by the Vineland-3 (i.e., Communication, Socialization, Motor Skills), regression analyses examined main effects of concern and risk status and their interaction on Vineland-3 scores.

**Results:** Caregivers of high- and low-risk infants were equally likely to report concerns in all domains, except for sensory/repetitive behavior and communication/language concerns, which were endorsed more often for high-risk infants (see Table 2). Infants with a communication concern had significantly lower Vineland-3 Communication scores than infants without a communication concern ( $p=.03$ ). However, this finding was specific to the Communication domain, as communication concerns did not predict Vineland-3 Adaptive Behavior Composite (ABC) scores. The same pattern was observed for fine motor concerns. Infants with a fine motor concern had lower Fine Motor v-scale scores ( $p=.001$ ), but comparable ABC scores.

However, gross motor concerns did not significantly predict Gross Motor or ABC scores. Social concerns also did not significantly predict Socialization or ABC scores. However, regression analyses revealed significant main effects of social concerns and risk status on Socialization scores ( $p < .001$  and  $p = .003$ ), as well as a significant interaction ( $p = .006$ ), suggesting that the relationship between caregiver social concerns and Vineland-3 Socialization scores differed across risk groups. Interactions between concern and risk status were not significant for Communication, Fine Motor, and Gross Motor.

**Conclusions:** Results suggest that caregiver concerns regarding their 12-month-olds' communication, fine motor, and social skills were predictive of lower scores in those adaptive behavior domains, regardless of autism risk status. Importantly, caregiver concerns were also specific, as they did not predict behavior broadly, only in the specific area of concern. Results are consistent with previous literature demonstrating the accuracy of caregivers in identifying areas of developmental concern. Results also highlight the importance of specifically probing for concerns by 1 domain, as many caregivers reported additional concerns when specifically probed. Given the accuracy and specificity of caregiver concerns, providers should consider incorporating concern into early screening efforts, as this method may improve upon the accuracy of questionnaire-based tools.

**509.037 (Virtual Poster)** Biological and Phenotypic Markers in the Contribution of ASD Subtypes and Prognosis.

**J. Portolese**<sup>1,2</sup>, **F. Franco**<sup>3</sup>, **F. Sumiya**<sup>4</sup>, **C. Santos**<sup>5</sup>, **P. Lourenço**<sup>5</sup>, **M. Colla**<sup>5</sup>, **L. Escudero**<sup>4</sup>, **M. Fondello**<sup>5</sup> and **H. Brentani**<sup>4</sup>, (1)Medical School, Sao Paulo, Brazil, (2)Clinical Hospital, São Paulo, Brazil, (3)University of Sao Paulo, BRAZIL, SÃO PAULO, Brazil, (4)University of Sao Paulo, BRAZIL, São Paulo, Brazil, (5)University of Sao Paulo, BRAZIL, Sao Paulo, Brazil

---

**Background:** Autism Spectrum Disorders (ASD) manifest in early stages of development. The growing focus on the constellation of ASD behavior brings the complexity of the phenotype and associated behaviors and, therefore, great challenges for diagnosis, prognosis and therapeutic response. There is great heterogeneity in the phenotypic presentation of ASDs and severity of behavioral symptoms, determining great variability in the levels of adaptive functioning to activities of daily living, cognitive, clinical, psychiatric, neurological and emotional regulation comorbidities. Complex genetic architecture also contributes to phenotypic heterogeneity. In Brazil, in addition to the difficulty of training professionals, there is a lack of translated, adapted, standardized and validated instruments. This emphasizes the importance of early development of accurate methods. Well-characterized phenotypes are important in the search for these biological markers, allowing for more homogeneous groupings of patients, identifying as causes and being clinically useful in directing the intervention.

**Objectives:** Develop biological and phenotypic markers using eye tracking and multidisciplinary assessments, contributing to a definition of ASD subtypes and prognosis.

**Methods:** 150 children aged 0 to 17 years from the Institute of Psychiatry at FMUSP (Brazil). All children were followed up at the FMUSP Psychiatry Institute. The evaluation was performed by a psychiatrist according to the diagnostic criteria of the DSM-5. Screening scales (MCHAT, ASQ or ABC), CARS, Vineland, CBCL and SRS were applied with parents. The children were evaluated with the ADOS-2, WASI and eye tracking with the Tobii PRO equipment, according to the paradigms of biological movement, shared attention and shift in attentional focus. All data were collected in an electronic form and sent to a relational database.

**Results:** 1) Creation of a database of signals to monitor eye movements and typical development of Brazilian children with ASD. 2) Classification algorithm considering different types of input data (data from phenotypic scales, epidemiological signs and eye movement monitoring) and processing techniques together, to test whether the two types of data together increase accuracy to aid diagnosis and ASD subtypes.

**Conclusions:** Brazilian study to work on the development of biological, phenotypic and epidemiological markers, to contribute to the definition of ASD subtypes, prognosis, training and expansion in the national territory.

**509.038 (Virtual Poster)** Characterizing Cognitive Rigidity and Thought Disruption in Autism

**E. L. Reckner**, **S. Srinivas**, **L. D. Yankowitz**, **J. D. Herrington**, **R. T. Schultz** and **B. E. Yerys**, Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA

---

**Background:** Cognitive rigidity and thought disruption (CR) refer to the impaired capacity to sustain coherent discourse and maintain the organization and expression of thought. For autistic youth, these features are often collapsed into broader measures of repetitive behavior or executive functioning. This creates challenges for quantifying CR independently. Research in non-autistic clinical populations indicates that CR plays an important role in real world functioning; however, these relationships have been characterized incompletely in autistic youth. Characterizing CR independently from other related constructs will provide valuable insight in how this specific feature impacts the lives of autistic youth.

**Objectives:** To generate a measure of CR, characterize this feature in autistic youth, and examine its associations with adaptive behavior outcomes.

**Methods:** 46 autistic youth (ASD: mean age 11.8 years, 78.3% Male), and 31 typically developing youths (TD: mean age 12.3 years, 74.2% Male) were included in this secondary data analysis study. To create the CR score, relevant items were selected the following measures: Social Responsiveness Scale - 2<sup>nd</sup> Edition (SRS-2), Behavior Rating Inventory of Executive Function (BRIEF), Behavior Assessment Scale for Children - 2<sup>nd</sup> Edition (BASC-2), and the Child Behavior Checklist (CBCL). The nine items selected for inclusion in the novel CR score captured rigid thinking and cognitive inflexibility, while excluding items related to intense interests and behavior rigidity. Analyses included: 1) psychometric properties of our CR score (internal reliability and factorial validity), 2) testing for group differences in CR scores, 3) associations of CR with age and IQ, and 4) associations of CR with functional outcomes (The Vineland Adaptive Behavior Scales-2<sup>nd</sup> Edition (VABS-II)).

**Results:** Test of Cronbach's alpha revealed high internal reliability ( $\alpha=0.94$ ). All CR items sufficiently loaded onto one factor explaining 65% of the variance. Factor loadings ranged from 0.70-0.89. To generate the CR total score, items were summed, resulting in a possible score range from 0-18. The ASD group endorsed more CR than the TD group, and the effect was large (See Table 1). Among autistic youth, CR scores did not significantly correlate with age or IQ, but CR scores had moderate, significant correlations with Communication and Daily Living subscales (See Table 2).

**Conclusions:** This is the first study to show that autistic youth experience challenges specifically with CR, and that these challenges are associated with difficulties in adaptive functioning. These findings align with that of other clinical populations, providing additional evidence that CR may be a transdiagnostic feature. Psychometric analyses reveals that the novel CR measure is internally consistent and captures some latent construct of rigidity, however more rigorous analyses are needed to demonstrate scale validity. Data entry of item-level data is ongoing for an additional 259 participants and will be completed by the conference, allowing for a robust evaluation of psychometric properties of CR. Our current analysis supports further investigation of CR as distinct from other repetitive features of autism and identifies CR as a potential mutable factor that could be targeted as part of an adaptive behavior intervention designed to support the independence of autistic youth.

**509.039 (Virtual Poster)** Concurrent Validity of the Brief Observation of Symptoms of Autism (BOSA)

**J. M. Wolff<sup>1</sup>, C. C. Cukar-Capizzi<sup>1</sup>, M. E. Johnson<sup>2</sup>, C. E. Finn<sup>3</sup>, L. M. Pisani<sup>1</sup>, C. Stevens<sup>4</sup>, M. A. Azu<sup>1</sup>, C. J. Franke<sup>1</sup>, R. Iqbal<sup>1</sup>, G. T. Han<sup>1</sup>, A. Naples<sup>1</sup> and J. McPartland<sup>4</sup>,** (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Child Study Center, Yale University, New Haven, CT, (3)McPartland Lab - Yale Child Study Center, Yale School of Medicine, New Haven, CT, (4)Child Study Center, Yale Child Study Center, New Haven, CT

**Background:** The Autism Diagnostic Observation Schedule, 2<sup>nd</sup> Edition (ADOS-2; Lord et al., 2012) is considered the “gold standard” observational measure in the diagnostic assessment of autism spectrum disorders (ASD). However, the COVID-19 pandemic has presented challenges to diagnostic assessment, as the ADOS-2 cannot be validly administered when examiner/examinee faces are obscured by masks. In response to this challenge, Lord et al. (2020) developed the Brief Observation of Symptoms of Autism (BOSA), an observational measure that can be administered through pandemic-friendly procedures (e.g., observation of parent-child interactions through a one-way mirror). Activities and coding procedures for the BOSA were derived from the ADOS-2 and the Brief Observation of Social Communication Change (BOSCC; Grzadzinski et al., 2016). Although the BOSA was widely adopted by ASD assessment clinics and research programs to meet pandemic-related challenges, limited research has evaluated its validity.

**Objectives:** To assess the validity of the BOSA in relation to established measures of social communication.

**Methods:** 191 participants with an existing diagnosis of ASD were administered the ADOS-2 Module 3 or 4 (pre-pandemic, without mask restrictions; N=152) or the BOSA Module F1 or F2 (coded on ADOS-2 Module 3 or 4; N=51). 12 of these participants received an ADOS-2 pre-pandemic and a subsequent BOSA; 21 received two ADOS-2 administrations prior to pandemic protocols (mean time between administrations: 51.56 and 52.56 months, respectively). Participants were administered additional social communication measures, including the Social Responsiveness Scale-2<sup>nd</sup> Edition (SRS-2), the Autism Diagnostic Interview-Revised (ADI-R), and the Vineland Adaptive Behavior Scales-3<sup>rd</sup> Edition (Vineland-3). Participants receiving the BOSA were also administered the Childhood Autism Rating Scale-2<sup>nd</sup> Edition (CARS-2).

**Results:** The BOSA algorithm total was significantly correlated with the CARS-2 T-score (Module 3:  $r(12)=-.68$ ,  $p=.008$ ; Module 4:  $r(34)=-.74$ ,  $p<.001$ ) but was not correlated with any other social communication measures. The ADOS-2 comparison score (CSS), in contrast, was significantly correlated with the ADI-R Reciprocal Social Interaction ( $r(109)=.22$ ,  $p=.021$ ) and Communication ( $r(109)=.26$ ,  $p=.005$ ) domain totals, and the Vineland-3 Communication ( $r(112)=-.19$ ,  $p=.049$ ) and Socialization ( $r(112)=-.20$ ,  $p=.034$ ) domain standard scores. The BOSA Module 4 did not correlate with ADOS-2 CSS administered at a prior timepoint ( $r(7)=.07$ , n.s.). However, the ADOS-2 CSS similarly did not correlate with the ADOS-2 CSS obtained at a previous timepoint ( $r(19)=-.004$ , n.s.).

**Conclusions:** The BOSA showed concurrent validity with another clinician-rated measure (CARS-2) but not with parent- or self-report measures of social communication. This is in contrast to the ADOS-2, which exhibited concurrent validity with several parent-report measures. Counter to predictions, neither the BOSA nor the ADOS-2 correlated with prior ADOS-2 administration, although results were limited by a small sample size. These findings suggest that the BOSA holds promise as a brief measure of ASD-related symptoms but may not be as robust a clinical measure as the ADOS-2. Additional research is needed to replicate these findings with a larger sample size and to expand the validity investigation to additional BOSA modules. BOSA validity should also be revisited when a cross-module BOSA comparison score, comparable to the ADOS CSS, has been developed.

**509.040 (Virtual Poster)** Discriminating Features of Autism through a Play Assessment Method - Inter Rater Reliability

**B. Kumarswamy<sup>1</sup>, P. Srikanthapuram<sup>1</sup>, V. Raman<sup>2</sup>, S. Rajagopalan<sup>3</sup>, A. Mysore<sup>4</sup> and A. Joseph<sup>1</sup>,** (1)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India., Bengaluru, India, (2)St.Johns Medical College Hospital, Bengaluru, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India., Bangalore, India, (4)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India

**Background:**

Autism Spectrum Disorder (ASD) assessments include professionals using interviews and observation schedules that require intensive training and are time consuming. Impairments in social interaction in children with ASD are observed as early as 12-24 months (Zwaigenbaum et al., 2015) but

ASD is not diagnosed before age 3 years (Bussu et al., 2018). Research has shown that play can be used to elicit early social behaviours (Dominguez et al., 2006). There is a need for ASD screening measures that are cost-effective, observational and culturally appropriate to the Indian context.

#### Objectives:

- To identify discriminating features of autism using a newly developed play behaviour protocol in toddlers
- To explore the inter-rater reliability of scoring such features using videos.

#### Methods:

For the pilot study, we recruited 12 children (4 children with ASD, 4 children with developmental delay and 4 Typically developing children) in the age ranges 12- 42 months and engaged them in structured and semi-structured play activities involving an examiner, parent and the child. 26 social behaviours and play behaviours categories were identified and defined. The session was video recorded with parental consent and coded for chosen play and social responses. We studied the distribution of those social and play responses across different stages of the play protocol for all three groups. Two trained psychologists independently coded a sample of three videos to establish inter-rater reliability. Concordance of ratings was recorded while Cohen's Kappa statistic was computed using SPSS version 26.

#### Results:

The most discriminating behaviours between the 3 groups was social smile, eye contact, initiation of social interaction and social engagement. TD children had frequent reciprocal social behaviours and this was not observed in DD and ASD children. Similar findings were reported by Zwaigenbaum et al., (2005) that children with ASD lacked social responsiveness and social engagement and these behaviours can be observed as early as 12 months. In terms of play skills, all 3 groups had similar frequency of sensorimotor play and functional play. Symbolic play was present in children with TD and DD. Although the mean age of children in the TD group was lower than that of the other two groups, they displayed more symbolic play. Similar findings were reported by Rutherford (2003) that deficits in symbolic play were specific to children with ASD. Cohen's Kappa statistic results indicate moderate agreement for ASD group ( $k = 0.552$ ,  $p=0.000$ ) and DD group ( $k= 0.447$ ,  $p= 0.000$ ) and substantial agreement for the TD group ( $k=0.624$ ,  $p=0.000$ ). The overall Cohen's Kappa statistic indicated moderate agreement ( $k= 0.554$ ,  $p=0.000$ ).

#### Conclusions:

The pilot study findings support discriminating validity of the play behaviour protocol. It has the potential to be a screening measure for autism.

#### **509.041** (Virtual Poster) Do ADHD Symptoms Accelerate Diagnostic Timing of Autism in School-Age Youth?

A. Khuu, L. Kenworthy, A. Verbalis and A. B. Ratto, Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC

Background: Autism spectrum disorder (ASD) is characterized by social communication difficulties and restricted and repetitive behaviors, whereas attention deficit/hyperactivity disorder (ADHD) is characterized by inattention, hyperactivity, and impulsivity.<sup>1</sup> Previous literature documents a strikingly high comorbidity rate, estimating 30-80% of autistic youth have a co-occurring diagnosis of ADHD.<sup>2</sup> Individuals with co-occurring ASD+ADHD are at significant risk for delayed ASD diagnosis, in part due to symptom overlap and diagnostic overshadowing from the presence of ADHD symptoms.<sup>2,4,6</sup> This is particularly true for youth first identified after the early intervention period.<sup>4</sup> Delayed identification of ASD poses risk for social and emotional difficulties.<sup>4</sup> As such, it is important to parse ADHD-specific symptoms to identify predictors of age of ASD diagnosis in individuals with co-occurring ASD+ADHD.

Objectives: To investigate whether ADHD symptoms (inattention and hyperactivity) predict age of ASD diagnosis in individuals with co-occurring ASD+ADHD who receive a first diagnosis of ASD after early childhood (age  $\geq 5$  years).

Methods: Archival data from a clinical database was extracted for 208 individuals with co-occurring ASD+ADHD seen for neuropsychological evaluation who received a first diagnosis of ASD after the age of 5 (76.0% male; 38.9% white). Age of ASD diagnosis ranged from 5 to 18.3 years ( $M = 9.97$ ). Full-scale IQ (FSIQ) ranged from 45 to 137 ( $M = 95.68$ ). Pearson correlations examined the relations between age of ASD diagnosis and a) sex-assigned-at-birth, b) FSIQ, c) ASD symptom severity (SRS total T-scores), and d) ADHD symptoms (ADHD Rating Scale subdomain T-scores). Hierarchical linear regressions further probed significant relations to determine whether specific ADHD symptoms predicted age of ASD diagnosis, after controlling for sex-assigned-at-birth, FSIQ, and ASD symptom severity.

Results: Age of ASD diagnosis was negatively correlated with hyperactivity,  $r(208) = -.159$ ,  $p=.022$ , such that increased hyperactivity symptoms were associated with earlier diagnosis. Age of ASD diagnosis did not have a significant association with inattention ( $r=.019$ ,  $p=.785$ ). A hierarchical linear regression model examined the association of hyperactivity with age of ASD diagnosis, after controlling for sex-assigned-at-birth, FSIQ, and ASD symptom severity. Increased hyperactivity,  $\beta = -.053$ ,  $t = -2.84$ ,  $p=.005$ , significantly predicted earlier age of ASD diagnosis. For every one-point increase in hyperactivity T-score, age of ASD diagnosis decreased by approximately 0.053 years.

Conclusions: Hyperactivity predicts age of ASD diagnosis in individuals with co-occurring ASD+ADHD who have not yet been diagnosed by the age of 5. Findings suggest youth with more hyperactivity are being diagnosed with ASD earlier, despite concerns about symptom overlap and diagnostic overshadowing putting youth with ASD+ADHD at risk for delayed ASD diagnosis. It is possible that increased hyperactivity elevates

familial distress about symptoms or raises the salience of a developmental disorder for teachers, who serve as a primary source of referral for further assessment for the school-age youth who comprise our sample. These youth also may have failed initial treatments for ADHD, bringing them to additional clinical attention. In turn, findings suggest youth with co-occurring ASD+ADHD without significant hyperactivity may be at greater risk for delayed ASD diagnosis.

## VIRTUAL POSTER SESSION — DIAGNOSTIC, BEHAVIORAL & INTELLECTUAL ASSESSMENT

### 518 - Diagnostic, Behavioral & Intellectual Assessment II --- (V)

**518.081** (*Virtual Poster*) Mealtime Problem Behaviors in Italian Children with Autism Spectrum Disorders: Insights into the Role of Sensory Atypicalities Assessed with the Italian Child Sensory Profile 2

**I. Basadonne<sup>1</sup>, J. Frinzi<sup>2</sup>, M. Proserpi<sup>3</sup>, R. Nencioi<sup>2</sup>, V. Passani<sup>2</sup>, S. Isoli<sup>2</sup>, F. Zuccolo<sup>3</sup>, R. Atzei<sup>4</sup>, P. Venuti<sup>5</sup>, L. Zoccante<sup>1</sup> and R. Tancredi<sup>2</sup>,**  
(1)Department of Psychology and Cognitive Science, University of Trento - Italy, Rovereto, Italy, (2)IRCCS Stella Maris Foundation, Pisa, Italy, (3)Child Neuropsychiatry Unit, AOUI Verona, Verona, Italy, (4)NPM Bambini in Movimento SCS, Firenze, Italy, (5)Department of Psychology and Cognitive Science, University of Trento, Rovereto, Italy

**Background:** Mealtime is crucial for the child's development due to its impact on nutritional state and weight, on autonomy acquisition, and on experiencing rewarding social relationships. Since children with Autism Spectrum Disorders (ASD) often show mealtime problem behaviors, a dedicated assessment tool has been developed, the Brief Autism Mealtime Behavior Inventory (BAMBI). As sensory peculiarities often characterize the functional profile of ASD children, a possible impact on mealtime problem behaviors has been studied, but which sensory patterns are specifically implicated is still under debate. Moreover, since a cultural influence on sensory patterns must be taken into account, tools standardized on study population are needed. Thanks to the recent standardization of the Child Sensory Profile 2 (SP-2) on the Italian population, sensory atypicalities can now be studied also in Italian ASD children.

**Objectives:** The purpose of this study was to explore if specific sensory patterns and sensory channels, as conceptualized and measured by the Child SP-2, are associated with mealtime problem behaviors in Italian children with ASD.

**Methods:** Parents of 40 ASD children aged 3-7 years (mean age 4.88 years  $\pm$  1.10, 34 males and 6 females), completed the Child SP-2 and the BAMBI. Spearman correlation was calculated between sensory patterns/sensory sections and BAMBI total score. A linear regression model with BAMBI total score as the dependent variable and sensory patterns as independent variables was tested. Moreover, a linear regression model for the BAMBI total score was explored with the sensory sections as independent variables. A stepwise procedure was run on both regression models. A Bonferroni correction for multiple comparisons was applied to all analyses.

**Results:** 73% of the participants had at least one sensory pattern and 70% at least one sensory section with a higher than normal score. 22 children resulted as problematic feeders according to BAMBI cut-off score ( $\geq 34$ ). The patterns Sensitivity ( $p < 0.0001$ ) and Seeking ( $p = 0.004$ ) correlated positively with the BAMBI total score. Sensitivity was the only independent variable significantly related to the BAMBI total score in the corresponding reduced model ( $p < 0.00001$ ). The BAMBI total score also correlated positively with the sensory sections Touch ( $p = 0.01$ ) and Oral ( $p < 0.0001$ ), the latter being the only variable included in the reduced model ( $p < 0.00001$ ).

**Conclusions:** As expected, most ASD participants showed sensory atypicalities and mealtime problem behaviors. High Sensitivity and Oral processing scores were associated with worse mealtime behavior. Sensitivity is characterized by a low sensory threshold and a passive attitude of the child, which does not help preventing sensory overload. Thus, problem behaviors could be the expression of this discomfort. Moreover, mealtime is rich in oral stimuli, therefore oral sensory atypicalities can plausibly be related to greater discomfort and problem behaviors. A better understanding of the impact of sensory pattern on mealtime behaviors can lead to a deeper reflection on the characteristic of the sensory stimulation during mealtime and refine the intervention in this direction to reduce problem behaviors and boost the child's and caregivers' wellbeing.

**518.082** (*Virtual Poster*) Objective Measurement of Gaze and Social Smile in Children with Suspected Autism Spectrum Disorder during Autism Diagnostic Observation Schedule-2

**Y. A. Ahn<sup>1</sup>, J. M. Moffitt<sup>1</sup>, Y. Tao<sup>2</sup>, S. Custode<sup>1</sup>, A. L. Beaumont<sup>2</sup>, S. M. Cardona<sup>1</sup>, M. Parladé<sup>1</sup>, J. Durocher<sup>2</sup>, M. N. Hale<sup>3</sup>, M. Alessandri<sup>3</sup>, L. K. Perry<sup>1</sup> and D. S. Messinger<sup>3</sup>,** (1)Psychology, University of Miami, Coral Gables, FL, (2)University of Miami, Miami, FL, (3)University of Miami, Coral Gables, FL

**Background:** Autism spectrum disorder (ASD) is defined in part by persistent disturbances of social communication and interaction, such as eye contact (i.e., social gaze) and facial expressions (e.g., shared smiles). Current best practice for measuring children's ASD symptom severity is based on expert, but subjective, clinician observation during the Autism Diagnostic Observation Schedule-2 (ADOS-2; Lord et al., 2012). Objective, automated processing of children's gaze behaviors from videos captured with economical recording sensors has the potential to provide quantifiable measures for key behavioral features of ASD during clinical assessments. The current study examined associations between objective measurement of children's gaze behaviors and ASD symptom severity during the ADOS-2.

**Objectives:** To investigate associations between objectively quantified gaze behaviors (i.e., social gaze and gaze involving smile) measured with a low-cost adult-worn video camera and examiner-adjudicated ADOS-2 SA calibrated severity scores (CSS).

**Methods:** Sixty-six children (49 boys,  $M_{age}=39.97mo$ ,  $SD=10.58$ ) with suspected ASD (61 confirmed ASD) were administered the ADOS-2. A hypothesis-blind examiner provided a Social Affect calibrated severity score (SA CSS). Children's gaze and gaze involving smile directed toward adults during the assessment were recorded with a small camera (Pivothead or Orca) contained in eye-glasses worn by the examiner and parent. We processed first-person video from the camera with a gaze detection algorithm (Chong et al., 2020) and FACET's facial action unit detection algorithm (Littlewort et al., 2011; iMotions, 2016) to automatically detect child gaze and gaze involving smiles. Measures included the duration of gaze expressed as proportions of ADOS-2 duration and proportion of that gaze duration involving smiles.

**Results:** There were negative associations between the proportion of gaze at parent and SA CSS ( $r = -.32$ ,  $p = .01$ ). SA CSS was also negatively associated with the proportion of gaze involving smile directed toward parent ( $r = -.34$ ,  $p = .01$ ) and the proportion of gaze involving smile directed toward examiner ( $r = -.29$ ,  $p = .02$ ). The proportion of gaze at parent ( $b = -.29$ ,  $t(55) = -2.40$ ,  $p = .02$ ) and the proportion of gaze toward parent that involved smiling ( $b = -.37$ ,  $t(55) = -3.09$ ,  $p = .003$ ) significantly predicted variance in the SA CSS ( $F(2,55) = 9.53$ ,  $p < .001$ , adjusted  $R^2 = .23$ ).

**Conclusions:** The current study examined associations between objective measures of child gaze and smile behaviors (i.e. social gaze and gaze involving smiles) during the ADOS-2. Children who demonstrated more gaze toward parent and whose gaze involved more smiles tended to receive lower SA symptom severity scores. The objective measurement of key behavioral features of ASD appears to have the potential to produce quantitative indices of ASD symptoms.

**518.083 (Virtual Poster)** Problematic Internet Use Among Adolescents with Autism: Analyzing the Psychological Motives for Using the Internet  
**R. Cardillo<sup>1</sup>**, C. Marino<sup>2,3</sup>, C. Orefice<sup>2</sup> and I. C. Mammarella<sup>2</sup>, (1)Department of Developmental and Social Psychology, University of Padova (IT), Padova, Italy, (2)Department of Developmental and Social Psychology, University of Padova, Padova, Italy, (3)Division of Psychology, School of Applied Sciences, London South Bank University, London, United Kingdom

---

**Background:**

It has been shown that individuals with Autism Spectrum Disorder (ASD) are engaged in internet use to higher extent than their peers without ASD (Mazurek & Engelhardt, 2013), being at higher risk of Problematic Internet Use (PIU) (Murray et al., 2021; Normand et al., 2021). However, only few recent studies have compared samples with ASD and peers with Typical Development (TD) in their PIU levels, yielding contradictory results (MacMullin et al., 2016; Shane-Simpson et al., 2016; Umeda et al., 2019).

Previous studies revealed that problematic online behaviors are likely to be driven by relevant psychological motives among youths (Marino et al., 2018). However, no study, so far, has explicitly analyzed the psychological motives for using the Internet expressed by adolescents with ASD as compared to TD peers.

**Objectives:**

The present study aims to examine the levels of PIU in children and adolescents with ASD compared with a matched TD group. The motivations for Internet use will be investigated, in order to highlight similarities and differences between groups. The relationships between PIU, psychological motives, ASD symptoms, and loneliness/social dissatisfaction will be also considered.

**Methods:**

A total of 140 Italian children and adolescents (ASD group with no ID=70 (62 M); matched TD group = 70 (62 M); aged 8-18 years; mean age=13.5 years,  $SD=2.95$  years; no difference between groups in the Full Scale Intelligence Quotient ( $F(1, 138)=.98$ ,  $p=.32$ )) were recruited. Self-reports on the Internet use, psychological motives, loneliness/social dissatisfaction were administered. Participants in the ASD group received a clinical diagnosis following the DSM-IV-TR or ICD-10 criteria and they had also scored above the threshold for ASD in the Autism Diagnostic Interview-Revised (ADI-R; Rutter, Le Couteur, & Lord, 2005). Data were analyzed using R (R Core Team, 2015). First, a series of univariate ANOVAs were performed in order to highlight similarities and differences between ASD and TD groups. Second, correlation analyses were conducted to test for the associations among the variables of interest.

**Results:**

The levels of PIU were similar in the two groups  $F(1, 138)=.26$ ,  $p=.61$ . A different pattern of psychological motives for using the Internet emerged for adolescents with ASD as compared to the TD. Higher scores for enhancement  $F(1, 138)=19.99$ ,  $p<.001$ , coping  $F(1, 138)=8.26$ ,  $p=.005$ , and conformity  $F(1, 138)=4.26$ ,  $p=.04$  motives emerged in the former, while higher scores for social motive were found in the latter  $F(1, 138)=4.04$ ,  $p=.04$ . Interestingly, for the ASD group a positive correlation between repetitive behaviors/interests (ADI-R) and conformity ( $r=.312$ ,  $p=.008$ ) and a negative correlation between loneliness/social dissatisfaction and enhancement motivation ( $r=-.253$ ,  $p=.034$ ) emerged.

**Conclusions:**

Overall, our findings show similar levels of PIU in both ASD and TD groups. However, different psychological motivations for Internet use characterize the experiences of the two groups. In addition, repetitive behaviors/interests and loneliness/social dissatisfaction are associated with specific motivations. The clinical and preventive implications of these findings are discussed.

**518.084** (Virtual Poster) Stress Physiology: Cross-Sectional Comparison between Adolescents on the Autism Spectrum and Typically Developing Peers

**A. Thoen**<sup>1,2</sup>, **K. Alaerts**<sup>2,3</sup>, **J. Steyaert**<sup>2,4,5</sup> and **T. Van Damme**<sup>1,2,5</sup>, (1)Department of Rehabilitation Sciences, Research group Adapted Physical Activity and Psychomotor Rehabilitation, KU Leuven, Leuven, Belgium, (2)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium, (3)Rehabilitation Sciences, KU Leuven, Leuven, Belgium, (4)Center for Developmental Psychiatry, KU Leuven, Leuven, Belgium, (5)Child Psychiatry, Expertise center Autism, UPC Z.Org KU Leuven, Leuven, Belgium

---

**Background:** Lower cardiac vagal modulation has been found in individuals on the autism spectrum as compared to control groups. These lower levels have been associated with higher levels of autism-specific symptoms as well as more internalizing symptoms. However, methodological shortcomings in previous research prohibit the formulation of firm conclusions. Therefore, further research has been recommended.

**Objectives:** Research about this topic in adolescents on the autism spectrum is scarce. Therefore, the presented cross-sectional data comparisons provide more insight into differences in autonomic functioning between adolescents on the autism spectrum and their typically developing peers. To overcome some of the methodological shortcomings of prior research, a standardized stress-provoking protocol is used.

**Methods:** An age and gender matched group of adolescents on the autism spectrum (n=38) and typically developing peers (n=38) is included in this cross-sectional study, based on an a priori power-analysis with a medium effect size (g=0.59). A standardized stress-provoking protocol is used which contains a baseline measurement and the 'Stroop Word-Color Interference task' and the 'Social Stress Recall Task' as stress-provoking tasks. Physiological data is continuously gathered using the NeXus-10 MKII biofeedback device and Biotrace+ Software to register heart rate, breathing frequency, fingertip temperature and skin conductance. Saliva samples are collected to determine the level of cortisol at three time points during the assessment, reflecting the cortisol level at baseline and after both stress-provoking tasks. Behavioral data on physical activity, autism symptoms and internalizing and externalizing behavior is collected using questionnaires. Cardiac vagal modulation is used as the primary outcome measure to test the hypothesized aberrant levels of cardiac vagal modulation in adolescents on the autism spectrum. Additional physiological and behavioral parameters as well as cortisol measurements are included as secondary outcome measures to evaluate whether aberrant cardiac vagal modulation is associated with clinical and behavioral indices. A combination of Kubios HRV Premium (version 3.4.3, University of Eastern Finland, Kuopio, Finland), researcher-developed scripts in MATLAB R2020b (MathWorks, Natick, Massachusetts, USA) and SPSS (IBM SPSS Statistics, version 27) will be used for preprocessing and statistical analyses. A repeated-measures ANOVA with group (adolescents on the autism spectrum versus typically developing peers) as between-group factor will be used on the primary outcome measure. Pearson correlation analysis will be performed to examine correlations between the primary outcome measure and secondary outcome measures.

**Results:** The results of this cross-sectional study will be presented in line with the hypotheses as mentioned in the methods-section as data-collection is still on going.

**Conclusions:** More conclusive evidence will be provided for the hypothesized presence of aberrant cardiac vagal modulation during baseline measurement and the stress-provoking tasks in adolescents on the autism spectrum. In addition, the hypothesized association between these aberrant values of cardiac vagal modulation and physiological and behavioral indices will be clarified.

**518.085** (Virtual Poster) Synchrony Influences Intra-Individual Context-Related Social Communication in Minimal-Verbal Children with Autism  
**J. Kitzerow**<sup>1</sup>, **C. Lemler**<sup>2</sup>, **S. K. Kleber**<sup>2</sup>, **Z. Kim**<sup>2</sup>, **K. Teufel**<sup>2</sup> and **C. M. Freitag**<sup>2</sup>, (1)Autism Research and Intervention Center of Excellence Frankfurt, University Hospital Frankfurt; Department of Child and Adolescent Psychiatry, Frankfurt, Germany, (2)Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany, (3)Autism Research and Intervention Center of Excellence Frankfurt, Dept. Child and Adolescent Psychiatry, Psychosomatics & Psychotherapy, Goethe-University Frankfurt, Frankfurt, Germany

---

**Background:** Standardized *child-clinician* interaction has been established as part of the gold standard of the Autism Spectrum Disorder (ASD) diagnostic procedures. Blinded ratings of *child-clinician* interaction also have been recommended to establish the generalization of intervention effects. In addition, several measures of *child-parent* interaction have been proposed as valid outcome measures of clinical trials. A key methodological issue is the comparability of *child-clinician* or *child-parent* interaction measures. Parental synchrony has been found as relevant mediator of autism-symptom change and shows great variability across parents. In contrast clinician synchrony and its influence on child behavior has not been investigated yet. To date only a few studies have directly compared autism-symptom scores in different settings with different interaction partners, and none of these studies investigated a possible influence by the interaction partner's behavior, i.e. the responsiveness to the child.

**Objectives:** To explore intra-individual symptom differences across 4 different contexts (parent-child free play, play sessions and more standardized settings with unknown clinician) and examine the possible influence of the degree of synchronous behavior of the interaction partner.

**Methods:** A subsample of the A-FFIP randomized controlled, multi-center early intervention study was included (Kitzerow et al. 2020). Cross-sectional baseline data of the first N = 28 minimally verbal children, aged 2.5-5.5 years old are reported. The coding system from the *Brief Observation of Social Communication Change* for minimally verbal children (BOSCC MV, WPS publishing) was applied to four different standardized 12-minute video scenes: parent-child free play, BOSCC play session (with unknown clinician), Autism Diagnostic Observation Schedule (ADOS-2, unknown clinician), and Early Social Communication Scales (ESCS, unknown clinician). Synchronous behavior of the interaction partner was coded according to the *Dyadic Communication Measure for Autism – Revised* (DCMA). Three models with the BOSCC scores as dependent variable were compared by linear mixed models, model 1: main effect of setting; model 2: main effects of setting and synchrony; model 3: main and interaction effects of setting and synchrony. The most parsimonious model was chosen.

Results: For the BOSCC social communication subscale (SC) the third model explained the most variance ( $R^2=.28$ ;  $\chi^2=8.73$ ,  $p=.03$ ). A main effect for synchrony ( $F_{(1/95.6)}=37.78$ ,  $p<.001$ ) and an interaction effect of setting x synchrony ( $F_{(3/79.8)}=2.85$ ,  $p=.04$ ) was observed. For the BOSCC repetitive behavior subscale (RRB) models 2 & 3 were not superior to model 1 ( $\chi^2=0.17$ ,  $p=.68$ ;  $\chi^2=2.17$ ,  $p=.54$ ). Modell 1 showed a significant main effect of the setting ( $F_{(3/81)}=5.15$ ,  $p=.003$ ), which explained 7.7% of the variance. More details of the effects are presented at the conference.

Conclusions: Synchronous behavior of the interaction partner seems to have a great influence on the situational child's social communicative behavior. In contrast, restrictive, repetitive behaviors differed according to the setting and independent of synchrony. Context and interaction partner should sensitively be chosen according to the relevant research question. The degree of synchrony might be instructed in a more standardized way and additionally be assessed to ensure comparability.

**518.086 (Virtual Poster)** Validity and Acceptability of the Telehealth Autism Diagnostic Assessments (TADA) for Adults

**H. Rea<sup>1</sup>, S. J. Webb<sup>2</sup>, S. Murray<sup>3</sup> and E. C. Kurtz-Nelson<sup>1</sup>,** (1)Center for Human Development and Disability, University of Washington Psychiatry and Behavioral Sciences, Seattle, WA, (2)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (3)Psychology, University of Washington, Seattle, WA

Background: Research and clinical need for autism (ASD) diagnostic assessments for adults was exacerbated by the transition to telehealth during the COVID-19 pandemic (Hus & Lord, 2014). Early shifts to telehealth (e.g., TELE-ASD-PEDS; Wagner et al., 2020) and in-person assessments that utilized parents as administrators (e.g., BOSA; Lord et al., 2020) have been identified as feasible alternatives to the gold-standard ADOS-2 for young children. However, there are no fully remote options for adults who reside alone or are unable to complete assessments with others. Telehealth assessments may be particularly useful for adults with ASD, as these visits are more accessible to remote populations (Reese et al., 2013), occur in relatively comfortable, predictable, and consistent environments, and are more resource efficient (Lopez et al., 2018). Additionally, adults with ASD may feel relatively more comfortable in computer-based interactions, as suggested by elevated rates of screen-based media use among individuals with ASD (MacMullin et al., 2016).

Objectives: To assess the validity and acceptability of the Telehealth Autism Diagnostic Assessment (TADA) for adults, a semi-structured observational assessment of ASD based on the ADOS-2 (Lord et al., 2012).

Methods: Data collection is ongoing (n=50 projected), with preliminary report on 16 adults with ASD (18 to 30 years;  $M_{age}=23.4$ ; 7 females) who have completed the TADA and Childhood Autism Rating Scale 2<sup>nd</sup> Edition (CARS-2) via telehealth as well as the self-report SRS-2. Additionally, 7 participants have completed an in-person ADOS-2 Module 4. Participants were interviewed about their assessment experiences.

Results: Regarding feasibility, all participants reported that they could be their authentic selves during the TADA (16/16) and most believed the assessment was a good representation of their in-person interactions (13/16). Participants reported that some of their hand mannerisms could not be observed via telehealth as they were fidgeting under the table (8/16), but many appreciated the comfort of completing the assessment in their home (6/16). The TADA and ADOS-2 total scores were not correlated with the CARS ( $r=.40$ ,  $p=.14$ ;  $r=.08$ ,  $p=.87$ ) or the SRS-2 ( $r=-.210$ ,  $p=.513$ ;  $r=.198$ ,  $p=.706$ ). Two-way random ICCs for the in-person ADOS-2 and TADA were significant for the social affect scores (ICC = .808,  $p=.032$ ) and total score (ICC = .908,  $p=.006$ ), but not for the RRB scores (ICC = .535,  $p=.211$ ).

Conclusions: Test-retest reliability was better for the ADOS-2 and TADA social affect and total scores than it is for just the ADOS-2 (Janvier et al., 2021). A specific remote assessment for RRBs may be needed as some movements were out of view, although it is not clear these would have been captured by an in-person assessment. Based on participant interviews, self-report, interview questions related to RRBs should be considered. The CARS does not appear to be correlated with other ASD measures for adults via remote assessment. Feedback interviews about participant experiences provided significant guidance as to further development and modifications to remote adult autism measures.

**518.087 (Virtual Poster)** The DSM 5 Parent Interview on ASD - Preschool

**R. E. Nickel, OHSU, Eugene, OR**

Background: Obtaining information from parents or caregivers is a critical part of the diagnostic evaluation for autism spectrum disorder (ASD) in young children. There are few validated comprehensive interviews currently available for use with the families of young children. The Autism Diagnostic Interview-Revised (ADI-R) is widely used in research studies of children with ASD. Its length, however, makes it difficult to implement in clinical settings. The Toddler Autism Symptom Inventory (TASI) has recently become available and shows acceptable psychometric properties for 12-36 month olds (Coulter et al, 2021). Most diagnostic centers, however, continue to use structured interviews that are not normed or validated.

The DSM parent interview for ASD has been used regularly in a center-based diagnostic clinic for several decades, however, has not been formally studied (\_\_\_\_, 1988). It has been updated based on DSM 5 criteria and reformatted as a preschool form for use with community-based autism identification teams (\_\_\_\_, 2015, 2018). Questions are organized for each domain in both DSM 5 criteria. Each question is scored by checking Rarely, Sometimes or Often (R, S, O boxes). Boxes on the scoring form that indicate behaviors associated with ASD are shaded, for example, [Rarely]. In the past, domain scores and the interview rating were determined qualitatively and based on the authors experience and the information presented.

Objectives: Obtain preliminary data on the accuracy of a semi-quantitative scoring system for the DSM 5 Parent Interview on ASD – Preschool.

**Methods:** A semi-quantitative scoring system was developed to assist with scoring of interview domains and in part to address the needs of teaching use of the interview to trainees. In the current pilot project, the scores generated by the new scoring system were compared with qualitative domain and interview scores generated in diagnostic clinics by different experienced examiners. Clinical staff made copies of each DSM interview scored in clinic and shared copies with research staff. Research staff scored each interview with the new semi-quantitative scoring system and compared those scores with the interview scores determined in clinic and compared both scores with clinical diagnoses.

**Results:** 30 DSM 5 interviews have been scored in clinic and now scored by the new domain scoring system. Domains rated as likely or probably meeting criteria for ASD by the new scoring system were considered positive for ASD. Ages ranged from 19 to 57 months. 23 interviews were rated positive for ASD by clinical staff and 7 interviews were scored as negative. The new scoring system agreed with clinical scoring for all interviews and all save 4 domains (B1, B4, B4 and A2) which did not affect the interview scores. The rating for all interviews agreed with the clinical diagnosis (ASD or not) save one time. Clinical staff considered this child probably to have ASD and recommended re-evaluation.

**Conclusions:** Preliminary data support the accuracy of the semi-quantitative scoring system for the interview which may prove to be especially helpful in training programs. Further research is necessary.

**518.088 (Virtual Poster)** The Impact of Gender and “Disruptive” Behaviors on Identification of Autism Spectrum Disorder  
**J. Bisson<sup>1</sup>, R. Obeid<sup>2</sup>, S. Saade<sup>3</sup>, A. J. Harrison<sup>4</sup>, B. Kofner<sup>5</sup> and K. Gillespie-Lynch<sup>6</sup>,** (1)Clemson University, Clemson, SC, (2)Case Western Reserve University, Cleveland, OH, (3)American University of Beirut, Beirut, Lebanon, (4)Educational Psychology, University of Georgia, Athens, GA, (5)CUNY, NY, NY, (6)Department of Psychology, College of Staten Island, City University of New York, Staten Island, NY

---

#### Background:

Autism has historically been described as a male condition (Asperger, 1944). Autistic females are often diagnosed late or not at all (Goldman, 2013). Autistic traits may be more accepted in males (Cola et al., 2020) and clinicians may not recognize autism in women. Autistic women may exhibit more withdrawn behaviors relative to autistic men, who may exhibit more “disruptive” behaviors (Barglia et al., 2016). Educators more accurately identified autism in vignettes depicting a more “disruptive” vs a more “withdrawn” child and when the vignette character had a male rather than a female name (Whitlock et al., 2020). We evaluated if similar biases are observed among a larger sample of university students (who have less experience with children).

#### Objectives:

Examine whether males are rated more likely to be autistic than females despite the same behaviors. Explore whether “disruptive” or “withdrawn” characteristics of autism are associated with greater autism identification.

#### Methods:

960 participants from five universities participated in a 2 (vignette type: “withdrawn” vs “disruptive” behaviors) x 2 (character gender: male vs female name) between-subjects design. Participants read one of two vignettes depicting an autistic individual displaying either “disruptive” or “withdrawn” behaviors. Half of the participants read a vignette with a male character and half of the participants read a vignette with a female character. They rated the likelihood (Very Unlikely - 1 to Very Likely - 5) that the character had each of several diagnoses and/or characteristics (e.g., ASD, shy, etc.). They also wrote in responses for the following question: “What condition or disorder do you think this child has, if any?” Responses were coded into the diagnoses and characteristics mentioned above.

#### Results:

Two-way ANOVAs compared ratings based on vignette type and character gender (Table 1). Participants were more likely to rate a character as having ASD when the character presented “disruptive” (as opposed to “withdrawn”) behaviors. Participants rated the “disruptive” character as more disruptive yet more likely to be accepted, more likely to have: ADHD, LD, ODD, and CD, and less likely to: be “typically developing” or shy and to have anxiety or depression. Male characters were rated more likely to have CD, ADHD and ODD. No interactions between character gender and vignette were observed.

Logistic regressions were used to compare open-ended responses based on vignette type and character gender (Table 2). Participants reported significantly more ASD and ADHD for the “disruptive vignettes” and more anxiety and shyness for the “withdrawn” vignettes. Males were rated more likely to have ADHD.

#### Conclusions:

Findings extend upon prior work with educators (Whitlock et al., 2020) by showing that the tendency to overlook more “withdrawn” characteristics of autism is present among students who have likely received little education about autism. This suggests a possible bias in preventing autistic females from obtaining needed evaluations and services. Furthermore, findings suggest that the underidentification of females may be extended to other diagnoses. In ongoing work, we are examining if implicit biases contribute to the explicit biases documented here.

#### Background:

There is strong consensus that early, specialized intervention for children with Autism Spectrum Disorder (ASD) can have a profound impact on outcomes, and a concurrent rise in autism prevalence and screening rates has led to an increase in the number of children accessing ASD-specific early intervention. With large numbers of children engaging in early intervention services, it is important to have tools that can quickly and accurately measure behavior change to track developmental gains or regressions and assess the efficacy of intervention. The 118-item Parent Interview for Autism (PIA; Stone and Hogan, 1993), and its condensed version, the 93-item Parent Interview for Autism-Clinical Version (PIA-CV; Stone et al., 2003), are parental-report measures that were developed out of the pressing need for instruments to document behavioral change in young children with ASD in research and clinical settings. The PIA-CV provides information about the presence and severity of ASD symptomatology across 11 behavioral rationally derived domains and has been shown to have strong psychometric properties for children under the age of three (Stone et al., 2003). The four domains of social relating, language understanding, nonverbal communication, and imitation comprise the social communication section, which has been used as a stand-alone measure and has been shown to be sensitive to change (Stone et al., 2003). However, the construct validity of this shortened version has not yet been examined.

**Objectives:** To examine whether a confirmatory factor analysis supports the four rationally derived PIA-CV domains comprising the social communication section.

**Methods:** Participants were 242 caregivers of children ranging in age from 16–35 months-old (Mean = 26.81, SD = 4.72) who completed the PIA-CV social communication section: social relating (17 items), language understanding (7 items), nonverbal communication (12 items), and imitation (4 items). The PIA-CV is scored using a 5-point Likert scale, ranging from 1 (“almost never”) to 5 (“almost always”). Item scores are summed to obtain total scores for each domain. Participant data from four different studies were included. The data were prepared for analysis using R software and the confirmatory factor analysis was performed using M-Plus.

#### Results:

Overall, summary CFA fit indices indicate support for the four rationally derived domains (Table 1). Item-level fit reveals that 13/17 (76%) of items in the social relating factor have good fit ( $>.70$ ); 7/7 (100%) of items in the language understanding factor have good fit ( $>.70$ ); 9/12 (75%) of items in the nonverbal communication factor have good fit ( $>.70$ ); and 4/4 (100%) of items in the imitation factor have good fit ( $>.70$ ). Table 2 includes a complete list of items and factor loadings.

**Conclusions:** A CFA revealed statistical support for the four rationally derived categories that comprise the social communication section, adding strength to the validity of the PIA-CV.

**518.090 (Virtual Poster)** Topography and Clinical Correlates of Restricted and Repetitive Behaviors in Autism Spectrum Disorder  
**M. Udhnani, S. Y. Kim and L. Lecavalier, Nisonger Center, The Ohio State University, Columbus, OH**

---

#### Background:

Repetitive and restricted behaviors and interests (RRBI) serve as one of the two core features of autism spectrum disorder (APA, 2013). There is general agreement on the multi-dimensionality of RRBI as well as the relationship between clinical correlates and subtypes of RRBI (Uljarevic et al., 2021). However, little is known about the prevalence of specific topographies within subtypes of RRBI and their association with key demographic and clinical variables.

#### Objectives:

The current study investigated the prevalence of specific RRBI topographies and domains, and their association with key demographic and clinical variables (i.e., age, gender, IQ, social communication, adaptive functioning, and behavior problems). We hypothesized great variability across specific RRBI topographies, as well as different relative prevalence and associations with demographic and clinical variables across gender.

#### Methods:

A large sample from the Simons Simplex comprising 2,757 children with ASD was used ( $M_{age} = 9$  years,  $SD = 3.6$ ; 86% male; 30% co-occurring intellectual disability [ID]). Prevalence of RRBI were calculated by the proportion of individuals who endorsed individual items as a *moderate problem* or a *severe problem* on the Repetitive Behavior Scale-Revised (RBS-R; Bodfish et al., 2000). The relationship between RRBI and demographic and clinical variables was examined with Chi Squares, correlations, and regression analyses.

#### Results:

Fifty-nine percent of the sample endorsed stereotyped behavior, 17% endorsed self-injurious behaviors (SIB), 48% endorsed compulsive behaviors, 65% endorsed ritualistic behaviors, 67% endorsed need for sameness, and 60% endorsed restricted interests. Rates of overall RRBIs did not differ across genders, with both demonstrating highest rates in need for sameness (M: 66%, F: 68%) and lowest rates in SIBs (M: 26%, F: 32%). The prevalence varied by IQ. The group with IQ > 70 reported highest rates in ritualistic behaviors (65%) whereas the group with IQ < 70 reported highest rates in stereotyped behaviors (75%). The most prevalent topography was *Fascination and preoccupation with a subject or activity* (52.4%), while the least common one was *Hits self with object* (2.8%). Topographies of all 43 RRBIs will be presented in a Figure by gender and IQ.

Some of the associations with key demographic and clinical variables follow. Age and gender were not significantly correlated with any of the RBS-R scales. IQ ( $r = -.33, p < .001$ ) and adaptive functioning ( $r = -.32, p < .001$ ) were negatively correlated with stereotyped behavior. Both social communication challenges and behavior problems were positively correlated with ritualistic behaviors ( $r = .33, r = .32$  [ $ps < .001$ ]) and need for sameness ( $r = .41, r = .39$  [ $ps < .001$ ]). Additional analyses will be presented.

#### Conclusions:

This is one of the only reports on the relative prevalence of specific RRBIs using a large and well-characterized sample of youth with ASD. There was great variability across specific RRBIs topographies. Different RRBIs, as well as their association with clinical variables, varied across level of functioning. Efforts at refining the behavioral phenotype will ultimately help to unravel the etiology of ASD.

**518.091** (Virtual Poster) Translation and Cultural Adaptation of the Malay Version of Social Responsiveness Scale Second Edition (SRS-2) N. F. Sulaiman<sup>1</sup>, S. Kamaralzaman<sup>2</sup>, A. N. Rauf<sup>3</sup>, F. B. Adnan<sup>3</sup>, K. Ilias<sup>4</sup>, H. Toran<sup>5</sup> and H. Harun Rasit<sup>6</sup>, (1)GENIUS Division, GENIUS Kurnia Centre, Kuala Lumpur, Malaysia, (2)Faculty of Health Sciences, Universiti Kebangsaan Malaysia, Kuala Lumpur, Malaysia, (3)GENIUS Division, GENIUS Kurnia, Kuala Lumpur, Malaysia, (4)Department of Psychology, Jeffrey Cheah School of Medicine and Health Sciences, Monash University Malaysia, Bandar Sunway, Malaysia, (5)Faculty of Education, Universiti Kebangsaan Malaysia, Bangi, Malaysia, (6)Regional Centre for Special Educational Needs, Southeast Asian Ministers of Education Organization, Melaka, Malaysia

---

**Background:** The Social Responsiveness Scale-Second Edition (SRS-2) is a 65-item self-rating scale designed to measure deficits in social behavior associated with autism spectrum disorder (ASD).

**Objectives:** The main objective of this study is to translate and cross-culturally adapt the original version (English) of Social Responsiveness Scale Second Edition (SRS-2) into a Malay version.

**Methods:** The adaptation process of the SRS-2 questionnaire was done on 50 parents in a school setting in the Klang Valley, Malaysia. This adaptation involved three phases: 1) translation and adaptation of the original Social Responsiveness Scale Second Edition (SRS-2), English version into Malay version 2) content validation and 3) pre-testing, which were cognitive interviewing and internal consistency.

**Results:** The Content Validity Index (CVI) showed a high agreement among expert reviewers which was relevant (CVI= 94.3%), simple (CVI=96.4%), clear (CVI=97.2%) and no ambiguity (CVI=97.2%). Through the pretest among 10 parents, 5 out of 65 items were mostly commented on and suggested for improvements. The total SRS-2 translated Malay Version subscale showed adequate and good internal consistency with Cronbach's Alpha 0.958.

**Conclusions:** The findings from the present study provided preliminary support for the psychometric properties of the SRS-2 Malay Version as a valid and reliable instrument to be used in Malaysia.

---

#### Background:

The diagnosis of Autism Spectrum Disorder (ASD) requires substantial clinical experience. The diagnostic decision is particularly difficult in the context of other disorders with behavioral symptoms in the domain of social interaction and communication, e.g. anxiety related disorders (ANX), attention deficit hyperactivity disorder (ADHD), or conduct disorder (CD). Observation measures such as the Autism Diagnostic Observation Schedule (ADOS) together with anamnestic information and further clinical information are currently the "Gold Standard" of clinical assessment.

#### Objectives:

Using machine learning methods we aimed to i) train specific models for the classification of ASD vs. differential diagnoses for improved sensitivity and specificity, and ii) to reveal item importance profiles of the specific models to identify those ADOS-items which are of particular relevance for the differential diagnostic decision of ASD versus ANX, ADHD, or CD.

## Methods:

We used a well-characterized clinical sample of individuals (n=1262) that had all received detailed outpatient evaluation for the presence of an ASD diagnosis (n=481) but also covered a range of additional differential or overlapping diagnoses (including ANX (n=100), ADHD (n=440), and CD(n=192)). We focused on ADOS module 3, covering the age range with particular high prevalence of such diagnoses. Using the clinical best estimate diagnosis of ASD as the target, we trained random forest models on ADOS single item scores in the context of specific differential diagnoses (i.e. ASD vs. ANX, ASD vs. ADHD, ASD vs. CD) and an unspecific model using all available data. We used nested cross-validation for parameter optimization (Bayesian tuning and averaging after 5 x 5 repeated cross-validation), training, and model evaluation (averaging of 10x5 repeated cross-validation) to calculate unbiased estimates of classification performance (ASD vs. non-ASD). To demonstrate the potential of this approach for translation into clinical practice, we programmed a web app ([https://msrlab.shinyapps.io/ml\\_beta\\_app\\_v3/](https://msrlab.shinyapps.io/ml_beta_app_v3/)) that allows for easy testing of our final models with ADOS item level data.

## Results:

We obtained very good overall sensitivity (0.89-0.94), specificity (0.87-0.89), and area under the receiver operant characteristic curve (ROC- AUC, 0.94-0.96). In particular for individuals with less severe symptoms (around the ADOS cut-off) our models showed increases of up to 20% in sensitivity or specificity in comparison to the ADOS-2 algorithm. Furthermore, we analyzed item importance profiles of the ANX-, ADHD- and CD-models in comparison to the unspecific model. These analyses revealed distinct patterns of importance for specific ADOS-items with respect to differential diagnosis (Fig. 1).

## Conclusions:

We could demonstrate, for the first time, the feasibility of constructing optimized models of ASD-classification in the context of specific differential diagnoses in a typical clinical population. This strategy may improve clinical decisions by utilizing the full range of information from comprehensive and detailed diagnostic observation such as the ADOS. Importantly, this might be of particular relevance for individuals with less severe symptoms that typically present a very difficult decision for the clinician.

**518.093 (Virtual Poster)** Using Smartphone-Recorded Vocalizations for Assistive Diagnoses of Children with Autism Spectrum Disorder  
D. Lehmann<sup>1</sup>, M. V. Marques<sup>1</sup>, W. L. Owotoki<sup>1</sup>, F. Oringe<sup>2</sup> and P. O. Owotoki<sup>1</sup>, (1)Vitafluence.ai, Kronberg im Taunus, Germany, (2)Kenyatta University, Nairobi, Kenya

---

**Background:** According to the world health organization 1-2% of the global population has autism spectrum disorder (ASD). Diagnosis and early intervention for children with ASD is crucial for their healthy development. However, diagnosis of children with ASD may not be feasible on a large scale, especially in countries with less developed medical infrastructure. In the last five years, many proof-of-concept scientific works, from both academia and industry, have shown the significant potential of Artificial Intelligence (AI). This study demonstrates the viability of such an approach. Non-invasive biomarkers, aim to distinguish typical from atypical development via objective methods, such as voice samples captured using a widely available digital device like a smartphone.

**Objectives:** Our goal was to provide a reliable tool that helps shorten the journey to a diagnosis of ASD. Providing diagnosis as early as possible would increase children's opportunities to have multidisciplinary interventions during the early stages of life. Several studies have shown the value of early intervention on outcomes for at-risk infants and their parents' quality of life experience on multiple levels.

**Methods:** After signing Informed Consent forms and with the help of legal guardian, voice samples were collected using an app on their own smartphones. To obtain the voice samples, participants were asked to name a set of pictures. Our cohort consists of N = 82 [25 ASD, 57 CTRL] children between the age of 2.0 and 16.0 (All: Min Age: 2.0, Max Age: 16.0, Mean Age  $\pm$  std: 7.43  $\pm$  3.44. ASD: Min Age: 3.0, Max Age: 16.0, Mean Age  $\pm$  std: 7.37  $\pm$  3.8. CONTROL: Min Age: 2.0, Max Age: 16.0, Mean Age  $\pm$  std: 7.46  $\pm$  3.26).

**Results:** Children with ASD showed a higher variability in their pitch spectrum. The pitch standard deviation in Hertz was 112.84  $\pm$  19.55 for children with ASD and 91.77  $\pm$  27.76 for controls (AUC: 0.71). The pitch spectra were binned into pitch histograms. The square root sum of squares of the pitch histograms represents a metric which is capable of distinguishing between ASD and CTRL with a ROC AUC of 0.77. Furthermore, we utilized machine learning techniques to combine several features obtained from the pitch histograms to further leverage the performance. The best machine learning models reached an ROC AUC of 0.80 (95% CI: 0.7599 - 0.8463) in a cross-validation setting.

**Conclusions:** Using the square root sum of squares of the pitch histograms, we created a metric to clearly discriminate the variability density estimation of the pitch of the vocalizations that can be used to indicate ASD. By combination of several metrics using traditional machine learning methods such as SVMs we can further improve the decision boundaries for diagnosis. Since our diagnosis system relies on self-reported voice samples recorded by smartphones, our approach has enormous potential in terms of scalability and is therefore a convenient option to pre-screen children for autism.

**518.094 (Virtual Poster)** Validating a the Counseling Center Assessment of Psychological Symptoms for Autistic College Students: A Step Toward Better Understanding of Mental Health

#### Background:

Autistic college students advocate for mental health services on campus from providers with experience with autism (Freedman, 2019). Nationally, many college counseling centers use the Counseling Center Assessment of Psychological Symptoms (CCAPS-62) to screen for mental health concerns when a student initiates services. However, this instrument is not validated for the autistic population. Also, little is known about the mental health challenges exhibited by autistic college students compared to non-autistic counterparts. A better understanding of experiences in mental health can lead to the design of more targeted interventions for the college autism community.

#### Objectives:

- Aim 1: Examine the internal construct validity of the CCAPS-62 for students on the autism spectrum
- Aim 2: Understand the mental health needs of college students with autism when compared to college students with other disabilities and no disabilities
- Aim 3: Explore predictors of mental health needs of autistic college students

#### Methods:

Aim 1: Autistic students (n=1268) were matched (3:1) with non-autistic students on race, gender, international status. A confirmatory factor analytic framework was used to conduct invariance testing of model fit by autism status. General model fit was assessed (Table 1) and invariance was established if there was a decrease of 0.01+ in CFI or increases of 0.01+ in RMSEA or 0.015+ in SRMR.

Aim 2: Descriptive analysis using t-tests and graphs were used to determine CCAPS subscale differences between the autism, other disabilities, and no disability groups.

Aim 3: Logistic regression was used to examine socio-demographic predictors of poor mental health outcomes in the autism group.

#### Results:

(see tables in image)

Aim 1: An 8-factor model displayed optimal fit (Table 1). The CCAPS displayed strong invariance (RMSEA of 0.000, a change in CFI of 0.0013 and a change of SRMR of 0.0005.)

Aim 2: Autistic students had higher scores in depression, general anxiety, family distress, frustration/anger, and social anxiety ( $p < 0.05$ ). Autistic students had similar scores in academic distress and eating concerns and lower scores in substance use. Compared to peers with other disabilities, autistic students had elevated scores in all subscales except academic distress and substance use.

Aim 3: Due to limitations with missing data, we were only able to examine trauma and sexual orientation as predictors. Table 2 highlights statistically significant odds ratios.

Following the analysis, the results were then shared with an autistic advisory group at the University of Delaware in order to discuss, interpret and consider implications and recommendations.

#### Conclusions:

The CCAPS-62 has evidence of internal construct validity. Counseling professionals and researchers may use the instrument to assess mental health in autistic college students. Higher levels of social anxiety and anger/frustration compared to other populations of college students suggests that colleges might consider targeted interventions in these areas for autistic college students, and incorporate stronger trauma-informed practices. Colleges should consider how their infrastructure contributes to increased social isolation and frustration among college students with autism and how this might be improved to promote inclusion on campus.

**518.095 (Virtual Poster)** The Anxiety Scale for Autism-Adults Is a Valid Tool for Autistic but Not Non-Autistic Cis-Gender Males and Females  
**H. L. Moore<sup>1</sup>, J. Rodgers<sup>2</sup> and S. A. Cassidy<sup>3</sup>,** (1)Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Population Health Sciences Institute, Newcastle University, Newcastle upon Tyne, United Kingdom, (3)School of Psychology, University of Nottingham, Nottingham, United Kingdom

---

#### Background:

High rates of anxiety are found in autistic adults. Previous research indicates that autistic people may experience different symptoms to non-autistic adults, and may interpret questions on anxiety questionnaires differently to non-autistic adults. Tools designed to assess anxiety in non-autistic people may, therefore, not be suitable for identifying anxiety in autistic individuals. An autism-specific measure of anxiety called the Anxiety Scale for Autism-Adults (ASA-A) has been proven reliable and valid for autistic adults, and cut-offs indicative of anxiety developed. However, research has not yet assessed whether the measurement properties are the same for males and females, nor for autistic and non-autistic individuals.

#### Objectives:

To assess the measurement invariance of the ASA-A for 1) autistic cis-gender males and females, 2) non-autistic cis-gender males and females, and 3) autistic and non-autistic adults.

#### Methods:

Autistic and non-autistic adults were recruited through volunteer databases and social media. Individuals who do not identify with their birth gender assignment may have a different mental health experience to cis-gender individuals, and sample size did not allow invariance in alternative gender identities to be explored, so cis-gender adults only were included in these analyses. Data were available for 342 autistic participants and 316 non-autistic participants. Among other measures relevant to the wider study, participants completed the ASA-A. The previously established bi-factor model was first tested using confirmatory factor analysis (Figure 1). Configural, metric, scalar, and residual measurement invariance were assessed using SPSS AMOS Version 27. Invariance was established through three measures of degradation of model fit: A nonsignificant change in chi-square compared to the configural model, a decrease in CFI of  $<.01$ , and a decrease in RMSEA of  $<.015$ . If invariance was found, then the next level was tested.

#### Results:

Confirmatory factor analysis established good model fit for the whole sample (CFI=.983, TLI=.978, RMSEA=.043, PCLOSE=.966), and both autistic (CFI=.965, TLI=.955, RMSEA=.049, PCLOSE=.581) and non-autistic adults (CFI=.966, TLI=.957, RMSEA=.052, PCLOSE=.356). Residual invariance was confirmed for both cis-gender autistic males and females ( $\Delta\text{CFI}=-.003$ ,  $\Delta\text{RMSEA}=.006$ ,  $\Delta\chi^2=68.494$ ,  $p>.05$ ), and also cis-gender non-autistic males and females ( $\Delta\text{CFI}=-.005$ ,  $\Delta\text{RMSEA}=.007$ ,  $\Delta\chi^2=61.902$ ,  $p>.05$ ). However, metric non-invariance was established between autistic and non-autistic adults ( $\Delta\text{CFI}=.014$ ,  $\Delta\text{RMSEA}=-.005$ ,  $\Delta\chi^2=141.516$ ,  $p<.001$ ). Exploration showed metric invariance on most items in the three-factor structure, but  $>50\%$  of item loadings on the general factor structure were non-invariant.

#### Conclusions:

The ASA-A is a suitable measure of anxiety in cis-gender autistic males and females, suggesting that the same clinical cut-offs can be used for both groups, and it can be used to compare the groups. However non-autistic adults did not respond to the ASA-A in the same way as autistic adults, suggesting (unsurprisingly) that this measure does not adequately capture anxiety for non-autistic adults. While the individual factors might be used with some modification for comparisons in research, the general factor is not appropriate to compare anxiety in autistic and non-autistic adults.

#### **518.096** (Virtual Poster) What Is the Concordance between Parent- and Teacher-Reported Adaptive Functioning in Autistic Children Using the VABS-II?

**H. L. Moore<sup>1</sup>**, A. Le Couteur<sup>2</sup>, T. Charman<sup>3</sup>, J. Green<sup>4</sup>, V. Grahame<sup>5</sup> and P. G. C. PACT-G Consortium<sup>6</sup>, (1)Newcastle University, Newcastle upon Tyne, United Kingdom, (2)Newcastle University, Newcastle Upon Tyne, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)University of Manchester, Manchester, United Kingdom of Great Britain and Northern Ireland, (5)Cumbria, Northumberland, Tyne and Wear NHS Foundation Trust, Newcastle upon Tyne, United Kingdom, (6)The University of Manchester, Manchester, United Kingdom

#### Background:

Autistic children often experience adaptive functioning difficulties, i.e. difficulties with the practical, everyday skills that an individual needs to meet the demands of their environment. Informant-report measures, such as the Vineland Adaptive Behaviour Scales-II (VABS-II) are frequently utilised. Autistic children may vary their behaviour depending on context, such as between home and school, and parent/teacher concordance rates in previous research have varied, from small-large correlations, as well as variation in who rated performance higher. Research is limited on lower ability autistic children, and it is not clear whether agreement at the domain level translates to similarities in reported behaviour at the item level. Differences could indicate behaviour varying by context or differences in understanding/perception of abilities.

#### Objectives:

Using a lower ability sample of autistic children, this study explored domain- and item-level concordance between parents and education professionals on the VABS-II, as well as patterns in reporting disparities.

#### Methods:

Data were available from 235 children, aged 3-11yrs, who took part in the Paediatric Autism Communication Trial-Generalised (PACT-G). The baseline characterisation data for this study includes VABS-II survey form (parent) and teacher questionnaire (Adaptive Behaviour Composite

(ABC), domains: Communication, Daily Living Skills (DLS), Socialisation, Motor Skills), as well as child ability measures of nonverbal ability, language, and autism severity. The education professional most familiar with the child completed the teacher VABS-II. To investigate domain level concordance, we compared means, and examined inter-rater reliability using ICCs. Linear regression enter method explored child factors that influenced the level of disagreement, calculated as the difference between parent and teacher VABS-II ABC/domain scores. There were 165 identical (or near identical) parent and teacher VABS-II items (43% of parent items and 74% of teacher items), and we compared item level concordance using weighted kappa cross-tabulations for non-unique raters, with simes correction for multiple comparisons.

#### Results:

Parents scored their children higher than education professionals on VABS-II ABC scores, as well as Socialisation and Motor Skills, but not Communication or DLS (see Table). Difference in VABS-II scores was significantly negatively associated with child nonverbal , predicting 10-35% of the variance. Autism severity and language were not significantly associated with discrepancy. Weighted kappa scores were calculated for 147 items (89.1%), and 32.7% had significant inter-rater agreement (see Table). Where disagreements arose (99/147), education professionals rated behaviour in the 'sometimes or partially' category more frequently, whereas parents were more likely to rate behaviours as 'never' or 'usually'.

#### Conclusions:

Inter-rater agreement at both the domain and item level is low, but domain-level agreements are closer when child nonverbal ability is higher. Parents and education professionals chose different item level rankings but it is not clear whether this is due to differences in perception/understanding, or context-dependent differences in performance, which future research should explore further. Multiple informant ratings are necessary to gain a full picture of a child's adaptive abilities.

#### **518.097** (Virtual Poster) Using the Brief Observation of Social Communication Change (BOSCC) to Measure Longitudinal Changes in Social Communication Behaviors

**A. Jones<sup>1</sup>, A. Pellegrino<sup>2</sup>, S. Dvorak<sup>3</sup>, S. H. Kim<sup>4</sup> and S. Faja<sup>5</sup>, (1)Boston Children's Hospital Labs of Cognitive Neuroscience, Brookline, MA, (2)Boston College, Boston, MA, (3)Harvard College, Cambridge, MA, (4)Psychiatry, Center for Autism and the Developing Brain, White Plains, NY, (5)Boston Children's Hospital, Boston, MA**

**Background:** The Brief Observation of Social Communication Change (BOSCC) was designed as an observational instrument for reliable and objective measurement of changes in the social-communication behaviors of children with ASD. To date, most published research using the BOSCC has consisted of cross-sectional studies or smaller clinical trials. Only one longitudinal study examines whether the BOSCC can reliably capture changes in social-communication behaviors over a 1-year period.

**Objectives:** The present analysis aims to test whether the BOSCC coding scheme can be used to assess social communication changes in children with ASD longitudinally across a 2- to 3-year period. We will specifically examine whether skills observed in the context of a standard parent-child interaction can be coded across age and developmental level during the preschool period, because the current BOSCC coding scheme has not been applied to children with fluent speech.

**Methods:** Data collection and coding is ongoing (to date, n = 10 with ASD age 28 to 90 months) with an anticipated sample of n=50. Children completed the Autism Diagnostic Observation Schedule (ADOS-2) with varying levels of language ability from minimal spontaneous speech to fluent speech (spanning ADOS-2 Module T to Module 3). Participants and their parents were asked to play freely and recorded for 10 minutes, twice, 2 to 3 years apart and BOSCC rating was applied to the videos. Total, social affect (SA), and restricted/repetitive behaviors (RRB) change scores (T1-T2) were created for the BOSCC and ADOS-2 calibrated severity scores (CSS). Spearman rank correlation coefficients were used to compare the BOSCC's sensitivity to change over time relative to the ADOS-2.

**Results:** We first examined the feasibility of coding the BOSCC in this age range by checking floor or ceiling scores at either time point. No children earned minimum or maximum scores for the possible range of 0-75 points. Next, we examined whether scores improved for children between timepoints at an individual level. Seventy percent of children earned total BOSCC scores that were lower at the second timepoint (i.e., stronger social communication skills and lower levels of repetitive behavior); 10% obtained scores that differed by 0-1 points (i.e., no change); 20% obtained higher scores (i.e., worse skills at the second time point). Finally, we examined whether changes on the BOSCC corresponded with changes on the ADOS-2 CSS score. For the total and social affect domains, ADOS-2 CSS changes did not significantly correlate with BOSCC changes. However, the change score of ADOS-2 RRB CSS significantly correlated with changes on the BOSCC restricted and repetitive behavior items ( $\rho(8) = 0.64, p = 0.045$ ).

**Conclusions:** Our preliminary results suggest that the BOSCC is a feasible measure of change that can capture differences related to autism symptomatology over a 2–3-year period among children with language abilities ranging from minimally verbal to verbally fluent. As expected, most children showed some progress in their skills over this period and data suggest that changes detected by the BOSCC track with changing levels of symptom severity on an established measure in the restricted/repetitive behaviors domain.

#### **518.098** (Virtual Poster) Initial Validation of the Mandarin Translation of the Stanford Social Dimensions Scale (SSDS)

**X. Su<sup>1</sup>, J. Ge<sup>2</sup>, J. M. Phillips<sup>3</sup>, A. Y. Hardan<sup>3</sup> and M. Uljarevic<sup>4</sup>, (1)Early Childhood Education, Faculty of Education, East China Normal University, Shanghai, China, (2)Special Education School of Xiaoshan District, Hangzhou City, Hangzhou, China, (3)Psychiatry & Behavioral Sciences, Stanford University, Stanford, CA, (4)School of Psychological Sciences, University of Melbourne, Stanford, CA, Australia**

**Background:** Impairments in social functioning are a diagnostic feature of autism spectrum disorder (ASD). Importantly, social functioning is a complex and multifaceted domain, encompassing several distinct processes, each of which can be differently affected in individuals with ASD. However, despite its prominence and multifaceted nature, there is a paucity of open-source instruments specifically designed to quantify individual differences in different aspects of social functioning. A recently developed Stanford Social Dimensions Scale (SSDS), was specifically designed for such a purpose. Initial validation has shown preliminary evidence that the SSDS can capture different aspects of social motivation, social communication and mental state understanding in a valid and reliable way.

**Objectives:** To provide an initial validation of a Mandarin translation of the Stanford Social Dimensions Scale (SSDS) by investigating its factor structure, discriminant, convergent and divergent validity.

**Methods:** Parents of 468 children with ASD ( $Mean_{age}=9.02$ ,  $SD=3.79$ ), 74 children with intellectual disability (ID) without ASD ( $Mean_{age}=10.44$ ,  $SD=3.69$ ), 54 children with language delay (LD) ( $Mean_{age}=5.36$ ,  $SD=1.80$ ) and 160 children who were typically developing (TD) ( $Mean_{age}=7.16$ ,  $SD=3.66$ ) from 22 provinces and Municipalities in China completed the translated SSDS and the appropriate versions of the Social Responsiveness Scale (SRS-2) and the Strengths and Difficulties Questionnaire (SDQ). Data on children's full-scale intellectual quotient (FSIQ) was also available.

**Results:** Confirmatory application of the Exploratory Structural Equation Modelling indicated that an original five-factor model encompassing Social Motivation (SM), Social Affiliation (SA), Expressive Social Communication (ESC), Social Reception (SR) and Unusual Approach (UA) provided adequate to excellent fit to the data in ASD group (comparative fit index [CFI]=.962, Tucker Lewis Index [TLI]=.949, root mean square error of approximation [RMSEA]=.058 [95% CI: .054, .062], standardized root mean square residual [SRMR]=.032). With the exception of items on UA factor that showed lower loadings when compared to the original validation in the US sample, majority of items constituting SM, SA, ESC and SR factors. Discriminant validity was excellent with ASD group showing significantly lower scores (poorer ability) across all SSDS subscales when compared to ID, LD and TD groups, in turn, ID and LD groups showed poorer performance than TD group. Convergent and divergent validity across all SSDS scales was strong as indexed by the pattern of correlations with relevant SRS-2 and SDQ domains and with FSIQ scores.

**Conclusions:** The ability to characterize and quantify individual differences in key processes crucial for social functioning in ASD is an essential step towards better understanding concurrent functioning and long-term outcomes as well as for informing personalization of treatments. This study provided preliminary validation of the Mandarin translation of the SSDS by largely replicating the original factor structure and showing evidence for a strong discriminant, convergent and divergent validity. This study has also identified potential aspects where further refinement and potential expansion of the SSDS are needed. Our findings provide initial validation of a new scale designed to comprehensively capture individual differences in social motivation and other key social dimensions in ASD.

**518.099 (Virtual Poster)** Examining Sources of and Interventions for Distress in Autistic Individuals with Complex Needs – a Systematic Review of Procedural and Measurement Issues and Practice

N. Edwards<sup>1</sup>, S. Donald<sup>1</sup>, S. B. Gaigg<sup>2</sup> and A. Remington<sup>3</sup>, (1)City University of London, London, United Kingdom, (2)Autism Research Group, City, University of London, London, United Kingdom, (3)UCL Centre for Research in Autism and Education, London, United Kingdom

Background:

Autistic individuals are disproportionately susceptible to experiencing forms of distress e.g. anxiety or depression. Existing reviews of distress literature focus primarily upon individuals with average or above-average levels of adaptive or cognitive functioning and language ability. Studies examining distress in those with additional intellectual disabilities (ID) remain scarce, potentially due to methodological challenges. Consequently, underpinning causes and contributing factors remain poorly understood. Additionally, relevant literature has not been reviewed comprehensively because distress is often narrowly operationalised in terms of specific externalising behaviours e.g., challenging behaviour or aggression. Distress, however, may also be felt and expressed differently in autistic individuals with ID.

Objectives:

To comprehensively review methodological approaches used to operationalise and measure distress in autistic individuals with ID including strategies used for engaging, recruiting and retaining this group in research processes. Current knowledge concerning the sources of, and interventions for distress are also examined systematically.

Methods:

Electronic databases were searched using a broad range of keywords relating to distress and autism and ID, to identify English-language primary studies reporting relevant outcome measures. Data extraction and synthesis followed PRISMA guidelines. Quality appraisal was completed with an adapted grid method used in Glod et al., (2015), facilitating concurrent utilisation of multiple frameworks. Full details of the review methodology are available in the pre-registration protocol [PROSPERO CRD42021249840].

Results:

Of 2955 studies screened, 256 were selected for full text review and analysis. Distress operationalised in terms of measures of anxiety, depression and different forms of behaviour labelled as 'challenging' (including repetitive behaviour and aggression). Consensus was limited regarding the most appropriate distress measure, the most common involved caregiver, teacher or clinician reports. Self-report, neurological, behavioural, and psychophysiological measures were less common. Measures relying on reports from others risk biases and rely on the verbalisation of experiences to

a parent or clinician. Such measures potentially limit the voice of the autistic individual with ID. Additionally, there was little reporting of how recruitment and retention processes were managed or adapted for this population.

In synthesising findings, several conceptual challenges were found. First, literature varied regarding how ID within autistic individuals was defined and operationalised. ID was most often defined as  $<70$  on an IQ scale. Alternatively, or in conjunction with IQ scales, a measure of adaptive functioning was given ( $<70$ ). Additionally, participant groups often involved autistic individuals with and without ID, making it difficult to assess the role of additional ID in distress-related outcome measures more.

Distress was attributed to different sources e.g., atypical sensory processing, sleep quality, inability to cope with environmental changes and anxiety or frustration at poor communication with others.

#### Conclusions:

The voice and collaboration of autistic individuals with ID is underrepresented in distress research. A key output from this review will be the development of guidelines to support inclusion and partnership of this population. Future research should focus on development and use of inclusive participatory approaches supporting collaboration across research processes, and more objective means of capturing distress such as psychophysiological measures could mitigate reliance upon caregiver/clinician reports.

#### **518.100** (Virtual Poster) Me Reporting on Myself: Further Evidence in Support of the Validity of the Theory of Mind Inventory-Self Report When Completed By Autistic Adults

**E. L. Coderre<sup>1</sup>** and **T. Hutchins<sup>2</sup>**, (1)University of Vermont, Burlington, VT, (2)UVM, Burlington, VT

---

**Background:** Although self-report is being more widely used to assess a variety of characteristics in autism spectrum conditions (e.g., anxiety, depression), self-assessment of social cognition remains a woefully understudied topic. The Theory of Mind Inventory: Self-Report-Adult (ToMI-SR-Adult) was recently developed for this purpose. The ToMI-SR-Adult consists of 60 statements tapping advanced aspects of social cognition (e.g., metalinguistics, humor, deception) as applied in real world behavior. Initial examination of the ToMI-SR-Adult showed that it reliably distinguished autistic adults with subtle symptomology from neurotypical adults matched on age, gender, and socioeconomic status.

**Objectives:** Our objective was to further evaluate the psychometric properties of the ToMI-SR-Adult in a pilot sample of autistic adults who were capable language users but who were more diverse in their autism, language, and intellectual profiles.

**Methods:** Participants were 13 autistic adults ages 22-64 years ( $M = 41$ ; 7 male, 6 female) representing a range in symptom severity and language and intellectual abilities. Participants completed the ToMI-SR-Adult at two time points (retest interval approximately 4 weeks). At time 1, they also completed assessments of intelligence (Kaufman Brief Intelligence Test, K-BIT-2), receptive vocabulary (Peabody Picture Vocabulary Test, PPVT-4), autism symptomology (ADOS-2; Autism Quotient, AQ; Social Responsiveness Scale, SRS-2), empathy (Empathy Quotient, EQ-10-Adult), and psychological conditions (Achenbach System of Empirically Based Assessment, ASEBA-Adult-Self-Report). Our examinations involved a variety of self-report indices only to control for methods variance. Test-retest reliability and convergent and discriminant validity were assessed using Pearson's correlations. For the purposes of this pilot, an alpha of .10 was adopted to guard against the potential for type II errors.

**Results:** The ToMI-SR-Adult demonstrated good test-retest reliability ( $r = .89, p < .01$ ). To assess convergent validity, we reasoned that a construct valid measure of advanced ToM would demonstrate strong correlations with theoretically-related constructs. As expected, we observed significant associations between scores on the ToMI-SR-Adult and the EQ10, the AQ, the SRS composite score, the SRS Social Awareness subscale, the SRS Social Cognition subscale, and the ASEBA thought disturbances subscale (Table 1). Surprisingly, we also observed a significant correlation with the SRS-RRB subscale. We also conducted tests of discriminant validity, reasoning that a construct valid measure of advanced ToM would demonstrate weaker correlations with constructs with more tenuous conceptual links to theory of mind. As expected, we observed weaker, non-significant associations between scores on the ToMI-SR-Adult and the SRS Social Motivation subscale, the ASEBA withdrawn subscale, and the ASEBA anxiety subscale (Table 1). We also observed a non-significant correlation with the SRS social communication subscale although this appears to be an artifact of insufficient power.

**Conclusions:** We found support for the test-retest reliability and convergent and discriminate validity of the ToMI-SR-Adult. This justifies further development and validation of the measure and supports the notion that autism does not preclude self-awareness and that often, autistic adults may be the best judges of their own subjective social-cognitive experiences.

#### **518.101** (Virtual Poster) Examining Provider Perspectives on the Process of Conducting Virtual Diagnostic Evaluations: A Double-Edged Sword

**R. Haine-Schlagel<sup>1</sup>**, **K. S. Dickson<sup>1,2</sup>**, **J. Byrnes-Fox<sup>1</sup>**, **M. Leraas<sup>1</sup>** and **R. Vedder<sup>3</sup>**, (1)San Diego State University, San Diego, CA, (2)Child and Adolescent Services Research Center, San Diego, CA, (3)San Diego Regional Center, San Diego, CA

---

**Background:** Serving autistic children is a significant public health concern. A diagnosis is typically the first step to obtaining services. Accessing an ASD diagnostic evaluation (DE) has historically been challenging (Wiggins et al., 2006), especially for families from underserved communities (e.g., rural, low-income, ethnically/racially diverse populations, populations with low English proficiency) (Robins et al., 2014). Access to DE's was further reduced during the COVID-19 pandemic. Virtual DE (DE-v) can improve access for underserved families (Maheu et al., 2001) and address the current safety concerns due to the pandemic (Narzisi et al., 2020). The minimal extant research on family perceptions of DE-v is generally positive (Gibbs et al., 2021). However, several challenges exist to delivering DE-v's for ASD. Beyond the lack of valid assessment tools, delivering DE-v's can be challenging given DE-v relies on parent-elicited interactions with the child as the primary source of observational data.

**Objectives:** To examine providers' attitudes about and experiences related to the DE-v process, including: 1) reasons for shifting to DE-v's during the pandemic; 2) adaptations for DE-v's; and 3) barriers to implementing DE-v's.

**Methods:** The ten psychologists that provided eligibility DE-v's for children ages 0-5 for the San Diego Regional Center (SDRC), purveyor of Developmental disability services, were invited to participate; 6 agreed. SDRC serves two racially/ethnically and geographically diverse counties. Participants were 66.7% female and all Non-Hispanic White; four reported working with early intervention populations and five with preschool populations and one provided DE-v's in Spanish. Participants took part in 60-minute semi-structured interviews that asked about: 1) reasons for shifting to DE-v's; 2) the structure of their DE-v's; and 3) similarities and differences between DE and DE-v's. Interviews were recorded and transcribed. Interview data were analyzed using elements of the Rapid Assessment Procedure (Palinkas & Zatzick, 2019), which included independent coding of transcripts using a summary template, template comparison and discussion to achieve consensus, and entering consensus templates into a matrix to generate themes. Participants also completed an electronic barriers to DE-v survey (14 items; 1 (not perceived barrier)-5 (highly perceived barrier), analyzed with descriptive statistics.

**Results:** For objective 1, primary reasons providers pivoted to DE-v's include family need for services and provider need for income. For objective 2, DE-v adaptations included: 1) a telephone call and/or preparatory session ahead of the evaluation; 2) coaching the parent to elicit interactions the provider needs to see; 3) inviting a sibling or neighbor to interact with the target child if applicable; 4) inability to conduct cognitive testing or use existing valid diagnostic assessment tools; and 5) inability to use typical engagement and comforting strategies during diagnostic feedback if needed. For objective 3, providers indicated low overall barriers ( $M=2.4$ ). Barriers to conducting DE-v's, with highest mean scores included available valid assessment measures ( $M=3.5$ ) and minimal professional benefits of providing DE-v ( $M=3.2$ ).

**Conclusions:** Results indicate several adaptations for DE-v and generally low perceived barriers to providing DE-v's. Future research with a diverse range of providers and families can further inform efforts to develop supports for psychologists and families to optimize the DE-v process.

**518.102 (Virtual Poster)** Factor Analyses of the Gilliam Autism Rating Scale-Third Edition Using Special Education Staff Ratings in Samples with ASD and Other Developmental Disabilities

**N. Bergamo<sup>1</sup>, M. A. Volker<sup>2</sup>, J. A. Toomey<sup>3</sup>, G. Lee<sup>3</sup>, K. M. Rispoli<sup>3</sup>, C. Sung<sup>4</sup>, M. Stoll<sup>5</sup>, S. L. Brennan<sup>1</sup> and R. Birnbaum<sup>3</sup>,** (1)*Counseling, Educational Psychology, and Special Education, Michigan State University, East Lansing, MI*, (2)*Summit Educational Resources, Getzville, NY*, (3)*Michigan State University, East Lansing, MI*, (4)*Department of Counseling, Educational Psychology and Special Education, Michigan State University, East Lansing, MI*, (5)*Pediatrics, Division of Pediatric Psychology, Michigan Medicine/University of Michigan, Ann Arbor, MI*

---

**Background:** The Gilliam Autism Rating Scale (GARS-3; Gilliam, 2013) is a commonly used level two screener for ASD (Aiello et al., 2017; Benson et al., 2019; Norris & Lecavalier, 2010). The GARS-3 is a substantial revision from the prior version, however, there is no independent research examining its factor structure. Previous GARS editions had notable psychometric issues (e.g., with screening performance, factor structure, and item-to-scale correspondence) when evaluated independently (Lecavalier, 2005; Pandolfi et al., 2010; South et al., 2002; Volker et al., 2016). This presentation will provide an independent examination of the internal structure validity of the GARS-3 in an ASD student sample rated by special education staff.

**Objectives:** Study one examined the internal structure of the GARS-3 via exploratory factor analysis (EFA) of special education teaching staff ratings in a sample of 204 students with ASD. Study two examined the fit of the published six-subscale model (Gilliam, 2013) and the model derived from the study one EFA using confirmatory factor analysis (CFA) in a separate validation sample of 200 students with ASD and other developmental disabilities with similar support needs.

**Methods:** GARS-3 data were collected at a large special education agency that serves students with ASD. For study one, an EFA was conducted on the inter-item polychoric correlation matrix using principal axis factoring with promax rotation. Factor retention criteria included: Kaiser criterion, scree plot, Velicer's MAP, parallel analysis, and factor interpretability. For study two, a CFA was conducted on a validation sample's inter-item polychoric correlation matrix using the Mplus weighted least squares mean variance estimator. The original GARS-3 six-factor model and the study one EFA-based model, with and without cross-loadings, were compared.

**Results:** In study one, a correlated six-factor model was retained that very closely aligned with the GARS-3 six-subscale structure. Noteworthy differences were a single item that loaded on a different factor and the presence of several cross-loadings. Five of the six factors had substantive positive inter-factor correlations, while the negative to near zero correlations involving the remaining factor suggested that minimum language requirements may need to be revisited for its items. In study two, both models showed evidence of good fit and did not substantively differ (i.e., original model [ $\chi^2 = 2323.440$ ,  $df = 1580$ ,  $p < .001$ ; RMSEA = 0.049; SRMR = 0.081; CFI = 0.981; TLI = 0.980; MLR-based AIC = 26367.365 and BIC = 26990.747], model from study one EFA [ $\chi^2 = 2361.659$ ,  $df = 1580$ ,  $p < .001$ ; RMSEA = 0.050; SRMR = 0.081; CFI = 0.980; TLI = 0.979; MLR-based AIC = 26338.297 and BIC = 26961.679]). Additional analyses indicated models that included cross-loadings fit significantly better.

**Conclusions:** The EFA and CFA generally supported the proposed six-factor structure of the GARS-3. However, results also suggested one item may be more appropriate for a different subscale, the pattern of inter-factor correlations implied a possible problem with the minimum language requirement for one subscale, and several significant cross-loadings indicated that the inclusion or interpretability of some items should be reconsidered.

**518.103 (Virtual Poster)** Identifying Patient Characteristics to Understand Which Children May Receive Diagnostic Clarity in a Virtual Autism Spectrum Disorder Evaluation

**R. A. Phelps<sup>1</sup>, E. Sample<sup>2</sup>, R. K. Greene<sup>3</sup> and S. W. Duvall<sup>3</sup>,** (1)*Oregon Health & Science University - CDRC, Portland, OR*, (2)*Pacific University, Forest Grove, OR*, (3)*Oregon Health & Science University, Portland, OR*

---

**Background:** Given long waitlists for autism spectrum disorder (ASD) evaluation coupled with the COVID-19 pandemic, it is crucial to triage patients to services where they are likely to receive diagnostic clarity. ASD evaluations are traditionally completed in-person and often include a diagnostic interview, behavioral observations, cognitive testing, and ASD specific measures, with some tools requiring in-person administration. Due to of COVID-19 safety precautions, ASD virtual evaluation (VE) has become common practice. VEs have potential to increase access to evaluation and expedite patient access to treatment. It remains unclear which patients are likely to receive diagnostic clarity during VE and which patients are likely to be referred for further testing. Additionally, it is unclear how information collected during VE may inform diagnostic outcomes during in-person evaluation (IPE).

**Objectives:** The current study investigates which patients are likely to receive diagnostic clarity during an ASD VE and which patients are likely to be referred on for further IPE. Bivariate relations between VE data and IPE data are investigated.

**Methods:** Eighty-seven youth (33% female;  $M_{age}=9.14$ ,  $SD_{age}=3.89$ ) and caregivers engaged in VE. A subset also completed an in-person evaluation. VE data included demographic variables, adaptive skills (i.e., Adaptive Behavior Assessment System, 3<sup>rd</sup> Edition; ABAS-3), psychiatric history, behavior and psychiatric concerns (i.e., Behavioral Assessment System for Children, 3<sup>rd</sup> Edition; BASC-3), educational services for ASD, ASD symptom severity (i.e., Childhood Autism Rating Scale, 2<sup>nd</sup> Edition (CARS-2), and outcome of virtual evaluation (i.e., ASD diagnosis, further testing recommended). IPE data included Brief Observation of Symptoms of Autism (BOSA) and diagnostic outcome. Of 87 participants who completed a VE, 38 received an ASD diagnosis, 7 had ASD ruled out, and 49 were referred for IPE. At time of analysis, 22/49 participants completed IPE.

**Results:** Group differences indicated older youth and those with more historical psychiatric diagnoses were more likely to be referred for IPE while those with school supports for ASD were more likely to receive ASD diagnosis at VE (see Table 1). Logistic regression suggested youth with educational services for ASD and higher ASD severity scores were more likely to receive ASD diagnosis at VE (see Table 2). Regarding the relations between VE and IPE behavioral observation, data did not yield significant relations between variables collected during VE and the BOSA. The majority of VE data did not relate to IPE diagnostic outcomes; however, the CARS-2 severity score ( $r=0.34$ ;  $p=.016$ ) and having a first degree relative with ASD ( $r=-0.46$ ;  $p=.031$ ) did relate to diagnosis of ASD at IPE.

**Conclusions:** VE have limitations such that not every patient is able to receive diagnostic clarity during virtual care, at which time a referral for IPE may be deemed appropriate. Age, psychiatric conditions, educational services for ASD, and ASD severity are important to consider for triaging patients to appropriate evaluation services. Ultimately, VE may decrease burden on families who may not require IPE and assist in addressing lengthy ASD evaluation waitlists.

#### **518.104 (Virtual Poster) Linkages Among Age of Diagnosis, Assigned Sex, Cognitive Functioning and Mental Health in ASD**

**J. V. Smith<sup>1</sup>, A. B. Ratto<sup>1</sup>, A. Verbalis<sup>1</sup>, G. A. McQuaid<sup>2</sup>, A. Jack<sup>3</sup>, J. F. Strang<sup>1</sup>, G. L. Wallace<sup>4</sup> and L. Kenworthy<sup>1</sup>,** (1)Center for Autism Spectrum Disorders, Children's National Hospital, Washington, DC, (2)George Mason University, Fairfax, VA, (3)Psychology, George Mason University, Fairfax, VA, (4)The George Washington University, Washington, DC

#### **Background:**

Timely Autism Spectrum Disorder (ASD) diagnoses are critical for establishment of care, including early intervention during a plastic period of development, and receipt of services, which ultimately drive long-term outcomes. Posited predictors of late ASD diagnosis include: sex assigned female at birth, co-occurring psychopathology (i.e., diagnostic overshadowing), relatively stronger cognitive skills, and relatively reduced ASD symptom severity.<sup>1-3</sup> Late diagnosis of ASD is associated with poorer quality of life and increased depressive/anxious symptoms.<sup>4,5</sup>

#### **Objectives:**

Examine the relationship between age of ASD diagnosis and key variables of interest: sex assigned at birth, anxious/depressive symptoms, and intellectual functioning.

#### **Methods:**

Participants included youth from a large clinical database ( $N = 1198$ ) who received their first clinical diagnosis of ASD at the time of a neuropsychological evaluation at an outpatient academic medical center. The children were predominantly male (77.3%) and were diagnosed with ASD between the ages of 1.3-19.7 years ( $[y]$ ;  $M = 7.26$ ,  $SD = 4.30$ ). For those over 6y who received IQ assessment at the time of diagnostic evaluation ( $n = 590$ ), full scale IQ (FSIQ) scores ranged from 37 to 141 ( $M = 96.29$ ,  $SD = 18.70$ ). FSIQ was obtained from the Wechsler intelligence assessments, Differential Ability Scales, or the Leiter International Performance Scale, as appropriate. Anxiety ( $n = 590$ ) and depressive ( $n = 582$ ) symptoms were captured from caregiver report on the Child Behavior Checklist, DSM-oriented scales.<sup>6</sup>

#### **Results:**

On average, youth assigned male ( $M = 7.10$ ,  $SD = 4.19$ ) versus female ( $M = 7.83$ ,  $SD = 4.61$ ) at birth received earlier diagnoses;  $t(411) = -2.34$ ,  $p = .006$ . A linear regression predicting age of ASD diagnosis from sex assigned at birth, FSIQ, and the interaction between sex and FSIQ was significant ( $R^2 = .03$ ,  $F = 5.85$ ,  $p = .001$ ); the interaction between sex and FSIQ emerged as the lone significant predictor of age of ASD diagnosis ( $\beta = .50$ ,  $t(589) = 2.31$ ,  $p = .02$ ). A linear regression predicting depressive symptoms from age of ASD diagnosis and assigned sex was significant ( $R^2 = .04$ ,  $F = 12.75$ ,  $p < .001$ ); age of ASD diagnosis was the sole predictor of depressive symptoms ( $\beta = .20$ ,  $t(581) = 4.79$ ,  $p < .001$ ). A linear regression

predicting anxiety symptoms from age of ASD diagnosis and assigned sex was significant ( $R^2 = .03$ ,  $F = 8.13$ ,  $p < .001$ ); age of ASD diagnosis emerged as the lone predictor ( $\beta = .16$ ,  $t(588) = 3.96$ ,  $p < .001$ ).

#### Conclusions:

These findings highlight that not only are assigned females diagnosed later than assigned males, but females with higher IQ experience later ASD diagnosis, suggesting a key group “missed” in either referral and/or diagnostic processes. Corroborating previous literature, later age of ASD diagnosis was associated with greater depressive and anxiety symptoms, regardless of assigned sex. Ultimately, these findings illustrate the importance of timely ascertainment and highlight factors that may be associated with diagnostic delay.

#### **518.105** (Virtual Poster) Measurement Invariance of the Vineland Adaptive Behavior Scales in Minimally Verbal Versus Verbal Autistic Individuals

**E. Wilkinson<sup>1</sup>**, V. H. Bař, C. Farmer<sup>3</sup> and E. Kleiman<sup>4</sup>, (1)Graduate School of Applied and Professional Psychology, Rutgers University-New Brunswick, Piscataway, NJ, (2)Graduate School of Applied and Professional Psychology, Rutgers University - New Brunswick, Piscataway, NJ, (3)National Institute of Mental Health, Bethesda, MD, (4)Psychology, Rutgers University, Piscataway, NJ

---

#### Background:

Adaptive behavior comprises a broad set of skills needed to function in everyday life. The Vineland Adaptive Behavior Scales, 3<sup>rd</sup> Edition (VABS-3; Sparrow et al., 2016) Parent/Caregiver Form divides adaptive behavior into 11 subdomains assigned to four domains (Communication, Daily Living Skills, Socialization, and Motor). Though there is general agreement that adaptive behavior is defined by the regular performance of skills in these areas, the factor structure of the VABS-3 has not been validated in autistic samples. Considering the widespread use of the VABS in autism research, it is necessary to establish its validity in autistic individuals across a wide range of abilities, including those who use minimal verbal language.

#### Objectives:

To examine measurement invariance (MI) of the VABS-3 Parent/Caregiver Form across minimally verbal (MV) and verbal autistic individuals, which would support use of the measure across a wide range of abilities represented in autism samples.

#### Methods:

The VABS-3 survey was electronically administered to parents of 9,549 autistic individuals aged 6-79 years ( $M=12.51$ ,  $SD=5.79$ ). The sample was split into two groups: minimally verbal (MV;  $n=913$ ) and verbal ( $n=8,636$ ; see Table 1 for demographic characteristics), based on a VABS-3 Expressive Communication raw score threshold of 34, which reflects use of up to 50 single words. MI between the MV and verbal groups was examined using the theoretical factor structure of the VABS-3, excluding the Motor domain which is administered only to children younger than 9 years (Figure 1). Due to the high number of items, subdomains were utilized as item-units, similar to previous research (Dovgan et al., 2019; Farmer et al., 2020). The fits of models using both raw scores and V-scale subdomain scores were evaluated.

#### Results:

The initial confirmatory factor analysis of the three-factor structure in the full sample yielded mediocre-to-poor fit (Raw scores: CFI=.910, TLI=.865, RMSEA=.185; V-scale scores: CFI=.948, TLI=.921, RMSEA=.134). Mediocre-to-poor fit was also observed within the MV (Raw: CFI=.883, TLI=.825, RMSEA=.155, V-scale: CFI=.922, TLI=.883, RMSEA=.130) and verbal (Raw: CFI=.898, TLI=.847, RMSEA=.171, V-scale: CFI=.935, TLI=.903, RMSEA=.129) groups. Because the structural model was not appropriate for either group, indicating lack of configural invariance with the population, MI between the MV and verbal groups could not be further examined.

#### Conclusions:

The three-factor structure of the VABS-3 Parent/Caregiver Form was not appropriate for the subdomain-level raw or V-scale scores in either the MV or verbal groups of autistic individuals. These findings reflect that the VABS-3's three-domain structure is based on the authors' theoretical construct of adaptive behavior, rather than an empirically-derived model. The lack of support for the factorial validity of the VABS-3 Parent/Caregiver Form indicates that scores from children with autism may not adequately assess these theoretical dimensions. Thus, autism research using the domain scores should exercise caution in interpretation. Future work should explore alternative latent structures for the VABS-3 Parent/Caregiver Form, and analyses are underway to evaluate a unidimensional model, which has some support in the VABS-3 normative sample (Farmer et al., 2020) and could support interpretation of the Adaptive Behavior Composite in autism research.

#### **518.106** (Virtual Poster) Play Behaviour Assessment for Children with Autism – Development and Feasibility

**B. Kumarswamy<sup>1</sup>**, P. Srikanthapuram<sup>1</sup>, V. Raman<sup>2</sup>, S. Rajagopalan<sup>3</sup> and A. Mysore<sup>2</sup>, (1)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India,, Bengaluru, India, (2)St.Johns Medical College Hospital, Bengaluru, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India,, Bangalore, India

---

## Background:

Play assessments can elicit a wide range of social behaviors and have been adapted for autism assessments like ADOS and AOSI. However, these assessments are set in a clinical environment, professional lead, require extensive training and are expensive. There is a need for assessments that are focused on observations of semi-structured, play-based social interaction between parent-child as well as examiner-child dyads and have the potential for implementation in low-resource settings.

## Objectives:

We aimed to develop a semi-structured play-based assessment to help screen children below 2 years for autism. Enabling this within tele-health care models using videos and computational approaches are additional objectives. We report here on the development and preliminary assessment of feasibility in our clinical setting.

## Methods:

After a detailed review of play behavior literature, in-depth interviews were conducted, by the authors with psychologists, psychiatrists and pediatricians. Based on the themes that emerged, such as availability of culturally appropriate toys, safety of children, early social and play behaviors and need to reduce distractions, a play protocol was designed having caregiver-child sessions and examiner-child sessions to elicit social and play responses. The activities were selected based on stages of play development which progressed from simple exploration (ball) to complex symbolic play (putting a doll to sleep). Informed consent was taken to video record the session for computational analysis. The cameras selected were such that they could be used in low-resource settings. To evaluate the feasibility of the protocol, it was pilot-administered to three groups of children (Autism Spectrum Disorder, Developmental Delay and Typical Development).

## Results:

The protocol was seen to take approximately 20-25 minutes for administration: the first five minutes included parent-child interaction and the following 15-20 minutes included structured examiner-child interaction. Based on the checklist of social and play responses, the videos were coded on a number of parameters by trained psychologists. To evaluate feasibility, the protocol was administered to three groups of children, n=30 (19 ASD, 6 TD, 4 DD). The sample consisted of 22 male (73.3%) and 8 female (26.7%) children. Mean age of the three groups is 24.7 months (SD= 8.220). The play protocol designed was seen to make children comfortable and remain at ease as they interacted with known adults. Feasibility was indicated by prompt consent and complete participation till the end of the protocol. Not having to abort any session appears to indicate acceptability of the protocol. We are further improving the protocol accordingly. We plan to develop computational models using machine and deep learning algorithms to understand and characterize child behaviors across three different groups. Though not a primary objective, it was noted that the play protocol was also able to elicit differences in social and play responses amongst the three groups. .

## Conclusions:

A culturally relevant play protocol has been developed. It was easy to administer. The acceptance by children with and without autism has been encouraging. Discriminant validation using computational approaches is currently underway.

## **518.107** (Virtual Poster) Psychometric Properties of Broadband Screening Tools for Developmental Delays in Infants at High- and Low-Risk for Autism

**M. Drye<sup>1</sup>, C. J. Zampella<sup>1</sup>, M. Fecher<sup>1</sup>, R. Benecke<sup>1</sup>, L. S. Cubit<sup>1</sup>, G. Megginson<sup>1</sup>, L. K. Steinbeck<sup>1</sup>, L. A. Wang<sup>1,2</sup>, R. T. Schultz<sup>1,3</sup> and W. Guthrie<sup>1,3,4</sup>,**  
(1)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (2)Department of Psychology, University of Pennsylvania, Philadelphia, PA, (3)Departments of Psychiatry and Pediatrics, University of Pennsylvania Perelman School of Medicine, Philadelphia, PA, (4)Center for Pediatric Clinical Effectiveness, Children's Hospital of Philadelphia, Philadelphia, PA

**Background:** Early developmental screening tools provide insight into a critical period of development and help predict developmental trajectories and outcomes. Given this, the American Academy of Pediatrics recommends that children be screened with a validated tool at 9, 18, and 30 months. A positive screen prompts providers to initiate further evaluation or intervention, which has been shown to improve developmental outcomes. Many factors contribute to the utility of screening tools, such as psychometric properties and feasibility in the target population. To date, few studies have examined how well broadband developmental screening tools predict performance on concurrent developmental assessment in infants at high and low familial risk for autism spectrum disorder (ASD). Performance of screening tools in this high-risk cohort is particularly important given their elevated rates of developmental delays.

**Objectives:** (1) Examine results of two developmental screening measures in high- and low-risk infants; (2) Analyze the relationship between screening outcomes and scores on subsequent clinical assessment.

**Methods:** Participants were 55 infant-parent dyads, including 19 infants at high familial risk for ASD (see Table 1). Parents completed two age-appropriate broadband screeners, the Survey of Well-being of Young Children Developmental Milestones (SWYC) and Ages and Stages Questionnaire, Third Edition (ASQ-3), up to 5 weeks before an in-clinic developmental assessment at ~12 months of age with the Bayley Scales of Infant and Toddler Development, 4th edition (Bayley-4).

**Results:** On the SWYC, 32 infants (58%) screened positive. Compared to the 23 infants that screened negative, the screen positive group had significantly lower standard scores on Bayley-4 Cognitive ( $p=0.03$ ), Language ( $p=0.02$ ), and Motor ( $p<0.001$ ) domains (see Table 2). However, only six infants (11%) showed developmental delays on the Bayley (i.e.,  $<85$  on one or more Bayley-4 domains). Despite the small sample, SWYC outcome significantly predicted developmental delay (Fisher's Exact Test  $p=0.04$ ). Overall, the SWYC's sensitivity in detecting delays and negative predictive value were 100%, but specificity (46.9%) and positive predictive value (PPV; 18.8%) were much lower. Parallel results will be presented for the ASQ-3, as well as results by ASD risk group.

**Conclusions:** Results suggest that the SWYC effectively detected developmental delays in infants at high and low risk for ASD at 12 months. It also falsely identified many who were found to be developmentally on track, resulting in a low PPV. Although this low PPV is partially due to the low base rate of developmental delays in this sample, it also suggests that a positive screen on the SWYC alone may not be sufficient to warrant referral for early intervention. The SWYC is becoming widely used in clinical practice, therefore it will be important to develop methods of reducing false positives, perhaps with a Level II screening tool. Future analysis will utilize a larger sample, including more high-risk infants, allowing for a broader range of developmental outcomes in analysis. ASQ-3 metrics in this sample will be contrasted with the SWYC, a meaningful comparison given that the ASQ is more established but also less feasible in practice due to its length and administration cost.

**518.108 (Virtual Poster)** Sensory Sensitivity in Adolescents with ASD: An Experience Sampling Study with Context Tracking

**E. Lutin**<sup>1,2</sup>, **K. Evers**<sup>3,4,5</sup>, **C. Van Hoof**<sup>2,6</sup> and **J. Steyaert**<sup>4,5</sup>, (1)Electrical Engineering-ESAT, KU Leuven, Leuven, Belgium, (2)imec, Heverlee, Belgium, (3)Parenting and Special Education Research Unit, KU Leuven, Leuven, Belgium, (4)Leuven Autism Research Consortium (LAuRes), KU Leuven, Leuven, Belgium, (5)Child Psychiatry, UPC-KU Leuven, Leuven, Belgium, (6)OnePlanet Research Center, imec the Netherlands, Wageningen, Netherlands

---

**Background:** Sensory processing difficulties are highly prevalent in individuals with ASD and have been associated with poorer outcomes regarding distress and behavioral difficulties. Current insights into sensory abnormalities in adolescents with ASD are obtained through parent or caregiver reports and standardized self-report questionnaires. However, the reliability of these is limited as individuals with ASD encounter difficulties in delayed reporting of their internal states. Therefore, studies in daily life, combining both subjective and objective measures, might result into a better understanding.

**Objectives:** This study aimed to examine the relationship between self-reported sensory sensitivity and context measures in the daily life of adolescents with ASD. In addition, the study set out to investigate if this relationship is modulated by items of the Adolescent-Adult Sensory Profile (AASP).

**Methods:** 41 adolescents with ASD ( $M_{age} = 13.6$  years,  $SD_{age} = 1.1$  years,  $N_{female} = 8$ ) participated in an experience sampling methodology (ESM) study for 14 consecutive days. Using a smartphone application, they completed momentary questionnaires at randomly varying times between 08:00 and 21:30, up to ten times a day. In this study, we focused on the following ESM item: "There are a lot of sensory stimuli in my environment." Participants expressed their agreement on a 7-point Likert scale. Objective measurements of context were gathered through the same smartphone application. In combination with a wearable sensor, clipped onto the participants' clothing, this application tracked location, sound characteristics, temperature, and light intensity. At the end of the study, participants were asked to complete a set of standardized questionnaires, including the AASP. A total of 35 participants completed all questionnaires.

A preliminary analysis was done by means of multilevel modelling. Firstly, a linear mixed effects model was built, predicting the stimulus sensitivity rating based on the previous stimuli rating, the covariates age and sex, and four context measures (location and the averages for sound level, temperature and light intensity) extracted from a 10-minute window prior to the ESM questionnaire. Secondly, a grouping variable based on AASP items was added to the model in interaction with the significant context measures.

**Results:** We collected 2863 ESM answers, of which 1824 answers included successful measurements of physical context. The previous stimulus sensitivity rating was a positive predictor of the next rating. Regarding the context measures, participants reported significantly more sensory stimuli at school in comparison to home and with increasing average sound level. In the follow-up analysis, a significant interaction appeared between the average sound level and a grouping based on the auditive items of the AASP for sensory sensitivity and sensory avoiding: participants in the high sensitivity group (based on subjective measures, gathered through the AASP) reported more sensory stimuli in case of loud noise (based on objective quantification in daily life).

**Conclusions:** This is the first study to examine sensory sensitivity in adolescents with ASD by combining subjective and objective measures in daily life. Momentary self-reported sensory stimuli were found to vary with changes in context. Self-reported sensory sensitivity, registered by the AASP, affected the strength of this relationship.

**518.109 (Virtual Poster)** Simple, High-Performance Classification Model for Autism Based on Machine Learning and Pupillary Response

**Q. Liu, W. You, X. He, D. Li, L. Shen and X. Gao, School of Medicine, Tsinghua University, Beijing, China**

---

**Background:**

Early diagnosis of autism spectrum disorder (ASD) in clinical practice is very important for improving autism treatment. Recent studies have investigated the early diagnosis of children with ASD using machine learning and eye-tracking. Many studies have proved that eye tracking and machine learning are feasible for the early diagnosis of ASD. However, the processing of eye-tracking data, especially pupillary response data, can

be further optimized. We are trying to find an eye-tracking and pupillary response feature extraction method based on relative pupil response to explore the abnormal pupillary response in children with autism. Furthermore, we hope to establish a classification model for autism.

### Objectives:

Find out the significant differences of pupillary response characteristics between children with ASD and children with typical development(TD), and explore a high-performance classification model for autism.

### Methods:

Twenty-five children with ASD and 50 children with TD were recruited. An SMI RED500 desktop eye-tracking system was used for stimulus presentation and data acquisition. The experiment consists of six white pictures, six black pictures and one gray picture. Firstly, we presented a 10s gray stimulus for baseline calibration, and then pictures were presented alternately in the order of black and white, each picture lasting for 5s.

Collecting the pupillary data of all subjects and the original data were interpolated and filtered. Seventy features are extracted from the minimum, middle, maximum, average and standard deviation of relative amplitude, time, velocity and latency of pupil response, and the feature of adequate picture number is added. Further statistical analysis and modeling classification was done by Python.

### Results:

In the two types of the subject (children with ASD and children with TD), there are 24 characteristics with significant differences ( $P < 0.05$ ). With these features, the optimal features are determined by the grid search method. Moreover, the model has an average classification accuracy of 90.67% and an average AUC of 92.24%. Compared with other methods, our model has better classification performance. (Refer to attached table 1)

### Conclusions:

The abnormal pupillary response of autistic children is mainly characterized by greater dilation and smaller contraction. These abnormal features may provide good help for the early diagnosis of autism in the future.

**518.110 (Virtual Poster)** The 16 Early Signs Checklist: A Brief Observational Screener to Improve Detection of Early Signs of Autism in Very Young Children

**J. L. Hooker<sup>a</sup>, A. Delehanty<sup>a</sup>, C. Nottke<sup>a</sup> and A. M. Wetherby<sup>a</sup>, (1)Florida State University Autism Institute, Tallahassee, FL, (2)Speech-Language Pathology, Duquesne University, Pittsburgh, PA**

**Background:** The median age of diagnosis of autism (ASD) has not changed in over a decade (Maenner et al., 2020). The availability of accurate, validated screening instruments continues to contribute to delayed identification of ASD (see Carbone et al., 2020 and Guthrie et al., 2019). Behavioral observations are a critical component of an evaluation for determining eligibility for ASD-specific services; yet they often require significant time and training to complete. There is limited research examining community-viable observational screeners for ASD in children under three.

**Objectives:** The purpose of this study is to explore the preliminary performance of the 16 Early Signs Checklist as an observational screener in distinguishing toddlers with ASD from those who are non-spectrum.

**Methods:** Participants include 211 children recruited from the community-based FIRST WORDS® Project (see Delehanty & Wetherby, 2021; Wetherby et al., 2008). Children received a best-estimate diagnosis of ASD (n=121), DD (n=46), or TD (n=44) near 36 months of age.

**Measures.** The Systematic Observation of Red Flags (SORF; Dow et al. 2016, 2020;) was used to code a video-recorded home observation of parent-child interaction collected at 20.25 months (SD=1.99; see Delehanty & Wetherby, 2021). The 16 Early Signs Checklist (Figure 1) comprises 16 early signs of ASD based on DSM-5 diagnostic criteria. Items are scored dichotomously as present/absent. The Checklist will be coded and compared across two methods: 1) from item-level scoring of the SORF, and 2) directly from the home observation. Research assistants coding the Checklist received no training on the SORF or ADOS and have limited knowledge of ASD. Coder training uses the *16 Early Signs by 16 Months Lookbook* and two short videos—*Can you spare 2 Minutes?* and *Another Minute?*

**Results:** Preliminary results of the Checklist scored from the SORF indicated high agreement between SORF subscales and the total number of early signs present ( $rs=0.54-0.98$ ). Child age at the observation was not significantly associated with the number of early signs ( $r=-.02$ ). Results of oneway ANOVA indicated a significant main effect of group on the total number of signs on the Checklist,  $F(2,208)=29.94, p<.001$ . Children with ASD had significantly more total signs compared to children in the DD ( $M_{diff}=1.09, p<.05$ ) and TD groups ( $M_{diff}=3.15, p<.001$ ). On average, children with ASD showed 6.25 signs during the home observation (SD=2.57). Coding of the Checklist scored directly from the video home observation is underway and will be completed and analyzed prior to the conference. Agreement between all three measures will be examined as well as differences in the number of identified early signs between diagnostic groups.

**Conclusions:** Results provide preliminary support for the simplified scoring scheme of the 16 Early Signs Checklist derived from the SORF scoring. The brevity of the required training will demonstrate the feasibility for use by community providers. The potential of the Checklist as a brief observational screener of ASD signs in the home environment, along with the companion parent-report version, is promising in accelerating the path to earlier detection and ASD-specific services.

**518.111** (*Virtual Poster*) Unpicking the Drivers of Neuropsychiatric Risk in Children with Autism Spectrum Disorders That Are Associated with Intellectual Disability

**J. Wolstencroft<sup>1</sup>, R. Srinivasan<sup>2</sup>, I. D. Imagine<sup>1</sup> and D. H. Skuse<sup>3</sup>,** (1)UCL GOS Institute of Child Health, London, United Kingdom, (2)UCL GOS ICH, London, United Kingdom of Great Britain and Northern Ireland, (3)Institute of Child Health, London, United Kingdom

**Background:**

IMAGINE-ID is a national UK study of children with Intellectual Disabilities (IDs) of known genetic origin that aims to identify genotype-phenotype risk. IDs are characterised by significant limitations in cognitive and adaptive skills and a substantially increased risk of ASD. Children with an ID with or without an associated ASD are at increased risk of internalising and externalising difficulties and their parents are reported to have elevated rates of psychological distress.

**Objectives:**

We aimed to identify the range and severity of co-occurring psychopathology in children with pathogenic CNVs or SNVs that were associated with both ASD and ID and to compare those comorbidities with children whose ID was not associated with ASD. We also tested the hypothesis that parents of children who had an ASD in addition to ID would experience significantly greater psychological distress than those whose child had ID alone, irrespective of the severity of their child's intellectual disability.

**Methods:**

3,031 children and young people (5-19 years) were recruited via UK National Health Services and patient support groups. The Development and Wellbeing Assessment (DAWBA), Strengths and Difficulties Questionnaire (SDQ) and the Everyday Feelings Questionnaire (EFQ) were administered to caregivers. The DAWBA is a comprehensive online interview used in national UK surveys of child mental health. An Index of Multiple Deprivation (IMD) was obtained from postcode data. Logistic regression models tested the association between ID (with and without ASD), co-occurring mental health, and parental psychological distress, controlling for children's sex, developmental level, physical health and IMD.

**Results:**

Of 1,904 participants (M=9.15, SD=3.75). 36.8% (n=701) had co-occurring ASD. Male-female ratio in those with ASD was 1.8 to 1 (1:1 in non-ASD group). Children whose ID was associated with ASD were at increased risk of ADHD (OR 2.18, 95% CI 1.75-2.72, p<.0001), emotional disorders (OR 2.1, 95% CI 1.56-2.83, p<.0001), and conduct disorders (OR 2.31, 95% CI 1.78-3.01, p<.0001) in univariable models, after adjustment for child sex, developmental level, physical health and IMD score.

Parents of children whose ID was associated with ASD reported significantly greater psychological distress (EFQ scores) than parents of children with IDD alone (p=.001). The statistical significance of this association remained after adjustment for child characteristics (sex, developmental level, physical health) and socio-economic deprivation, but not after adjustment for co-occurring child behavioural difficulties (p=.24).

**Conclusions:**

Children whose ID was associated with ASD had more severe, and a wider range of, behaviour difficulties compared to those with ID alone. This difference persisted after controlling for child characteristics and socio-economic deprivation. Parental distress was greater in families whose children had co-occurring IDD and ASD, compared to those with IDD alone. This difference also persisted after controlling for child characteristics and socio-economic deprivation. ASD (as a diagnostic category) was no longer significantly associated with parental psychological distress when co-existing behavioural problems were controlled, implying stress in families whose child has both ASD and ID is magnified by the behavioural problems specifically associated with ASD.

---

**Background:** To understand the origins of brain diversity including neurodevelopmental conditions such as autism, we need to look early in development. In these studies, we are using MRI to examine the neonatal brain and address the following questions.

**Objectives:** 1) What architecture in the young human brain supports subsequent development? 2) How does individual variation arise? 3) Are there any early brain signatures which are linked to early childhood differences in general development and/or social cognition?

**Methods:** All neonates were recruited and scanned as part of the developing Human Connectome Project (dHCP) and AIMS-2-TRIALS Brain Imaging and Development in Babies programmes as approved by the national Research Ethics Committee in the U.K. This dataset permitted analyses of multiple modalities of brain macro (sMRI) and microstructure (DTI) and function (resting-state fMRI). Where possible, participants attended for a follow-up developmental assessment at 18 months which included the Bayley Scales of Infant and Toddler Development and the Q-CHAT (Quantitative Checklist for Autism in Toddlers). Data acquired from up to  $n = 241$  neonates (including  $n = 63$  children scanned twice in the first few months of life) contributed to a range of analyses. Our initial analyses examined the development across whole brain networks. Our subsequent analyses focused on the development of networks of interest - namely cerebellar networks, because the cerebellum has been so closely linked to autism in older individuals.

**Results:** In our whole brain analyses: We observed dynamic changes in the structure of cortical networks over an 8-week period after birth across a large group of neonates. When examining maps of neural connections (connectomes) at the level of the individual we found that structural connectivity is already relatively stable by birth and indeed, may act like a 'fingerprint' of the individual. In contrast, the functional connectome is much more changeable. In our cerebellar network-of-interest analyses: We found that functional connectivity from Crus I/II to somatosensory-motor and frontal cortices, as well as from vermis to somatosensory-motor and frontal cortices at birth was significantly associated with social cognition assessed using the Q-CHAT at 18 months, but not with general cognitive and motor abilities. However, there were sex-differences. Lower functional connectivity between vermis and cortex in the neonatal period was associated with higher Q-CHAT scores at 18 months in males, but the opposite was true for females. Structural connectivity of cerebellar networks at birth was not predictive of 18 month outcomes.

**Conclusions:** Thus, around birth, brain structure is already highly organised and is relatively stable. However, the brain's functional networks are changing more rapidly, most likely because the young brain is exposed to the external world for the first time, and infants are rapidly learning new skills. Our data suggests that the functional maturation status of cerebellar networks at birth may be especially important for the emergence of social behaviours linked to autism.

#### **222.002 (Panel) Salience Network Functional Connectivity in Neonates with High Likelihood of Autism**

*D. Scheinost<sup>1</sup>, J. Chang<sup>2</sup>, C. Lacadie<sup>3</sup>, E. Brennan-Wydra<sup>4</sup>, R. T. Constable<sup>3</sup>, L. R. Ment<sup>5</sup> and K. Chawarska<sup>4</sup>, (1)Radiology & Biomedical Imaging, Yale School of Medicine, New Haven, CT, (2)Statistics and Data Science, Yale University, New Haven, CT, (3)Yale University, New Haven, CT, (4)Child Study Center, Yale University School of Medicine, New Haven, CT, (5)Pediatrics, Yale School of Medicine, New Haven, CT*

---

**Background:** Converging evidence from children, adolescents, and adults implicates alterations of the salience network—a large-scale brain network responsible for detecting and filtering salient stimuli of one's internal and external environment—in autism. Similarly, early behavioral markers of autism in later infancy and toddlerhood (e.g., reduced attention to social stimuli) are consistent with atypical patterns in salience network connectivity. However, functional connectivity of the salience network has not been examined in the context of neonates with differential likelihood of autism. Overall, salience network disruptions during the neonatal period could underlie later behavioral markers of autism during infancy and toddlerhood.

**Objectives:** To examine salience network connectivity in a neurodiverse group of neonates with and without familial history of autism (high likelihood, HL, and low likelihood, LL, respectively) and the developmental trajectories on these connections from the third trimester through the neonatal period.

**Methods:** 41 neonates (13 HL and 28 LL, 60% male) were scanned during natural sleep on a Siemens Prisma 3T scanner. The mean age was 3.89 weeks (SD=1.52). Standard functional connectivity preprocessing was performed. Functional connectivity was assessed using regions of interest (or seeds) placed in the left and right insula—key nodes of the salience network. Multiple comparisons correction was performed using cluster-based inference. In a subset of these participants, the First Year Inventory (FYI) was collected at 18 months in 10 HL and 15 LL toddlers. To assess developmental trajectories of these connections, low likelihood fetuses were scanned longitudinally at 30-32 weeks gestation ( $n=19$ ) and 34-36 weeks gestation ( $n=18$ ) as well as during the neonatal period. Analogous connectivity methods were used to assess connectivity in the fetuses.

**Results:** HL neonates exhibited greater connectivity between the left insula and angular gyrus edge when compared to LL neonates ( $p<0.05$ , corrected). In both groups combined, this connection correlated with social-communication scale of the FYI ( $r=0.589$ ,  $p=.002$ ,  $df=23$ ). In both fetal

time points, the insula exhibited only local (i.e., ipsilateral) connections. In contrast, after birth, the insula exhibited connectivity to the contralateral hemisphere.

**Conclusions:** Examining functional networks in the perinatal period can inform the associations between likelihood of autism and later phenotypes by identifying intermediary brain correlates that may ultimately underlie these behaviors. We show that atypical patterns of connectivity in the salience network are observable in neonates with high likelihood of autism, and these patterns predict behaviors a year later. Based on longitudinal fetal-neonatal connectivity, connections altered in neonates with high likelihood of autism develop across the perinatal period, particularly between the last month of the third trimester and the first postnatal month. Identifying patterns of functional connectivity in the fetal and neonatal periods as well as their associations to later behavior will pave the way for a better understanding of the developmental timing of putative alterations in brain and behaviors associated with autism.

**222.003 (Panel) Predictive Links between Salience Network Connectivity and Attention to Social Partners in Neonates with Familial History of Autism**

**A. Vernetti<sup>1</sup>, R. Ray<sup>2</sup>, D. Scheinost<sup>3</sup>, L. R. Ment<sup>4</sup>, S. Macari<sup>1</sup>, H. Neiderman<sup>5</sup>, C. Nutor<sup>1</sup>, C. D. Gershman<sup>1</sup>, H. Feiner<sup>1</sup>, R. Foster<sup>6</sup>, R. T. Constable<sup>7</sup>, J. Chang<sup>2</sup> and K. Chawarska<sup>1</sup>,** (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Statistics and Data Science, Yale University, New Haven, CT, (3)Radiology & Biomedical Imaging, Yale School of Medicine, New Haven, CT, (4)Pediatrics, Yale School of Medicine, New Haven, CT, (5)Psychology, University of Washington, Seattle, WA, (6)Child Study Center, Yale School of Medicine, New Haven, CT, (7)Yale University, New Haven, CT

**Background:** Selective attention to faces, known to be reduced in infants and toddlers with autism (Chawarska et al.,2013, Elsabbagh et al.,2013), is supported by several large-scale cortical networks including the salience network (SN), and the default mode network (DMN). The salience network has been shown to regulate attention to behaviorally meaningful stimuli and has been heavily implicated in autism (Menon & Uddin 2010). Functional connectivity studies have also shown atypical and age-varying connections between DMN regions in autism (Assaf et al.,2010; Burrows, Laird, & Uddin,2016). Although signs of altered social attention to dynamic faces in infants later diagnosed with autism have been reported in infants as young as 6 months of age (Chawarska et al.,2013; Shic et al.,2014; Macari et al.,2021), the early brain mechanisms that contribute to the emergence of this vulnerability have not been identified.

**Objectives:** To examine the predictive links between SN within-network and SN-DMN between-network intrinsic functional connectivity (iFC) at birth and attention to faces measured using eye tracking at 4, 6, 8, and 12 months in infants with (high-likelihood, HL) and without (low-likelihood, LL) familial history of autism.

**Methods:** 45 neonates (13 HL) were scanned during natural sleep on a Siemens Prisma 3T scanner at the mean age of 3.89weeks (SD=1.52). iFC was assessed using seeds placed in the left and right anterior insula (aInsula) and the anterior cingulate cortex (ACC), the key nodes of the SN, and SN-DMN iFC was assessed between left aInsula and angular gyrus node in the DMN. 24 of the neonates (9 HL, 54% male) completed a social selective attention eye-tracking task (SSA4.0) at 4, 6, 8, and 12 months involving watching a video of a person where gaze (direct/down) and speech (child-directed speech/silence) were manipulated. Linear mixed models (LMM) were used to evaluate the contribution of iFC at birth and age at the time of the eye-tracking task to percent looking to the face region during SSA4.0 and included main and interaction effects of iFC and age, main and interaction effects of speech and gaze conditions (all fixed effects), random intercepts for subject, and random slopes for age.

**Results:** The LMM models assessing contribution of the SN iFC and the SN-DMN iFC to attention to the face region during the first year of life indicate that, at 4 months of age, while higher iFC between the SN and DMN network nodes was associated with lower attention to faces ( $p<0.001$ , Fig1, left panel), higher iFC between the SN nodes was associated with higher attention to faces ( $p=0.018$ , Fig1, right panel).

**Conclusions:** Both lower between-network connectivity and higher within-network connectivity at birth, thought to respectively indicate better network segregation and synchronization in typical development, predicted higher attention to faces at 4 months, a highly formative age when infants begin to develop sophisticated face processing skills and engage in reciprocal interactions. This is the first demonstration of complex patterns of brain functional connectivity at birth associated with social attention that may be impacted in neonates who later develop autism.

**222.004 (Panel) Altered Theta-Beta Ratios in Infants at Elevated Likelihood of Neurodevelopmental Disorders**

**J. Begum Ali<sup>1</sup>, A. Goodwin<sup>2</sup>, L. Mason<sup>3</sup>, G. Pasco<sup>3</sup>, T. Charman<sup>2</sup>, M. H. Johnson<sup>1</sup> and E. J. Jones<sup>3</sup>,** (1)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom

**Background:** Neurodevelopmental disorders such as Autism Spectrum Disorder (ASD) and Attention Deficit Hyperactivity Disorder (ADHD) are typically diagnosed in early/middle childhood through a combination of clinical interviews and observer-reports. The genetic factors that predispose an individual towards these highly heritable conditions likely act predominately prenatally, affecting brain development for years before the consolidation of the full clinical phenotype (Faraone & Larsson, 2019). Identifying the brain changes that precede the onset of behavioural symptoms could help with earlier identification of individuals who require additional support, and could provide useful outcome measures for early interventions. One such neural change is the balance of theta and higher frequency oscillations (typically theta-beta ratio; TBR). Previous research has shown that a subset of children with ADHD show differences in TBR and its use as a prognostic indicator has been suggested (Arns et al., 2013).

**Objectives:** We endeavoured to examine TBR using a prospective longitudinal infant sibling design (e.g., in infants with an elevated likelihood of developing ASD, ADHD, ASD+ADHD or neither). Examining both ASD and ADHD allows us to investigate specificity of TBR alterations to either condition, or indeed whether atypicalities in TBR are more broadly related to neurodevelopmental disorders.

**Methods:** We used high density EEG (128-channels) to investigate the theta/low beta ratio in 10-month-old infants; with theta defined as 2-5Hz and low beta defined as 9-14Hz.

**Results:** Infants with an elevated likelihood of ADHD showed a lower TBR-Low than those with a lower likelihood of ADHD [ $F(1, 136) = 4.21, p = .042, \eta^2 = .03$ ; Figure 1]. There was no significant effect of an elevated likelihood of ASD [ $F(1, 136) = .93, p = .335, \eta^2 = .007$ ] or an interaction of ASD\*ADHD elevated likelihood [ $F(1, 136) = .006, p = .939, \eta^2 = 0$ ]. Lower TBR-Low in our elevated likelihood of ADHD group was driven by lower theta [ $F(1,136) = 5.25, p = .023, \eta^2 = .04$ ] and higher beta [ $F(1,143) = 4.32, p = .04, \eta^2 = .03$ ] in this cohort. Further, we found relationships between TBR-Low in infancy and ADHD-related temperamental traits at 2 years, specifically lower TBR associated with greater Surgency [ $r(25) = -.43, p = .03$ ], greater Impulsivity [ $r(24) = -.5, p = .01$ ] and greater Sociability [ $r(23) = -.53, p = .01$ ; Figure 2]. We will discuss possible explanations for these associations.

**Conclusions:** This is the first demonstration that alterations in TBR are present prior to behavioural symptoms of ADHD. However, these alterations manifest differently than those sometimes observed in older children with an ADHD diagnosis. Importantly, altered TBR was not seen in infants at elevated likelihood of developing ASD, suggesting a degree of specificity to ADHD. Taken together, these findings demonstrate that there are brain changes associated with a family history of ADHD observable in the first year of life.

## PANEL — EARLY DEVELOPMENT (< 48 MONTHS)

### 230 - The Neurodevelopment of Language in Infants at High Risk for Autism

**Panel Chair:** Lisa Yankowitz, *Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA*

**Discussant:** Meghan Swanson, *University of North Carolina, Chapel Hill, NC*

#### 230.001 (Panel) Brain Morphometry in Infants Later Diagnosed with Autism Is Related to Later Language Skills

Hazlett<sup>8</sup>, J. Pandey<sup>9</sup>, R. T. Schultz<sup>8</sup>, T. St. John<sup>9</sup>, J. Piven<sup>4</sup>, M. Swanson<sup>1</sup> and .. The IBIS Network<sup>3</sup>, (1)The University of Texas at Dallas, Richardson, TX, (2)Psychiatry and Computer Science, University of North Carolina, Chapel Hill, NC, (3)University of North Carolina, Chapel Hill, NC, (4)\*co-senior author, University of North Carolina, Chapel Hill, NC, (5)Communication Sciences and Disorders, University of Texas at Dallas, Richardson, TX, (6)University of Minnesota, Minneapolis, MN, (7)Radiology, University of Washington, Seattle, WA, (8)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (9)University of Washington, Seattle, WA

**Background:** Infants with autism show deficits in language as early as 12 months of age (Swanson et al., 2017) and 29% of school-age children with autism are nonverbal or minimally verbal (Tager-Flusberg & Kasari, 2013). Recent studies have indicated that atypical brain development may precede the emergence of the associated features of autism, like language (Emerson et al., 2017). The neurobiological basis for these impairments has yet to be fully explored during the pre-symptomatic period for autism. Such studies would contribute to our understanding of the development of early autism.

**Objectives:** The objective of the study was to explore the relationships between two sets of variables: 1) measures of regional brain morphometry (surface area and cortical thickness) at 6 and 12 months of age and 2) receptive language and expressive language subscales on the Mullen Scales of Early Learning (MSEL) at 24 months of age.

**Methods:** Surface area and cortical thickness measurements were obtained for 78 brain regions using the AAL atlas from a structural MRI scan at 6 and 12 months. At 24 months, infants completed the MSEL and were included if they had receptive language and expressive language t-scores. Covariates included: sex, mother's education, data collection site, age at data collection, total surface area (for surface area regions), and cube root of intracranial volume (for cortical thickness regions). We used partial least squares correlation (PLSC) to analyze associations between the two sets of variables. Separate PLSC analyses were run for three groups of infants: those with low probability of autism who were typically developing (LP-Neg,  $n = 80$ ), those with high probability of autism who did not receive an autism diagnosis (HP-Neg,  $n = 128$ ), and those with high probability of autism who received an autism diagnosis (HP-ASD,  $n = 31$ ).

**Results:** Results revealed significant patterns of association between the brain morphometry measures and language for all groups (Table 1 and Figure 1 for an example of data from 6 months). No regions were found to be consistently significant across all three groups. Some regions associated with classic language models were found to be significant. For example, in the HP-ASD group cortical thickness at 6 months in the left inferior frontal gyrus was significantly associated with language. However, there were also regions outside the classic language models that were significant. For example, in the HP-ASD group there was a significant association between surface area at 6 and 12 months in the left middle occipital gyrus and later language. All reported relationships were stable across bootstrap resampling.

**Conclusions:** While results indicated significant relationships between regional surface area and cortical thickness at 6 and 12 months and language skills at 24-months of age, the three groups did not show the same patterns of relationships. Significant regions were found in all lobes of the brain.

These results suggest that future research on the neurobiology of language in infants with autism take a more comprehensive approach when selecting regions of interest.

---

**Background:** The first two years of life are characterized by incredibly rapid growth in expressive communication ability, with infants progressing from babbles and coos to words and phrases. Little is known about the relationship between expressive communication and intrinsic functional connectivity in the infant brain, particularly with regard to individual vocalization behaviors. There is evidence that regions within the language network are weakly connected when infants are born, and develop increasingly adult-like connectivity over the first two years of life. A small number of studies suggest that increased connectivity between language regions in infancy and toddlerhood is associated with higher scores on standardized language measures (Bruchhage et al. 2020, Emerson et al., 2016). No studies have yet examined the relationship between fine-grained measures of vocalization behavior and language network connectivity.

**Objectives:** Test the hypothesis that infant vocalizations are positively associated with intrinsic functional connectivity between key regions in the adult language network (Broca's and Wernicke's areas) in a longitudinal sample of infants at high and low risk for autism spectrum disorder (ASD).

**Methods:** Functional connectivity was assessed using MRI (fcMRI) during natural sleep in infants aged 6m (n=107), 12m (n=131), and 24m (n=141) at high and low familial risk for ASD, drawn from the multisite Infant Brain Imaging Study. Vocalization variables were derived from video-recorded clinical interactions: speechlike rate (the number of speechlike vocalizations per minute of recording time), speechlike ratio (the proportion of vocalizations that are speechlike), canonical babbling ratio (the proportion of syllables that have a consonant, a vowel, and smooth transition between them, at 6 and 12 months only), and socially-directed proportion (the proportion of all vocalizations that are directed toward another person, at 6 and 12 months only). Regions of interest representing Broca's and Wernicke's areas were placed following a large meta-analysis (Tomasi & Volkow, 2012). Generalized linear models assessed relationships with each of the four vocalization variables, with z-transformed time-series correlations between Broca and Wernicke ROIs as predictors after controlling for site, sex, and maternal education (FDR-corrected within each age (q<0.05)).

**Results:** At 6 months, Broca-Wernicke connectivity was positively associated with canonical babbling ratio and the proportion of vocalizations that were socially directed (Figure, Table). At 12 months, canonical babbling ratio, speechlike rate, and proportion of vocalizations that were speechlike were all *negatively* associated with Broca-Wernicke connectivity. At 24 months, speechlike rate and proportion speechlike continued to be negatively associated with Broca-Wernicke connectivity.

**Conclusions:** Hypothesized relationships between infant vocalizations and connectivity among classic adult language areas were generally not supported, and diminished connectivity between Broca's and Wernicke's areas in the second year of life was associated with more mature vocalization types. These findings, which may be influenced by the exact selection of Broca's and Wernicke's regions of interest, represent a first attempt to relate infant vocalizations to functional connectivity.

---

**Background:** Autism spectrum disorder (ASD) is a highly heritable disorder. Approximately 20% of infants who have an older sibling with ASD go on to later develop ASD and an additional 28% display other developmental concerns including language delays. Language atypicalities are some of the earliest phenotypic indicators of ASD, detectable by 12 months of age and commonly persist throughout the lifespan. Previous research has linked white matter microstructure to cognitive development in non-clinical samples and to social development outcomes in ASD. However, the unique contributions of white matter microstructure to language development in ASD remains unexplored.

**Objectives:** This study sought to examine the longitudinal relationships between white matter microstructure and expressive and receptive language development in high-risk infant siblings and controls at 6, 12, and 24 months.

**Methods:** Participants were recruited from the Infant Brain Imaging Study and included 140 controls (low familial ASD risk; LR-Neg), 62 high-familial risk infants later diagnosed with ASD (HR-ASD), and 227 high-familial risk infants who were negative for ASD (HR-Neg). Infants contributed behavioral and imaging data at 6, 12, and 24 months. Measures of language development included the receptive and expressive age-equivalent scores from the Mullen Scales of Early Learning (MSEL). Diffusion weighted images were used to perform fiber tractography and compute fractional anisotropy (FA) at each age. Tracts of interest included the bilateral arcuate, uncinate, and inferior longitudinal fasciculus as well as the genu, splenium, and body of the corpus callosum. Preliminary correlations were conducted to evaluate the relationships between white matter FA and language variables at 6, 12, and 24 months.

**Results:** Significant relationships between white matter microstructure and language emerged uniquely in the bilateral arcuate fasciculus. At 6 and 12 months, the right arcuate (but not the left arcuate) was significantly related to expressive language (but not receptive language) in the HR-ASD group at both time points,  $r = .38$  and  $.37$  respectively,  $ps < .017$  (Fig. 1 and 2). The HR-Neg group also demonstrated significant correlations between expressive, receptive language and left and right arcuate microstructure at 6 months (but not the LR-Neg group); however, these relationships did not hold at 12 and 24 months. At 24 months, both the left and right arcuate were significantly associated with both receptive and expressive language age equivalent scores for the HR-ASD groups,  $rs > .43$ ,  $ps < .0023$ ; these relationships were not present in the LR-Neg and HR-Neg groups.

**Conclusions:** These findings emphasize the developmental role of the bilateral arcuate fasciculus in language development in early autism and suggest potential neurodevelopmental risk trajectories.

**230.004 (Panel) Quantitative Autistic Traits in Parents and the Development of Language and Language Circuitry in Infants**

**Background:** Atypical language development is present in children with autism spectrum disorder (ASD) as early as the first year of life (Estes et al., 2015, Swanson et al., 2017). Recent research has demonstrated that receptive language is an endophenotype of ASD, where at 24 months, high-risk (HR) siblings of children with autism exhibit a greater likelihood of lower language abilities (Marrus et al., 2018; Girault et al., 2020), regardless of an ASD diagnosis. Given the familial nature of language phenotypes, parental traits may serve as informative predictors of HR sibling development. Quantifying markers of elevated risk allows for earlier detection and establishes targets for early intervention.

**Objectives:** In this study, we examine the ability of parental quantitative autistic traits (QATs) to inform infant receptive language (RL) and expressive language (EL) development, as well as language-related white matter (WM) fiber tract integrity at 24 months of age.

**Methods:** Ninety-seven (97) high-risk infant siblings of children with ASD and 49 low-risk controls were included in this study. Clinical best estimate diagnosis was made at 24 months using DSM-IV-TR criteria; 20 HR children developed ASD (HR-ASD). Parent QATs were measured using the total score from the Social Responsiveness Scale, Second Edition (SRS-2). Parents were scored using the Informant Report form when completed and available, but if no Informant Report was available, Self-Report forms were used. Infant language was measured using the Mullen Scales of Early Learning (Mullen) RL and EL domains. Infant WM measurements were captured using diffusion tensor imaging; fractional anisotropy (FA) of the arcuate fasciculus was the primary WM measure of interest. The relationship between parental QATs and infant language and WM development was investigated using linear mixed models adjusted for age, sex, and study site.

**Results:** Among the HR-ASD group, maternal QATs were significantly associated with lower infant RL ( $\beta = -0.522$ ,  $p = 0.002$ ) and reduced right arcuate FA development ( $\beta = -0.699$ ,  $p = 0.037$ ) (Figure 1). This effect was not significant in the infant siblings that do not develop ASD (HR-NEG) or the typically developing controls (LR-NEG). Paternal SRS scores were not significantly related to infant language or white matter in any group.

**Conclusions:** This study suggests that maternal autistic traits correlate with both infant sibling language and white matter development at 24 months of age. These findings will help further characterize the familial nature of differential language development and neurodevelopment in ASD, ultimately identifying markers of ASD risk in the first two years of life.

## ORAL SESSION - 2A — EARLY DEVELOPMENT (< 48 MONTHS)

---

**Background:** Alterations in excitation/inhibition (E/I) balance are implicated in the aetiology of autism and other neurodevelopmental conditions. As most existing research has examined E/I balance in older individuals, it is unknown whether alterations in E/I balance precede autism symptom emergence. Additionally, recent frameworks hypothesise that emerging infant executive functioning-type abilities (e.g., executive attention) may moderate the impact of early neural alterations.

**Objectives:** To test whether 1) infants enriched for increased likelihood of autism outcomes are characterized by alterations in E/I balance, 2) alterations in infant E/I balance predict autism and attention-deficit hyperactivity disorder (ADHD) traits in toddlerhood, and 3) emerging executive functioning abilities moderate the association between infant E/I balance and neurodevelopmental traits in toddlerhood.

**Methods:** At-rest electroencephalography (EEG) recordings was collected from 10-month-old infants (N=155), who were at typical likelihood for autism and/or ADHD (N=24), or at elevated likelihood (EL) for neurodevelopmental outcomes, either by virtue of having a first-degree relative with autism (EL-autism; N=67), ADHD (EL-ADHD; N=24), or both (EL-autism+ADHD; N=19), or having a diagnosis of Neurofibromatosis 1 (NF1) (N=21).

A subgroup of infants (n=94) also completed assessments of executive attention at 24 months (using the Early Childhood Behavioral Questionnaire), and autism (using the Preschool Social Responsiveness Scale-2) and ADHD (using the Preschool Child Behavior Checklist) traits at 36 months.

Measurement of E/I balance was extracted from EEG data by estimating the aperiodic slope of the power spectrum (e.g., 1/f) using the fitting oscillations & one over f (FOOOF) pipeline. To test group differences in aperiodic slope, two mixed-effect models were run with region (frontal, central, posterior) as a within-subjects factor. The first compared NF1 against typical likelihood infants. The second compared typical and elevated likelihood groups, testing the effect of EL-autism and EL-ADHD status, and their interaction. Region, age at 10-month visit, number of EEG trials and sex were included as covariates.

Next, the average aperiodic slope across regions was calculated and two linear regressions were run, predicting 36-month autistic and ADHD traits respectively. We tested a direct effect of 10-month aperiodic slope and an aperiodic slope\*24-month executive attention interaction. We included age at 10-month visit, number of EEG trials, sex and group (EL-autism, EL-ADHD, and their interaction) as covariates.

**Results:** Mixed-effect models found infants with NF1 displayed steeper aperiodic EEG slopes than typical likelihood infants ( $b=.07$ ,  $p=.01$ ; Figure 1, left panel), indicative of enhanced inhibition. Infants at familial elevated likelihood for autism and/or ADHD did not display any alterations in E/I balance. Longitudinal analyses found a significant aperiodic slope\* executive attention interaction ( $b=-4.08$ ,  $p=.03$ ), such that steeper 10-month aperiodic slopes predicted greater 36-month autism traits, but only in infants who had lower executive attention (Figure 1, right panel). No associations were found with ADHD traits.

**Conclusions:** Results suggest increased cortical inhibition may be one feature on the developmental pathway to autism outcomes. However, early alterations in E/I balance did not predict autism traits in those with strong early executive function, highlighting the importance of considering interacting risk and resilience factors when seeking to understand neurodevelopmental outcomes.

**302.002** (Oral) Neonatal Neurobehavior in Infants with Autism Spectrum Disorder  
**J. Bradshaw<sup>1</sup>, D. Shi<sup>1</sup>, C. A. Saulnier<sup>2</sup> and C. Klaiman<sup>3</sup>,** (1)University of South Carolina, Columbia, SC, (2)Neurodevelopmental Assessment & Consulting Services, Decatur, GA, (3)Marcus Autism Center, Emory University, Atlanta, GA

---

**Background:** Neonatal neurobehavioral functioning is a critical component of the overall health and adaptability of the newborn. From birth, newborns engage a neurological and behavioral system designed to achieve and maintain a calm and alert state that supports successful caregiver–infant interaction. These neurobehavioral competencies include the ability to regulate body temperature and involuntary muscle movements, enact appropriate reflexes, and sustain attention during social exchanges. Neonatal neurobehavior in medically high-risk populations (e.g., preterm infants) is predictive of later developmental outcome, but neurobehavioral profiles for infants at elevated familial risk for ASD and who subsequently develop ASD is largely unexplored.

**Objectives:** This study used a longitudinal prospective design of infants at elevated and low familial likelihood of developing ASD to investigate neurological and behavioral maturation; that is, the neurobehavioral phenotype of newborns who later develop ASD. From 1 to 3 months of age, we evaluated neurological integrity and behavioral responsivity of the neonate using the NICU Network Neurobehavioral Scale (NNS).

**Methods:** Neonatal neurobehavior was examined monthly in 1- to 3-month-old infants at elevated and low familial likelihood of ASD ( $n=60$ ). At 2 years, infants were seen for a clinical best-estimate evaluation, resulting in 18 infants with ASD and 36 typically developing infants. Repeated-measures analysis of variance models were conducted to examine the effects of age, diagnostic groups, and their interactions.

**Results:** Statistical models revealed significant effects of time across both groups on the following NNNS variables: attention, regulation, excitability, quality of movement, non-optimal reflexes, and stress. There was a significant main effect of diagnostic group only for the attention scale ( $F_{1,42}=4.59$ ,  $p=0.038$ ), with typically developing infants scoring higher than infants with ASD. This model also revealed a significant interaction effect between diagnostic groups and time ( $F_{2,59}=3.31$ ,  $p=0.043$ ) where the difference increased with time. Upon further examination of the attention items, a significant effect of diagnosis was observed for visual (but not auditory) attention ( $F_{1,43}=6.68$ ,  $p=0.01$ ; TD > ASD) and a significant interaction between diagnosis and time was present for inanimate (object) attention ( $F_{2,60}=5.08$ ,  $p=0.01$ ), but not animate (face and voice) attention.

**Conclusions:** Overall, neurobehavioral functioning for infants with ASD was largely similar to that of typically developing infants. Both groups exhibited similar initial levels and subsequent change in arousal and excitability, self-regulation, and signs of stress. The only neurobehavioral function to differentiate infants with ASD from typically developing infants was the development of attention. Our findings suggest that a trajectory of diminished visual orienting and tracking in the first months of life is a distinct, quantifiable feature in infants who later develop ASD. Attention to objects was different for infants with ASD compared to typically developing infants as early as 2 to 3 months and predicted social-communication skills at 2 years. These findings are consistent with many studies identifying differences in attention for older infants with ASD. In a critical extension of these studies, we identified attention to objects, not faces, as a key indicator of ASD in the first 3 months of life.

### **302.003 (Oral) Dyadic Vocal Contingency in Infants Later Diagnosed with Autism Spectrum Disorder**

**R. K. Sandercock<sup>1</sup>, H. Hazlett<sup>2</sup>, S. S. Meera<sup>3</sup>, J. Parish-Morris<sup>4</sup>, L. D. Yankowitz<sup>4</sup>, S. Plate<sup>4</sup>, M. Swanson<sup>5</sup>, J. R. St. John<sup>11</sup>, J. Piven<sup>2</sup> and .. The IBIS Network<sup>5</sup>, (1)Developmental Behavioral Pediatrics, JFK Partners, University of Colorado School of Medicine, Aurora, CO, (2)\*co-senior author, University of North Carolina, Chapel Hill, NC, (3)National Institute of Mental Health and Neurosciences, Bangalore, India, (4)Center for Autism Research, Children's Hospital of Philadelphia, Philadelphia, PA, (5)University of North Carolina, Chapel Hill, NC, (6)\*Co-senior author, \*\*For the IBIS Network, Washington University School of Medicine, St. Louis, MO, (7)Speech and Hearing Sciences, University of Washington, Seattle, WA, (8)University of Alberta, Edmonton, AB, Canada, (9)Psychiatry (Child) and Radiology, Washington University School of Medicine, St. Louis, MO, (10)Radiology, University of Washington, Seattle, WA, (11)University of Washington, Seattle, WA**

**Background:** Identifying the earliest emerging signs of autism spectrum disorder (ASD) is a priority for understanding how the disorder unfolds and for facilitating the provision of early intervention services. Further, there is a gap in our understanding of mechanisms underlying prodromal differences in socio-communicative behaviors. Dyadic contingency – or, the extent to which one's social and communicative behaviors are temporally related to and dependent upon those of an interactional partner – may be one such mechanism (e.g., Pruett & Povinelli, 2016; Wan, Green, & Scott, 2018), as early contingent interactions scaffold key aspects of development (e.g., Warlaumont, Richards, Gilkerson, & Oller, 2014). The present study used a novel approach to analyze the timing and probability of infant vocal responsiveness to adult social partners.

**Objectives:** Analyze the relationship between contingent vocalization and later language abilities and symptom presentation in infants at low familial likelihood of ASD (LL) and infants at high familial likelihood of ASD with (HL-ASD) and without (HL-Neg) later ASD diagnoses.

**Methods:** A total of 42 infants participated (14 LL, 14 HL-ASD, 14 LL-Neg). Data at 12- and 24-month timepoints were contributed as part of a larger, ongoing longitudinal study – the Infant Brain Imaging Study. Using ELAN (2016), two coders blind to diagnostic outcome coded infant and adult vocalizations during the 12-month Communication and Symbolic Behavior Scales; contingent response probability was calculated using study-specific data extraction in R. Outcome data included language t-scores at 12 and 24 months on the Mullen Scales of Early Learning and diagnostic outcome and autism symptom severity scores (SS) on the Autism Diagnostic Observation Schedule (ADOS-2) at 24 months.

**Results:** At 12 months, the HL-ASD group demonstrated lower probability of vocalizing in response to adult vocalization as compared to the HL-Neg and LL groups ( $F(2,39)=4.30$ ,  $p=.02$ ,  $\eta^2=.18$ ). Across all infants, 12-month contingent vocalization probability was significantly related to 24-month language abilities ( $b=.31$ ,  $t=2.80$ ,  $p=.008$ ), such that infants with greater probability of contingent response at 12 months demonstrated higher combined expressive and receptive language t-scores 1 year later. Contingent vocalization probability was also significantly related to 24-month ADOS-2 SS ( $b=-.45$ ,  $t=-.70$ ,  $p=.001$ ) across all infants, such that lower contingent vocalization probability was significantly related to higher ADOS-2 SS 1 year later. Further, 12-month contingent vocalization probability was significantly related to diagnostic outcome at 24 months ( $\chi^2(2) = 22.63$ ,  $p < .001$ ), wherein every percentage increase in contingent vocalization probability was associated with a 20% decrease in likelihood of autism diagnosis ( $OR = 0.80$ ,  $b = -0.22$ ,  $SE = 0.09$ ,  $p = .009$ ).

**Conclusions:** Given that contingent probability was associated with later language and ASD outcomes, these findings suggest that targeting vocal responsiveness may offer a key opportunity for pre-diagnostic intervention, particularly for infants at heightened likelihood of ASD. This research also identifies a potential mechanism through which early symptoms of ASD are exacerbated, leading to cascading socio-communicative challenges. Continued research identifying patterns of contingent response has important implications for understanding prodromal behavioral markers of ASD, guiding early intervention, and supporting more positive socio-communicative outcomes.

### **302.004 (Oral) The P1 Event-Related Potential Response Is Associated with Sensory Responsivity in Infants with Fragile X Syndrome and High Familial Risk for Autism**

**M. W. Guy<sup>1</sup>, S. Conte<sup>2</sup>, A. L. Hogan<sup>3</sup>, A. Bursalioglu<sup>1</sup>, J. E. Richards<sup>1</sup> and J. Roberts<sup>3</sup>, (1)Loyola University Chicago, Chicago, IL, (2)University of South Carolina, Columbia, SC, (3)Department of Psychology, University of South Carolina, Columbia, SC**

**Background:** Atypical sensory processing and sensory responsivity is widely reported in research on autism spectrum disorder (ASD) and fragile X syndrome (FXS) and may result from atypical neural processing, signal integration, or gating. Examination of sensory processing in infancy could provide insight into the development of atypical sensory responsivity within these disorders. Event-related potentials (ERPs) are valuable for investigating relations between neural correlates of sensory processing and emerging behavioral sensory responsivity. In particular, the infant P1 ERP component is associated with visual sensory orienting, providing a sensitive index to examine early occurring neural responses in relation to observed behavioral sensory responsivity.

**Objectives:** To investigate neural correlates of sensory processing in 12-month-old infants at high-risk for ASD in relation to clinical measures of sensory responsivity concurrently and as a predictor of sensory responsivity in early childhood.

**Methods:** Twelve-month-old infants with FXS ( $n=15$ ), siblings of children with ASD (i.e., ASIBs;  $n=21$ ), and low-risk control (LRC) infants ( $n=21$ ) participated in an ERP study including presentations of familiar and novel faces and toys (Guy et al., 2018). Group differences in P1 amplitude were investigated. The Sensory Experiences Questionnaire (SEQ) total score was used to assess sensory responsivity in participants at 12 months and early childhood ( $M = 43.15$  months). SEQ scores were analyzed in relation to P1 responses.

**Results:** The groups differed on P1 amplitude,  $F(2, 972) = 55.97, p < .001, \eta^2 = .10$ . Amplitude was greater among participants with FXS,  $M = 18.39\mu V$ , than ASIBs,  $M = 10.71\mu V$ , or LRC participants,  $M = 11.01\mu V$ . At 12 months of age, there was an interaction of SEQ score and participant group on P1 amplitude,  $F(2, 864) = 5.16, p = .006, \eta^2 = .01$ . Higher SEQ scores at 12 months were associated with greater concurrent P1 amplitude responses for ASIBs, however, the opposite pattern was observed in LRC infants, and no relation was seen for infants with FXS. In predicting SEQ scores during early childhood from 12-month-olds' ERPs, there was an interaction of SEQ score, group, and stimulus type,  $F(4, 882) = 2.45, p = .045, \eta^2 = .01$ . Among participants with FXS, greater amplitude P1 was associated with higher SEQ scores across stimulus type, while LRC participants showed relations between P1 amplitude and SEQ varied based on stimulus type. There were no significant effects of SEQ scores in early childhood for ASIBs.

**Conclusions:** High-risk infant groups demonstrated unique patterns of P1 activation, which were uniquely associated with sensory responsivity concurrently during infancy and as a predictor during early childhood. Although infants with FXS demonstrated greater P1 amplitude responses than ASIBs or LRC infants, greater SEQ scores were observed only as a predictor of elevated sensory responsivity in early childhood. In contrast, elevated sensory responsivity was associated with greater P1 amplitude during infancy for ASIBs, despite not displaying elevated atypical P1 responses. Results indicate that P1 amplitude is associated with sensory responsivity, but that the nature and developmental timing at which these relations are observed varies based on risk group.

## ORAL SESSION - 12A — EARLY DEVELOPMENT (< 48 MONTHS)

### 318 - Early Communication and Cognition

**318.001 (Oral)** Links between Exposure to More Than One Language in the Home and Neuroanatomical Development in Language Regions in Young Children with Autism Spectrum Disorders

**L. Olson**<sup>1,2</sup>, **B. Chen**<sup>1,2</sup>, **J. S. Kohli**<sup>1,2</sup>, **C. Ibarra**<sup>2</sup>, **S. R. Peña**<sup>2</sup>, **A. Andriasyan**<sup>2</sup>, **L. Ringlee**<sup>2</sup>, **E. Mendez**<sup>2</sup>, **I. Sogutlugil**<sup>2</sup>, **R. A. Müller**<sup>1,2</sup>, **A. C. Linke**<sup>2</sup>, **R. A. Carper**<sup>1,2</sup> and **I. Fishman**<sup>1,2,3</sup>, (1)Joint Doctoral Program in Clinical Psychology, SDSU/UC San Diego, San Diego, CA, (2)Brain Development Imaging Laboratories, San Diego State University, San Diego, CA, (3)SDSU Center for Autism and Developmental Disorders, San Diego State University, San Diego, CA

**Background:** Exposure to more than one language in early childhood is positively associated with language and brain development (e.g., Kuhl, 2011; Costa & Sebastian-Galles, 2014). Children exposed to more than one language in the home have distinct neurodevelopmental trajectories of brain morphology compared to monolingual children (Pilatsikas et al., 2020). For example, bi/multilingual children have increased gray matter density and white matter integrity compared to monolingual peers (Pilatsikas et al., 2020; Li et al., 2014). It is unknown to what extent associations between early exposure to more than one language and structural brain adaptations are present in young children with ASD, given the particular vulnerability of language emergence and development in autism.

**Objectives:** To examine associations between language exposure in the home (1 language vs. > 1 language) and indices of brain morphology in language regions in toddlers and preschool children with ASD, in comparison to typically developing (TD) peers.

**Methods:** T1-weighted anatomical MRI data were acquired in 70 young children during natural sleep (ASD:  $n=39$ , mean age:  $38.7 \pm 13$ mo, bi/multilingual<sub>ASD</sub>  $n=25$ ; TD:  $n=31$ , mean age:  $37.6 \pm 14$ mo, bi/multilingual<sub>TD</sub>  $n=13$ ). ASD diagnoses (or clinical best estimates for younger children) were established according to DSM-5 criteria, supported by the Autism Diagnostic Observation Schedule (ADOS-2), Autism Diagnostic Interview, Revised (ADI-R), and expert judgment. Language skills were assessed with the Mullen Scales of Early Learning. FreeSurfer v.5.3.0 was used for cortical surface reconstruction and to calculate local gyrification index (LGI, a measure of brain folding), cortical thickness (CT), and surface area (SA). Multiple linear regression models were employed, with language exposure (1 language vs. > 1 language), diagnosis, and diagnosis by language exposure interaction terms as explanatory variables and neuroanatomical measures in canonical language regions (derived from the Desikan-Killiany atlas) as outcome variables. Total brain volume, sex, age, and socioeconomic status (SES) variables (e.g., income-to-needs ratio) were used as covariates.

**Results:** Children exposed to more than one language in the home did not differ from monolingual children in receptive or expressive language skills, after controlling for diagnosis (ASD vs. TD) and SES variables. There were no significant main effects of diagnosis or diagnosis by language exposure interaction effects on any neural measures tested. Compared to monolingual peers, regardless of diagnosis, children exposed to more than

one language showed (a) higher local gyrification in the right inferior frontal gyrus, pars triangularis ( $t = 2.83, p = 0.006$ ) and pars opercularis ( $t = 3.6, p = 0.001$ ), and the right transverse temporal gyrus ( $t = 3.2, p = 0.002$ ), controlling for income-to-needs ratio and age, and (b) lower cortical thickness in the left middle temporal gyrus, controlling for age and gender ( $t = -3.0, p = 0.003$ ).

**Conclusions:** Findings suggest that early exposure to more than one language is linked with a more mature neuroanatomical profile in language-related regions in both autism and typical development. These results suggest that hearing more than one language in the home may confer a neural advantage for language development in both children with ASD and TD children.

**318.002 (Oral)** Developmental Milestone Attainment in 17,000 Individuals with Autism Spectrum Disorder and 4,000 Unaffected Siblings: Relationships with Comorbid Intellectual Disability, Genetic Etiology, and Cohort

**S. S. Kuo**<sup>1,2</sup>, **C. van der Merwe**<sup>1,2</sup>, **C. E. Carey**<sup>1,2</sup>, **S. Bishop**<sup>3</sup> and **E. B. Robinson**<sup>1,2</sup>, (1)Stanley Center for Psychiatric Research, Broad Institute of MIT and Harvard, Cambridge, MA, (2)Center for Genomic Medicine, Massachusetts General Hospital, Boston, MA, (3)University of California San Francisco, San Francisco, CA

---

**Background:** Individuals with autism spectrum disorder (ASD) show diverse patterns of behavioral development starting from early childhood. Characterizing developmental milestone norms can provide individuals with ASD, caregivers, and clinicians with a clearer understanding of early developmental progress in ASD.

**Objectives:** We aimed to characterize the ages which individuals with ASD attain developmental milestones and evaluate differences based on whether they had comorbid intellectual disability (ID), carried a rare disruptive genetic variant associated with ASD or neurodevelopmental disorders, and were ascertained in an earlier or later cohort.

**Methods:** We harmonized four cohorts including Autism Genetic Resource Exchange (AGRE), The Autism Simplex Collection (TASC), Simons Simplex Collection (SSC), and Simons Foundation Powering Autism Research for Knowledge (SPARK), for a total sample of 21,243 participants comprising 17,098 participants with ASD (mean age 9.15 years, 80% male) and 4,145 siblings without ASD or ID (mean age 10.2 years, 50% male). Caregivers reported ages at which participants attained milestones across four domains, including gross motor skills (sitting upright, crawling, and walking), fine motor skills (spoon-feeding self), expressive language skills (speaking word and speaking phrase), and physiological regulation skills (acquiring bladder control and acquiring bowel control). 5,270 ASD participants and all siblings were genotyped. We conducted survival analysis to evaluate time to milestone attainment across the ASD subgroups and the sibling sample.

**Results:** Compared to siblings without ASD or ID, delays in milestone attainment for ASD were on average less than 1 year for gross and fine motor skills, 1 to 2 years for expressive language skills, and more than 2 years for physiological regulation skills. Individuals with comorbid ID showed more severe and variable delays than individuals without comorbid ID, with some being up to 7 years delayed in attaining milestones. Approximately 5% of individuals with ASD who were genotyped had a rare disruptive genetic variant, which substantially increased delays across all milestones except for smiling. Furthermore, individuals with ASD in this sample were ascertained from as early on as 1997 in the AGRE cohort, 2008 in the TASC and SSC cohorts, and 2016 in the SPARK cohort. Compared to ASD participants who were ascertained more recently, ASD participants who were ascertained in earlier cohorts showed generally similar delays for gross motor skills but showed greater delays for later milestones in expressive language and physiological regulation.

**Conclusions:** In the largest study to date of developmental milestone attainment in ASD, more severe and more variable delays were associated with having comorbid ID, carrying a rare disruptive genetic variant, and being ascertained in earlier cohorts. We extended prior work demonstrating that individuals with ASD who have comorbid ID or carry a rare disruptive genetic risk variant show substantial delays in attaining gross motor milestones and expressive language milestones and also show greater delays for fine motor and physiological regulation skills. Furthermore, the cohort differences suggest that though these widely used cohorts measured the same behaviors, they ascertained different groups of individuals with ASD in part based on shifting diagnostic criteria over the past two decades.

**318.003 (Oral)** Early Predictors of Language Outcomes at 36-Months in Infants Who Have an Older Sibling with Autism Spectrum Disorder: A Baby Siblings Research Consortium Study

**M. Pecukonis**<sup>1</sup>, **G. S. Young**<sup>2</sup>, **J. A. Brian**<sup>3</sup>, **T. Charman**<sup>4</sup>, **K. Chawarska**<sup>5</sup>, **J. M. Iverson**<sup>6</sup>, **S. Jeste**<sup>7</sup>, **R. Landa**<sup>8</sup>, **D. S. Messinger**<sup>9</sup>, **A. J. Schwichtenberg**<sup>10</sup>, **S. J. Webb**<sup>11</sup>, **L. Zwaigenbaum**<sup>12</sup> and **H. Tager-Flusberg**<sup>1</sup>, (1)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (2)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (3)Holland Bloorview Kids Rehabilitation Hospital, Toronto, ON, Canada, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Child Study Center, Yale University School of Medicine, New Haven, CT, (6)University of Pittsburgh, Pittsburgh, PA, (7)University of California, Los Angeles, Los Angeles, CA, (8)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (9)University of Miami, Coral Gables, FL, (10)Purdue University, West Lafayette, IN, (11)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (12)University of Alberta, Edmonton, AB, Canada

---

**Background:** Several studies have investigated the early predictors of language outcomes in infants who have an older sibling with ASD (i.e., “infant siblings”). Most studies have identified behavioral predictors of language outcomes in infant siblings, such as gesture use (Choi et al., 2020), fine motor (LeBarton & Iverson, 2013), and visual reception abilities (Thurm et al., 2007), while fewer have focused on distal environmental predictors, such as maternal education level (Swanson et al., 2019). It is currently unknown whether these early predictors of language outcomes in infant siblings differ depending on diagnostic outcome (ASD or no ASD).

**Objectives:** (1) Identify the early behavioral and environmental predictors of 36-month language outcomes in infant siblings. (2) Determine whether these predictors vary across three diagnostic outcome groups – infant siblings diagnosed with ASD at 36-months (“Sibs-ASD”), infant siblings not diagnosed with ASD at 36-months (“Sibs-No ASD”), and typically-developing infants without a family history of ASD (“TD”).

**Methods:** Our sample included  $N=796$  infants ( $N=114$  Sibs-ASD,  $N=434$  Sibs-No ASD,  $N=248$  TD) from the Baby Sibling Research Consortium (BSRC). Maternal education level was collected via parent-report at time of enrollment (~12-months). The MacArthur-Bates Communicative Development Inventory–Words and Gestures (MCDI; Fenson et al., 1992) assessed infant gesture use at 12-months. The Mullen Scales of Early Learning (MSEL; Mullen, 1995) assessed infant fine motor, visual reception, and expressive and receptive language abilities at 12-months. The MSEL was re-administered at 36-months to assess language outcomes. Analyses involved two multivariate regression models. The baseline model included MSEL language subscale, sex, and diagnostic outcome group as predictor variables. The stepwise model included 12-month maternal education level, MSEL visual reception and fine motor age equivalent (AE) scores, and MCDI early gestures and late gestures scores as additional predictor variables. Backward elimination procedure was used in the stepwise model. Outcome variables for both models were 36-month MSEL language AE scores.

**Results:** For the baseline model, main effects of MSEL language subscale ( $X^2(1)=26.01, p<.001$ ), sex ( $X^2(1)=22.88, p<.001$ ), and diagnostic outcome group ( $X^2(2)=169.27, p<.001$ ), were significant. For the stepwise model, main effects of maternal education level ( $F(1,442.68)=19.28, p<.001$ ) and 12-month MCDI late gestures scores ( $F(1,448.68)=5.68, p<.05$ ) were significant. Interactions between 12-month MCDI late gestures scores and diagnostic outcome group ( $F(431.96)=4.47, p<.05$ ; Figure1) and maternal education level and diagnostic outcome group ( $F(432.06)=7.71, p<.001$ ; Figure2) were also significant.

**Conclusions:** Findings suggest that early predictors of language outcomes in infant siblings differ depending on diagnostic outcome. Gesture use predicted language outcomes in infant siblings, although the direction of this relation differed between diagnostic outcome groups (negative in Sibs-ASD, positive in Sibs-No ASD). Maternal education level positively predicted language outcomes in Sibs-ASD, but not in Sibs-No ASD. Findings suggest that both behavioral and environmental predictors play a role in language development for Sibs-ASD. Variability in these early predictors may explain why language outcomes are heterogeneous across the autism spectrum. Further research focus on both environmental variables, such as maternal education level, and behavioral variables, such as infant gesture use, could strengthen our understanding of language development in infant siblings.

#### **318.004 (Oral) Does EEG Spectral Power Predict Language Development in the Early Years?**

**S. Huberty<sup>1</sup>, C. O'Reilly<sup>2</sup>, V. Carter Leno<sup>3</sup>, M. Steiman<sup>4</sup>, S. J. Webb<sup>5</sup>, & The BASIS Team<sup>6</sup> and M. Elsabbagh<sup>7</sup>,** (1)McGill University, Montreal, QC, Canada, (2)École Polytechnique Fédérale de Lausanne, Geneva, Switzerland, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (4)Azrieli Centre for Autism Research, Montreal Neurological Institute-Hospital, Montreal, QC, Canada, (5)Psychiatry and Behavioral Sciences, University of Washington, Seattle, WA, (6)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (7)Neurology and Neurosurgery, McGill University, Montreal, QC, Canada

**Background:** Younger siblings of children with autism spectrum disorder (ASD) diagnoses are more likely to experience developmental concerns, including language impairment. Better early language development is often associated with more positive long-term outcomes, however early language development in ASD is highly heterogeneous, and there is increasing interest in understanding the neural processes that are associated with it. Measures of neuronal synchrony, such as EEG spectral power, have previously been found to be associated with language ability in both typical and atypical development. However, few studies to date have tested whether early brain measures are indicative of the developmental trajectory of language in infants at familial risk for ASD.

**Objectives:** The aim of this study was to examine the association between EEG spectral power within the first year of life and the developmental trajectories of expressive and receptive language.

**Methods:** We used 410 EEG recordings from 191 unique infants from two longitudinal studies of typically developing infants and infants at familial risk for ASD, which were standardized and accessible as part of the International Infant EEG Data Integration Platform (EEG-IP). Using a linear growth curve model, we assessed trajectories of expressive and receptive language across 6, 12, 18, 24, and 36 months, as measured by the mullen scales of early learning. We tested whether absolute power in the delta, theta, alpha, beta, and gamma frequency bands at 6 months predicted trajectories of expressive and receptive language ability, while controlling for non-verbal cognitive ability, biological sex, and familial risk-status.

**Results:** 6-month alpha-band power was concurrently associated with expressive language in both typically developing and at-risk infants ( $b=1.119, p=0.018$ ). An alpha-power by risk-status interaction term was included to test whether this association was moderated by risk-status, but it was non-significant ( $p > .05$ ). Spectral power did not predict later trajectories of language development in any of the specified frequency bands (all  $p$  values  $> .05$ ).

**Conclusions:** While infants at-risk for ASD have been reported to differ in spectral power from typical-risk controls, the observed association between 6-month alpha-band spectral power and 6-month expressive language scores was not moderated by risk-status. This suggests that there is some continuity between autism and typical development in the underlying neural processes of language, which could help to identify infants that would benefit most from developmental supports. Measures of spectral power that are sensitive to temporal properties have also been linked to language processes, and future studies should assess whether they may be stronger indicators of later language development.

## POSTER SESSION — EARLY DEVELOPMENT (< 48 MONTHS)

### 423 - Early Development (< 48 months)

#### **423.013** (Poster) Differential Cognitive and Behavioral Development from 6 to 24 Months in Autism and Fragile x Syndrome

**L. J. Mullin<sup>1</sup>, J. Rutsohn<sup>2</sup>, J. Gross<sup>3</sup>, A. M. Estes<sup>4</sup>, J. J. Wolff<sup>5</sup>, K. Botteron<sup>6</sup>, M. D. Shen<sup>7</sup>, J. Piven<sup>7</sup>, H. Hazlett<sup>7</sup> and J. B. Girault<sup>8</sup>**, (1)Carolina Institute for Developmental Disabilities, Chapel Hill, NC, (2)University of North Carolina, Chapel Hill, NC, (3)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (4)Speech and Hearing Sciences, University of Washington, Seattle, WA, (5)University of Minnesota, Minneapolis, MN, (6)Washington University School of Medicine, St. Louis, MO, (7)\*co-senior author, University of North Carolina, Chapel Hill, NC

**Background:** Fragile X syndrome (FXS) is a heritable genetic condition caused by a mutation in the *FMR1* gene on the X chromosome. FXS is associated with intellectual disability and autistic features, and approximately one third of boys with FXS will meet diagnostic criteria for autism spectrum disorder (ASD). Previous research has unveiled markedly lower language, motor, and visual reception abilities in infants with FXS compared to infants with an older sibling with ASD, who are also at an increased likelihood of later diagnosis of ASD. However, these studies do not distinguish within the family history group, infants who receive an ASD diagnosis from those who do not, and do not examine differences between groups in a longitudinal manner. Examining longitudinal developmental differences in key cognitive and behavioral domains between these groups allows for an understanding of the etiologically distinct developmental profiles and intervention needs of children with FXS, and has important implications for parsing heterogeneity among children diagnosed with ASD.

**Objectives:** Compare skill trajectories among infants with FXS, infants with a family history of ASD who are diagnosed with ASD (FH+), infants with family history but are not diagnosed with ASD (FH-), and infants with no family history of ASD (NFH) in a longitudinal manner from 6 to 24 months of age in the domains of language, motor, visual reception, and nonverbal developmental quotient (NVDQ).

**Methods:** Infants were assessed with the *Mullen Scales of Early Learning* by trained researchers at approximately 6, 12, and 24 months of age as part of larger longitudinal brain and behavior studies. A total of 20 FXS infants, 61 FH+ infants, 228 FH- infants, and 143 NFH infants were included in the analyses. To compare longitudinal skill trajectories between groups, regression analyses with the FXS group and the 6-month timepoint as reference categories were executed for each skill domain. Bonferroni correction for multiple comparisons was applied and significant results are reported after correction.

**Results:** Analyses revealed that FXS infant performance is significantly lower than performance of FH+ infants on NVDQ at 6 months of age, on all domains except receptive language at 12 months, and on all domains at 24 months. FXS infants also underperformed compared to FH- and NFH infants on gross motor and NVDQ at 6 months and on all domains at 12 and 24 months.

**Conclusions:** Results reveal longitudinal trajectories of skill in expressive language, fine and gross motor, and visual reception in which infants with FXS differ from FH+ infants by 12 months and in NVDQ by 6 months. Identifying lower performance for FXS infants than FH+ infants in multiple domains in the first year of life highlights opportunities for early, specialized intervention for infants with FXS, especially since FXS can be diagnosed at birth.

#### **423.014** (Poster) Imagine It in Movement: Motor Development in Children with and without Autism Spectrum Disorder in New Zealand

**P. Araya-Herrera**, School of Psychology, The University of Auckland, Auckland, New Zealand; School of Physiotherapy, University of Valparaiso, Vina del Mar, Chile

**Background:** Although motor impairments are not a critical diagnostic feature in Autism Spectrum Disorder (ASD), increased clumsiness is typically expected. A gross motor skill (like walking or throwing) is also essential for development. It can evolve into more complex movements that allow the child to engage in other aspects of physical activity and, indeed, to learn by engaging in the world around them. Research has shown that deficits in motor impairments are associated with lower cognitive processing. Motor skills have also been shown to impact social interaction and one's ability to move around their environment, which may influence the child's ability to learn from others and the environment. Furthermore, object exploration supports learning their properties and participating in games with their caregivers. This link facilitates and enriches the experiences of linguistic and social knowledge.

**Objectives:** Increased participation in physical activity has been related to a positive influence on the occurrence of stereotypic behaviour in ASD, social functioning, and health-related outcomes. However, gross motor skills are often necessary to participate in physical activity. Given that people with ASD may be prone to motor deficits, they may also be intensifying their other behavioural excesses and deficiencies. This study aimed to understand how motor development trajectory is similar or different in children with and without Autism Spectrum Disorder in New Zealand.

**Methods:** Sample with and without ASD included 150 participants from the Growing Up in New Zealand project (ASD diagnosis was obtained by parent-report and formal diagnosis at four and a half and eight years), and developmental outcomes were obtained from Data Collection Wave data sets at six weeks, nine months, two years, four and a half years and eight years. Information of prevalence and trajectories was obtained by mother and child questionnaires, child observation and observation instruments to assess motor outcomes of child development. Mediating factors such as ethnicity, maternal education, and socioeconomic status were considered, plus gestational age at birth, body mass index, nutrition, and physical disability. Ethics approval from the Growing Up in New Zealand Data Access Committee (N° IA 21\1014).

Results: A decrease in body mass index, nutrition and motor alterations were observed in Maori group in children with and without ASD.

Conclusions: The lower decrease of motor development in Maori children with and without ASD could be due to protective factors of New Zealand's heritage. Further studies are required in a larger population.

**423.015 (Poster)** A Demonstration of Limited Attention to Parent Faces during a Live Eye-Tracking Task in Toddlers with Elevated Autism Symptoms

A. Vernetti<sup>1</sup>, C. Banarjee<sup>2</sup>, A. Boxberger<sup>1</sup>, E. Diamond<sup>3</sup>, K. All<sup>1</sup>, S. Macari<sup>1</sup> and K. Chawarska<sup>1</sup>, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Child Study Center, Child Study Center, Yale School of Medicine, New Haven, CT, (3)Yale University, New Haven, CT

**Background:** Reduced attention to dynamic faces in autism has been documented during screen-based studies under specific conditions, particularly those involving social engagement cues such as child-directed speech and eye contact (Chawarska et al., 2013; Shic et al., 2014; Shic et al., 2020). However, many important aspects of genuine social encounters are absent from screen-based studies such as social presence, familiarity, and motivation to engage in reciprocal interactions. Social difficulties in children with autism may be more acute during live interaction (Drysdale et al., 2018; Cañigueral & Hamilton, 2019) but may be less pronounced with familiar social partners (Gillespie-Smith et al., 2014). The influence of social cues such as speech and gaze on attention to faces during interactions with parents in real-world contexts remains to be investigated.

**Objectives:** To examine 1) attention to the face of a familiar person (parent) in a neurodiverse group of toddlers in a live interaction context during which the presence of speech and gaze was manipulated; and 2) the association between attention to face and autism severity.

**Methods:** The gaze patterns of 11 toddlers with and without autism ( $M_{age}=23.1mo$ , 55% male, ASD:n=5) were recorded by a stand-alone Tobii Eye-Tracker as they sat facing their parent who was: 1) naturally speaking (SP+) and looking at them (EC+), or, 2) silent (SP-) and looking down (EC-). Each condition lasted 15 seconds and was repeated twice. Areas of interest comprised the overall scene and face regions. Social impairments were quantified using the ADOS. Eye-tracking calibration accuracy ( $M=0.08^\circ$ ,  $SD=0.05$ ) was excellent compared to field standards. The percent valid looking time (%Valid: looking time at overall scene/duration of condition) and percent looking time to the face (%Face: looking time at face/valid looking time) between the speech and gaze conditions were compared using t-tests. Correlational analyses were computed between %Face during each condition and ADOS calibrated social affect scores.

**Results:** T-tests revealed reduced %Valid ( $p=0.039$ ) and %Face ( $p<0.001$ ) during the (SP-EC-) compared to the (SP+EC+) condition such that all toddlers looked longer at the scene ( $M=46\%$ ,  $SD=18$ ) and at the face ( $M=82\%$ ,  $SD=17$ ) during (SP+EC+) compared to (SP-EC-) (Scene: $M=35\%$ ,  $SD=15$ ; Face: $M=50\%$ ,  $SD=23$ ) (Figure 1, top panel). %Face in the (SP+EC+) condition was negatively correlated with social affect scores ( $r(9)=-0.70$ ,  $p=0.033$ ), unlike in the (SP-EC-) condition ( $r(9)=-0.12$ ,  $p=0.774$ ) suggesting that lower attention to the parent's face during a face-to-face interaction is associated with higher autism severity scores (Figure 1, bottom panel).

**Conclusions:** All toddlers attended to the scene and the parent's face but the duration of looking depended on social engagement cues. Namely, they looked more when the parent spoke and looked at them. Consistent with screen-based eye-tracking studies, (Shic et al., 2020) speech and direct gaze constitute powerful attentional cues in neurodiverse samples of toddlers. However, toddlers with higher autism symptom severity were less sensitive to the contingencies and attended less to their parents' speaking face. This preliminary study demonstrates the feasibility of studying attention to a parent during a naturalistic setting in young children with and without autism and prompts the need to further investigate social attention to familiar partners during live interaction to understand looking behavior closely resembling everyday experiences of toddlers with autism.

**423.016 (Poster)** A Prospective Study of Anxiety and Perceptual Sensitivity As Early Markers for Restricted and Repetitive Behaviours in Infants with Typical and Elevated Likelihood of Autism and ADHD: Replication and Extension in an Independent Cohort.

N. Narvekar<sup>1</sup>, V. Carter Leno<sup>2</sup>, G. Pasco<sup>3</sup>, M. H. Johnson<sup>4</sup>, E. J. Jones<sup>5</sup> and T. Charman<sup>1</sup>, (1)IoPPN, Institute of Psychiatry, KCL, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, Institute of Psychiatry, Psychology & Neuroscience, London, United Kingdom, (3)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (4)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (5)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom

**Background:** Earlier models link anxiety to Restrictive Repetitive Behaviours (RRB); however, prospective studies are needed to test this further. A previous study on the elevated likelihood group indicated that infant anxiety and perceptual sensitivity traits were not specific to later RRB alone but were also related to Social Communication Interaction (SCI). Hence, we examine whether we could replicate this model and whether a more refined measure of sensory processing would show greater specificity.

**Objectives:** The study aims to; 1) replicate results in an independent sample. 2) extend findings by using a more specific measure of sensory processing. 3) explore specificity of effects to autism traits as compared to ADHD traits.

**Methods:** As part of the Studying Autism and ADHD Risks (STAARS), 161 infant-siblings participated in a longitudinal study. All participants had at least one older-sibling with a diagnosis of ASD (elevated-likelihood-Autism (EL-ASD;  $N=80$ )), or first degree relative with ADHD (elevated-likelihood-ADHD (EL-ADHD;  $N=31$ )) or both (elevated-likelihood-ASD&ADHD (EL-ASD/ADHD;  $N=21$ )). All typical-likelihood (TL) participants ( $N=29$ ) had no known immediate family members with a diagnosis of ASD or ADHD. Parents rated infant's traits of early anxiety and perceptual sensitivity using the Infant Behavior Questionnaire (IBQ; Fear and Perceptual Sensitivity subscales) at 10 and 14-months, and the Early Childhood Behavioral Questionnaire (ECBQ; Shyness and Perceptual Sensitivity subscales) at 24-months, RRB and SCI were assessed using subscales of the parent-rated Social Responsiveness Scale (SRS-2) at 36-months; along with Infant Toddler Sensory Profile (ITSP), which was

administered at all timepoints. Longitudinal cross-lag structural equation models tested 1) predictive pathways from fear/shyness and perceptual sensitivity at 10-24-months and RRB and SCI at 36-months, 2) bidirectional pathways between fear/shyness and hypo and hyper sensitivity quadrants of ITSP between 10-24-months.

Results: We found significant auto-regressive pathways (e.g., within-domain continuity) for both fear/shyness and perceptual sensitivity between 10-14 and 14-24-months (Figure 1). The cross-lagged auto-regressive model provided a good fit to the data ( $\chi^2(2) = 0.78, p = 0.68$ ; CFI = 1.000, RMSEA < .001). Interestingly, perceptual sensitivity at 8-months predicted RRB symptoms at 36-months. Higher levels of shyness at 24-months were significantly associated with heightened levels of RRB at 36-months. The cross lagged model with ITSP (Figure 2a and 2b) indicated within domain continuity to next timepoint in both hypo and hyper sensitivity. Cross-lagged paths indicated that higher levels of shyness at 24-months were associated with higher levels of hyper sensitivity at 14-months but not with hypo sensitivity.

Conclusions: Consistent with previous findings, relative stability was found over time in fear/shyness and perceptual sensitivity. At a trait level, early infant manifestations of anxiety (e.g., fear/shyness) was specifically related to later RRB and not SCI, this was inconsistent with previous finding. The novel model with the ITSP found that developmental continuity of traits and association of fear was specific to hyper sensitivity compare to hypo sensitivity. Future planned analyses will test whether a similar pattern of results is found with later ADHD symptoms.

#### **423.017 (Poster) ASD Assessment and Timing of Diagnosis: The Impact of Sex and IQ**

**J. Davis<sup>1</sup>, D. Askins<sup>2</sup>, D. A. Bilder<sup>3</sup>, W. M. McMahon<sup>3</sup>, A. V. Kirby<sup>4</sup>, C. Kingsbury<sup>5</sup> and J. Gutierrez<sup>6</sup>,** (1)Educational Psychology, University of Utah, Salt Lake City, UT, (2)University of Utah, Salt Lake City, UT, (3)Psychiatry, University of Utah, Salt Lake City, UT, (4)University of Utah College of Health, Salt Lake City, UT, (5)Children with Special Health Care Needs, Utah Department of Health, Salt Lake City, UT, (6)University of Utah, SALT LAKE CITY, UT

---

#### **Background:**

Identifying individuals with autism spectrum disorder (ASD) is complex due to the continuum of behavioral topographies and symptom severity differences. This study describes how sex and IQ impact timing of diagnosis and diagnostic classifications on the ADOS/ADOS-2.

Males are diagnosed with ASD approximately three to four times as often as females. The state of the literature is mixed regarding sex differences in ASD. Some studies suggest that sex and IQ may impact core symptom expression on the ADOS/ADOS-2 as well as timing of ASD diagnosis with males and individuals with lower IQ scores potentially diagnosed earlier.

#### **Objectives:**

Do males and females with ASD have similar rates of ASD classification on the ADOS?

Is there a significant difference between males and females on the timing of initial ASD diagnosis?

Is there a significant difference between males and females on the timing of ASD diagnosis by IQ score?

#### **Methods:**

Secondary analysis of population-based data from multiple sites collected by the CDC's Autism and Developmental Disabilities Monitoring (ADDM) Network. The study sample included eight-year-old, confirmed ASD cases for surveillance years 2000-2016 [N = 33,324; n = 27,265 (81.82%) males; n = 6,059 (18.18%) females]

Descriptive and inferential statistics were conducted using SPSS & R software. Specifically, multilevel logistic regression (MLR) analyzing sex differences on the ADOS/ADOS-2, and survival analysis using Kaplan-Meier estimates for analyzing sex differences on timing of diagnosis. Survival curves were compared using the Tarone-Ware  $\chi^2$  test

#### **Results:**

In a MLR model controlling for ascertainment site, year, and assessment's practitioner credential, males were = .56 (95% CI .45, .71) times more likely to have an autism classification with the ADOS. Individuals with IQ below 70 were = 3.14 (95% CI 2.46, 4.02) times more likely to have an autism classification with the ADOS. There were no significant sex differences in the timing of ASD diagnosis (Tarone-Ware  $\chi^2(1) = 0.026, p = 0.871$ ).

When IQ was considered, there were significant sex differences. The survival analysis resulted in mean Kaplan-Meier estimates of 60.37 months for males with IQ scores above 70, 59.62 for females with IQs above 70, 51.0656 for males with IQs at or below 70, and 53.02 for females with IQs at or below 70. The survival distributions comparing timing of ASD diagnosis by sex when considering IQ using the Tarone-Ware  $\chi^2$  test were statistically different ( $\chi^2(3) = 736.217, p < 0.0001$ ).

#### **Conclusions:**

This study found that there were sex differences in ADOS/ADOS-2 ASD classifications, particularly for individuals with IQ scores above 70. It is recommended that clinicians utilize data from multiple sources in combination with the ADOS/ADOS 2 to inform diagnosis. In contrast, these results suggest there were significant sex differences in timing of diagnosis when IQ was considered. This suggests that IQ may impact timing of ASD diagnosis more than sex as both males and females with IQs above 70 were diagnosed approximately one year later than those with IQs at or below 70.

**423.018 (Poster)** Age of First Screen-Positive Status in Children Diagnosed with Autism Spectrum Disorder: A Comparison across Multiple Measures

**C. Parikh<sup>1</sup>, R. Ni<sup>2</sup>, D. N. Gangi<sup>3</sup>, M. M. Hill<sup>4</sup>, S. Maqbool<sup>5</sup>, E. Solis<sup>2</sup>, G. S. Young<sup>4</sup>, S. Park<sup>3</sup> and S. Ozonoff<sup>1</sup>**, (1)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (2)UC Davis MIND Institute, Sacramento, CA, (3)Psychiatry and Behavioral Sciences, University of California, Davis, MIND Institute, Sacramento, CA, (4)University of California at Davis, MIND Institute, Sacramento, CA, (5)UC Davis MIND, Sacramento, CA

**Background:** Symptoms of ASD may be present as early as 9-12 months, but are rarely identified at this age, in part because there are few screeners validated for use in the first year of life. Our team developed the Video-referenced Infant Rating System for Autism (VIRSA), a parent-report screener that utilizes video rather than written descriptions of behavior and is appropriate for infants 6-24 months of age (Young et al., 2020). In this study, we compared the VIRSA to two widely used screening measures, the Modified Checklist for Autism in Toddlers-Revised (M-CHAT-R; Robins et al., 2014) and the Infant Toddler Checklist (ITC; Wetherby et al., 2008).

**Objectives:** To examine the age of first-screen positive status across three different measures (VIRSA, M-CHAT-R, and ITC) in children screened within a community-based sample who were later diagnosed with ASD.

**Methods:** 1,781 parents of infants without a known family history of ASD completed the VIRSA and the ITC online at 6, 9, 12, 18, and 24 months and the M-CHAT-R at 18, 24, and 36 months. Any child screening positive on the M-CHAT-R (score of 3 or above), VIRSA (score of 3 or below), or the ITC (composite score below the 10<sup>th</sup> percentile) at any age were seen for a diagnostic evaluation at 24 and/or 36 months (n = 114). Additionally, 77 children who screened negative on all screeners at every age were randomly selected for a diagnostic evaluation at 24 and/or 36 months. The current analysis focuses on the 18 children diagnosed with ASD so far after the diagnostic evaluation.

**Results:** All 18 children diagnosed with ASD screened positive on at least one of the three measures (e.g., no randomized screen-negatives were diagnosed). 58% of the children screened positive first on the VIRSA, 26% first on the ITC, and 16% first on the M-CHAT-R (see Table 1). One participant screened positive first simultaneously on the VIRSA and the ITC. The mean age of first screen-positive status on the different screening instruments was 12 months on the VIRSA, 16 months on the ITC, and 24 months on the M-CHAT-R (see Table 1).

**Conclusions:** Results demonstrate the potential value of screening for ASD earlier in life. Over half of the children later diagnosed with ASD in this sample screened positive on the VIRSA and/or the ITC in the first year of life, earlier than when screeners are typically first administered in primary care (i.e., 18 months). The majority of the sample screened positive first on the VIRSA, suggesting that its use of video depictions of social-communication behaviors in infancy were helpful for identifying a child's delays in families with no prior knowledge and/or history of ASD. As part of an ongoing investigation, when the full sample of n = 2000 reaches 36 months, we will calculate the VIRSA's psychometric properties (i.e., sensitivity, specificity, positive and negative predictive values) to determine its early screening utility relative to current standard screening measures.

**423.019 (Poster)** Altered Locus Coeruleus-Norepinephrine Activity As Underlying Mechanism of Attenuated Social Attention in Preschoolers with ASD

**L. Polzer, C. M. Freitag and N. Bast**, Autism Research and Intervention Center of Excellence Frankfurt, Department of Child and Adolescent Psychiatry, Psychosomatics and Psychotherapy, University Hospital Frankfurt, Goethe University, Frankfurt, Germany

**Background:** Recent evidence suggested altered activity of the Locus Coeruleus-norepinephrine (LC-NE) system in ASD as a promising biomarker. Pupil dilation (PD) indexes LC-NE activity and has been shown to be attenuated in ASD in response to static social stimuli, which may indicate an implication of LC-NE activity in attenuated social attention. So far, it remained unclear whether aberrant PD patterns can also be elicited by dynamic video stimuli that more closely represent naturalistic visual exploration. A reliable measure to show altered social attention in ASD is a paradigm assessing the preference for competing social vs. geometric motion. In various studies, children with ASD showed an attenuated social motion preference compared to typically developing children (TD), which has also been applied as a prognostic risk assessment for a later diagnosis. LC-NE activity remains to be explored as underlying mechanism of altered social preferences in ASD.

**Objectives:** The aim of the current study was to examine 1) whether aberrant PD can be found in reaction to dynamic stimuli, 2) whether PD as measure of LC-NE activity can explain altered social preference and 3) whether combining social preference with PD measures can enhance the prediction of an ASD diagnosis.

**Methods:** 57 ASD and 39 TD children (age: 18-65 months) matched for developmental age were included. Participants watched simultaneously presented videos of social motion (grimacing actors) versus geometric motion (moving geometric objects) while an eye-tracker assessed their social preference and PD. Group differences and the prediction of social motion preference by PD were analyzed with Linear Mixed Models. Post-hoc comparisons for PD measures were done with Tukey-HSD, the prediction of the diagnosis with logistic regression models.

**Results:** PD analyses revealed a significant interaction effect between group (ASD vs. TD) and stimulus type (social vs. geometric;  $\beta = -0.577$ ,  $p < .0001$ ). Post-hoc comparisons showed that ASD participants had an attenuated PD in response to social motion ( $\beta = -0.282$ ,  $p = .026$ ), but a larger PD

to geometric motion ( $\beta=0.295$ ,  $p=0.016$ ). This was accompanied by an attenuated social motion preference ( $\beta=1.042$ ,  $p<.0001$ ). Higher social motion preference was associated with higher PD to social ( $r=.718$ ,  $p<.0001$ ) but lower PD to geometric motion ( $r=-.468$ ,  $p<.0001$ ). Social motion preference was explained by the combination of PD to geometric ( $\beta=-0.262$ ,  $p<.0001$ ) and to social motion ( $\beta=0.394$ ,  $p<.0001$ ; marginal pseudo  $R^2=0.358$ ). The ASD diagnosis was predicted by social motion preference ( $\beta=1.71$ ,  $p<.0001$ ), while this effect was mediated by inclusion of the significant effects of PD to geometric ( $\beta=-2.319$ ,  $p=.009$ ) and to social motion ( $\beta=1.851$ ,  $p=.044$ ; adjusted Pseudo  $R^2=0.626$ ).

**Conclusions:** This is the first empirical evidence of altered LC-NE functioning as underlying mechanism of altered social preference in ASD. In preschoolers with ASD, PD is altered in response to dynamic stimuli. In contrast to previous studies, we found increased PD to non-social geometric motion, which might indicate aberrant reactivity to sensory salience. PD to dynamic stimuli might be a predictive phenotype of ASD that explains altered social preferences. Underlying LC-NE activity seems worthwhile to consider in future etiological models as well as the investigation of diagnostic biomarkers.

#### **423.020 (Poster)** Association between Ultrasonography Fetal Anomalies and Autism Spectrum Disorder

O. Regev<sup>1</sup>, A. Hadar<sup>2,3</sup>, G. Meiri<sup>4</sup>, H. Fluser<sup>5</sup>, A. Michaelovski<sup>6</sup>, I. Dinstei<sup>7</sup>, R. HersHKovitch<sup>7</sup> and **I. Menashe<sup>7</sup>**, (1)Ben-Gurion University of the Negev, Beer Sheva, Israel, (2)Clalit Health Services, Beer Sheva, Israel, (3)Soroka University Medical Center, Beer Sheva, Israel, (4)National Autism Research Center of Israel, Ben-Gurion University of the Negev, Beer Sheva, Israel, (5)Zusman Child Development Center, Soroka University Medical Center, Beer Sheva, Israel, (6)Cognitive and Brain Sciences Department, Ben-Gurion University of the Negev, Beer Sheva, Israel, (7)Public Health Department, Ben-Gurion University of the Negev, Beer Sheva, Israel

#### **Background:**

Today, autism spectrum disorder (ASD) diagnosis is based on behavioral symptoms, which are typically manifested in the second year of life. Nevertheless, a growing body of evidence suggests the prenatal onset of abnormal neurodevelopment and abnormal embryonic organogenesis of different body parts in some children with ASD. Accordingly, there is emerging interest in examining the prenatal development of fetuses later developing into children diagnosed with ASD. Prenatal ultrasound, a commonly used pregnancy monitoring tool, is an excellent framework for this purpose as it allows physicians to survey fetal growth and organ development throughout different pregnancy stages. A primary prenatal ultrasound screening is the fetal anatomy survey, which is designed to detect various fetal structural anomalies and “soft markers” that may develop into congenital anomalies and diseases. Here, we present results from the the most comprehensive exploration to date of ultrasonography fetal anomalies (UFAs) associated with ASD, as reflected in the prenatal fetal anatomy survey.

#### **Objectives:**

To investigate the association between UFAs and ASD.

#### **Methods:**

A retrospective case-sibling-control study comprised of children diagnosed with ASD (cases); their own typically developing, closest-in-age siblings (TDS); and typically developing children from the [general] population (TDP), who were matched to cases by year of birth, sex (male/female) and ethnicity (Jewish/Bedouin). This case-sibling-control design allows accounting for familial and environmental exposures known to affect ASD risk. The case group was drawn from all children diagnosed with ASD at the National Autism Research Center of Israel (NARCI). Fetal ultrasound data from the fetal anatomy survey, which is conducted during gestational weeks 20-24 in Israel, were obtained from all the prenatal ultrasound clinics of Clalit Health Services (CHS), Israel's largest health maintenance organization (HMO), serving ~75% of the families enrolled at the NARCI.

#### **Results:**

The study comprised 659 children: 229 ASD, 201 TDS, and 229 TDP; 471 (71.5%) males. Differences in UFA rates between cases and controls are presented in **Figure 1**. UFAs were found in 29.3% of ASD cases vs. only 15.9% and 9.6% in the TDS and TDP groups (aOR=2.23, 95%CI=1.32-3.78, and OR=3.50, 95%CI=2.07- 5.91, respectively). Also, multiple co-occurring UFAs were significantly more prevalent among ASD cases. UFAs in the urinary system, heart, and head&brain were the most significantly associated with ASD diagnosis (aOR<sub>Urinary</sub> =2.08, 95%CI=0.96-4.50 and aOR<sub>Urinary</sub>=2.90, 95%CI=1.41-5.95; aOR<sub>Heart</sub>=3.72, 95%CI=1.50-9.24 and aOR<sub>Heart</sub>=8.67, 95%CI=2.62-28.63; and aOR<sub>Head&Brain</sub>=1.96, 95%CI=0.72-5.30 and aOR<sub>Head&Brain</sub>=4.67, 95%CI=1.34-16.24; vs. TDS and TDP, respectively). ASD females had significantly more UFAs than ASD males (43.1% vs. 25.3%,  $p=0.013$ ) and a higher prevalence of multiple co-occurring UFAs (15.7% vs. 4.5%,  $p=0.011$ ). No sex differences were seen among TDS and TDP controls. ASD fetuses were characterized by a narrower head and a relatively wider ocular-distance vs. TDP fetuses (OR<sub>BPD</sub>=0.81, 95%CI=0.70-0.94, and aOR<sub>Ocular-Distance</sub>=1.29, 95%CI=1.06-1.57). Finally, UFAs were associated with more severe ASD symptoms.

#### **Conclusions:**

Our findings shed important light on the abnormal multiorgan embryonic development of ASD and suggest fetal ultrasonography biomarkers for ASD.

#### **423.021 (Poster)** Associations Among Motor Speech, Arm and Hand Control, Social Communication, and Language Skills in Toddlers with and without Autism Spectrum Disorder

**Background:** Motor impairments are prevalent in children with autism spectrum disorder (ASD); yet often go undiagnosed (Bhat et al., 2021; Licari et al., 2019). Additionally, motor speech impairments commonly co-occur in children with ASD (Chenau et al., 2019; Velleman et al., 2010). Early motor skills and language development are significantly related in children with and without ASD and developmental delays (DD), and motor differences in the first two years of life provide important indicators of ASD- and DD-risk (Lim et al., 2021). However, few clinical observation measures of early motor control are available (McCauley & Strand, 2008).

**Objectives:** 1) To examine and compare measures of motor speech, arm, and hand control in toddlers with and without ASD; 2) to examine concurrent associations between motor and social communication skills, and 3) to examine prospective associations between motor and verbal and nonverbal developmental level.

**Methods:** Participants were 249 toddlers identified with ASD ( $n=48$ ), DD ( $n=33$ ), and typical development (TD,  $n=168$ ) recruited through screening in primary care by the FIRST WORDS® Project. Children completed a Communication and Symbolic Behavior Scales (CSBS) Behavior Sample at 20.0 months ( $SD=3.1$ ). The Early Motor Control Scales (EMCS; Hayden et al., 2006), a standardized tool that uses the observation of communication and play to evaluate motor control of arm, hand, oral, and vocal mechanisms was scored during the CSBS. The EMCS is based on the theoretical model and developmental framework tested in the Verbal Motor Production Assessment for Children (VMPAC; Hayden & Square, 1999). Children completed a follow-up evaluation at 37.2 months ( $SD=6.9$ ) that included the ADOS and Mullen Scales of Early Learning (MSEL).

## Results:

**EMCS.** Children with ASD and DD had significantly lower Motor Speech Composite and Total Scores than TD,  $F(2,247)=36.15$ ,  $p<.001$  and  $F(2,247)=52.52$ ,  $p<.001$ , respectively. Effect sizes for group differences (ASD-TD: Cohen's  $d=1.26$ , and DD-TD:  $d=0.86$ ) were observed to be large. All three groups differed significantly on the Arm and Hand Composite, with TD scoring highest, followed by DD and ASD,  $F(2,247)=39.27$ ,  $p<.001$ . The ASD-DD and DD-TD group differences were medium in effect size ( $d=0.50$  and  $0.79$ , respectively), while the ASD-TD  $d=1.35$  was large.

**Concurrent relationships: CSBS.** Medium and large correlations were observed between the EMCS Motor Speech Composite and the CSBS Social ( $r=.54$ ), Speech ( $r=.79$ ), and Symbolic ( $r=.54$ ) Composites, as well as between the Arm and Hand Composite and CSBS Social ( $r=.51$ ), Speech ( $r=.44$ ), and Symbolic ( $r=.54$ ) Composites.

**Prospective relationships: MSEL.** Medium and large correlations were observed between the Motor Speech and Arm and Hand Composites and MSEL Visual Reception, Fine Motor, Expressive Language, and Receptive Language T scores (range  $r = .42-.52$ ).

**Conclusions:** Findings provide evidence that 1) delays in early motor control may be identified in toddlers with ASD and DD during a clinical assessment of communication and play, and 2) these skills were observed to be related to social communication and language skills. Observational measures of early motor control may contribute to earlier detection and provide toddlers at risk of developmental delays and ASD with the opportunity to access targeted interventions.

## 423.022 (Poster) Associations between Autistic Traits and Behavioral/Emotional Problems in Toddlers with Autism

Q. O. Wedderburn<sup>1</sup>, M. Siller<sup>2</sup>, L. Morgan<sup>3</sup> and S. Furlmeister<sup>4</sup>, (1)Emory University, Atlanta, GA, (2)Emory University School of Medicine, Atlanta, GA, (3)Emory University-Marcus Autism Center, Atlanta, GA, (4)Marcus Autism Center; Children's Healthcare of Atlanta, Atlanta, GA

---

## Background:

The Social Responsiveness Scale (SRS) is a quantitative parent report of autistic traits in children aged 4-18 years old (SRS; Constantino & Gruber, 2005). The scale measures impairment in social reciprocity, a key developmental domain which is often diminished in children with ASD. Scores on the SRS are continuous and normally distributed in a general population study (see Bolte, Poustka, & Constantino, 2008 for review). Further, twin studies have demonstrated a high degree of heritability on the scale. Higher scores on the SRS are indicative of a higher risk for an ASD diagnosis and a higher risk for emotional/behavioral issues, as measured by the Child Behavior Checklist (CBCL; Achenbach, & Rescorla, 2001).

The Video-referenced Rating of Reciprocal Social Behavior (VrRSB) is an extension of the SRS, aiming to measure autistic traits in social reciprocity in children between 18-30 months (Marrus et al., 2015). In the general population, the scale demonstrates continuously distributed scores and appears to be highly heritable based on twin study designs.

## Objectives:

To investigate concurrent associations between parent ratings of autistic traits and parent-reported behavioral or emotional problems in young children with ASD.

## Methods:

Parents who sought enrollment at a university-based, inclusive preschool for children with and without autism were invited to complete a battery of surveys. Parents were included in the current study if (1) children were < 30 months, and (2) children presented significant concerns about ASD. The sample included 24 children (20 male; age: 20 to 30 months;  $M = 25.38$ ,  $SD = 2.9$ ).

Parents of 17 children reported a prior diagnosis of ASD ( $N=17$ ). In addition, clinical review of parent surveys (CDI, M-CHAT, parent concerns) identified seven additional children who were classified as 'likely ASD'. For the current analysis, parents completed the VrRSB and the CBCL.

The VrRSB Scale video referenced score, repetitive and restrictive behavior subscale, and social communication subscale were calculated for each family. The Child Behavior Checklist is a 99-item parent questionnaire used to capture standardized scores on behavioral and emotional issues. The CBCL 1.5-5 is a 99-item continuous and normally distribute rating scale used for children aged 1.5 to 5 years (Achenbach, & Rescorala., 2001). Additional calculations were made for the CBCL standardized total problem score, externalizing problems T score, and the internalizing problems T score.

#### Results:

Preliminary results revealed that neither measure (CBCL, VrRSB) was significantly correlated with age. Pearson correlations demonstrated a significant correlation between the total score on the VrRSB ( $M = 56.5$ ,  $SD = 13.54$ ) and the CBCL Total Problems T-score ( $M = 48.54$ ,  $SD = 9.44$ ) ( $r(24) = .77$ ,  $p < 0.001$ ). A scatter plot illustrating the association between the VrRSB Total Score and the CBCL Total Problems T-score is displayed in Figure 1. Correlations between all subscales are reported in Table 1.

#### Conclusions:

The current study found significant positive correlations between continuous, quantitative measures of autistic traits (VrRSB) and emotional/behavioral problems (CBCL) in toddlers with diagnosed or likely ASD. Similar relations have been identified in older children with and without ASD.

#### **423.023 (Poster)** Asymmetries in the Development of Infant-Caregiver Social Contingency in Typical Development and ASD

**G. Ramsay<sup>1</sup>**, M. Edwards<sup>2</sup> and K. Little<sup>1</sup>, (1)Marcus Autism Center, Children's Healthcare of Atlanta, and Emory University School of Medicine, Atlanta, GA, (2)Emory University, Atlanta, GA

**Background:** Increasing evidence suggests that prodromal symptoms of autism may emerge over time within the first year of life, suggesting that early developmental trajectories may form the basis for biomarkers of autism risk and resilience. In previous studies, we found evidence for a developmental cascade in vocal development discriminating high-risk and low-risk siblings, beginning by 12 months, with deficits in vocal contingency leading to later deficits in adult then infant volubility, all of which were predictive of speech and language outcome at 24 months. Existing studies of conversational turn-taking in infancy suggest that vocal contingency between infant and caregiver is asymmetric and changes over time, as each learns to initiate and then respond to vocal signals from the other. This was not captured in our previous measures of vocal interaction, which tested for statistical dependence but not mutual causality. Accordingly, we revisit our analysis to examine the directionality of infant-caregiver signaling and response, in typical development and ASD.

**Objectives:** The goal of this research is to examine developmental progressions in infant-caregiver vocal interaction, to determine whether there are asymmetries in the emergence of vocal contingency between infant and caregiver, and differences between autism and typical development.

**Methods:** As part of an NIH Autism Center of Excellence (NIH P50 MH100029), we tracked vocal development among 45 high-risk infant siblings and 35 low-risk controls. Each child wore a LENA recorder one day every month from 0-24 months to provide audio recordings of their vocal environment. Using multitaper harmonic analysis, we identified the onset and offset of each infant and caregiver vocalization. From the mean rate of event markers, we determined the number of vocalizations per hour for infant and caregiver, as an index of volubility. Following our previous research, we used the mutual information between event marker sequences to calculate an index of vocal contingency. In the present study, we further used the transfer entropy, an information-theoretic metric of statistical causality between the past history of one stochastic process and the future of another, to derive a new index of directional vocal contingency between infant and caregiver, and caregiver and infant. Using Functional Data Analysis, we then determined developmental trajectories for these measures for each infant-caregiver dyad, and mean trajectories for each risk group. Permutation tests were used to identify significant ( $P < .05$ ) differences between risk groups.

**Results:** Previous results provided evidence for a developmental cascade, beginning with differences in overall vocal contingency between low-risk and high-risk infants over the first 12 months of life. Results from the present study revealed developmental asymmetries in vocal contingency between caregiver and infant. Infant contingency upon caregiver was weaker than caregiver contingency on infant near birth, but rose from 4-6 months. The change was significantly weaker in high-risk relative to low-risk infants.

**Conclusions:** These results suggest that early deficits in social contingency that later characterize autism may originate in deficits in infant contingent responding to caregiver within the first 6 months of life, whereas caregiver responding to infant appears to remain intact.

#### **423.024 (Poster)** Autism Spectrum Disorder (ASD) Screening Project: How to Increase Community ASD Screening and Improve Linkage to Care in an Underserved Region?

**Background:** The American Academy of Pediatrics (AAP) recommends all children be screened for Autism Spectrum Disorder (ASD) at 18 and 24 months-of-age. However, there is a persistent gap between the time of parental concern for ASD and the time of first professional evaluation, particularly in underserved communities. The delay in ASD detection may be related to lack of an effective screener and inadequate follow up with children who screen at-risk for ASD.

**Objectives:** This study will test whether implementing an ASD Screening Program, with the inclusion of peer support for mothers, will increase ASD screening and referral to services through a Newark-based pediatric practice. Additionally, this study examined information from practitioners to identify barriers and challenges to screening.

**Methods:** The ASD Screening Project is an ongoing study initiated in 2020 at the Rutgers-New Jersey Medical School (NJMS) Pediatric Continuity Care Center (PCCC). Cooperating with practice physicians, we enhanced routine ASD screening using a novel, brief, and reliable ASD screener, the Psychological Development Questionnaire for Toddlers (PDQ-1), for children between 18 and 36-months. Children who screened positive (i.e., at-risk for ASD) were contacted by a liaison and connected with Mom2Mom, a peer support group for mothers of children with special needs. In conjunction with this project, a 12-question survey regarding in-office developmental and ASD screening was sent via email to New Jersey AAP members.

**Results:** The ASD screening project led to a 15% increase (36.5% to 51.3%) in developmental screening from 2019 to June 2021. The percentage of young children (PCCC patients) referred to the local Early Intervention Program (EIP) and developmental specialists increased from 68.7% to 88.0% and from 43.7% to 76.0%, respectively.

Out of 53 physicians who responded to the AAP survey, 77.4% used a general development screener and 90.6% used an ASD screener. Less than 10% of respondents used the Center for Disease Control and Prevention's (CDC) "Learn the Signs, Act Early" program materials, but nearly 80% were interested in learning more about and receiving further information regarding early childhood development.

**Conclusions:** The ASD Screening Project was overall successful in improving linkage to care for children in an underserved community. These results emphasize that applying a similar model elsewhere may lead to similar improvements. Based on the AAP survey, there is a strong desire by clinicians to learn more about this type of intervention, which may lead to expansion of the project and further improvement in ASD screening and early referrals across the state.

While the ASD Screening Project showed positive results, screening at the PCCC is still less than perfect with only 1 in 2 children being screened for ASD. The AAP survey results suggest that barriers to screening may be avoided with the implementation of continued education, specifically regarding the general understanding of development and the use of general development screeners.

#### **423.025 (Poster) Differences in Object Manipulation in Infants at Low and Elevated Likelihood for Autism Spectrum Disorder**

A. Federico<sup>1</sup>, E. Platt<sup>2</sup>, A. Dea<sup>2</sup> and J. Bradshaw<sup>2</sup>, (1)The University of South Carolina, Columbia, SC, (2)University of South Carolina, Columbia, SC

---

#### **Background:**

Deficits in motor skills have been identified in the first year of life for infants who later develop autism spectrum disorder (ASD). These infants show atypical fine and gross motor skills and object manipulation behaviors, including differences in mouthing, visual exploration, and grasping (Kaur et al., 2015). Generally, studies have used broad definitions for object exploration. To better understand object exploration differences in infants at a genetic likelihood for ASD (EL infants), the current study examines differential patterns of exploration between EL infants and infants at a low likelihood for ASD (LL).

#### **Objectives:**

This study aims to investigate differences in proportion of time 6 and 9 month old infants at LL and EL for ASD spent exploring an object during a brief interaction with an age-appropriate toy, and identify associations between object exploration and cognitive and motor skills.

#### **Methods:**

Participants (LL=24, EL=11) were enrolled in a study of infant development. At 6 and 9 months of age, participants completed a brief interaction with an age-appropriate object and the Bayley Scales of Infant Development. Videos of infant interactions with the object were coded for the amount of time spent exploring (i.e., holding/touching/moving fingers across the object).

By March 2022, 5 more unique participants will have participated in this study and all participants will have undergone 12-month assessments, which will allow for the evaluation of change in object exploration over time and longitudinal predictive relationships between object exploration and motor and cognitive skills.

## Results:

Results revealed significant differences in the proportion of time that EL and LL 6-month-old infants explored objects. EL infants spent a significantly higher proportion of time exploring objects ( $M=92.05\%$ ) than LL infants ( $M=77.30\%$ ;  $t(29.04)=2.97$ ,  $p=0.01$ ). Surprisingly, there were no differences in the proportion of time that 9-month-old EL and LL infants explored objects ( $EL=46.56\%$ ,  $LL=50.89\%$ ,  $t(8.28)=-0.28$ ,  $p=0.79$ )

Multiple regressions were used to examine the relationship between proportion of time spent exploring the object and concurrent cognitive and motor skills across all participants. Model results showed that at 6 months, exploration of objects were associated with cognitive ( $F(31)=4.52$ ,  $p=0.04$ ) and gross motor skills ( $F(31)=4.05$ ,  $p=0.05$ ), but not fine motor skills ( $F(31)=0.56$ ,  $p=0.46$ ). At 9 months, cognitive ( $F(16)=0.12$ ,  $p=0.74$ ), gross motor ( $F(16)=0.00$ ,  $p=0.94$ ), and fine motor ( $F(16)=1.15$ ,  $p=0.30$ ) skills were nonsignificant.

## Conclusions:

This study documents that EL infants spend a higher proportion of time exploring the object compared to LL infants at 6 months of age, but no differences emerged at 9 months of age. Positive associations between object exploration and cognitive skills, and negative associations between object exploration and gross motor skills were also observed at 6 months of age, but not 9 months of age. Evidence has been provided for the idea that EL infants engage in more repetitive play than LL infants (Thomas & Smith, 2004). Thus, EL infants may spend time repetitively exploring the object, whereas LL infants may explore and engage in other, more complex actions. Further investigation is needed to parse out the differences in object exploration across the first year of life.

### 423.026 (Poster) Examining Clinical Phenotype Sex Differences Among ASD Toddlers

*S. Ramos-Cabo<sup>1</sup>, J. Zahiri<sup>2</sup>, C. Carter<sup>2</sup>, S. Arias<sup>2</sup>, S. Nalabolu<sup>2</sup>, E. Courchesne<sup>2</sup> and K. Pierce<sup>2</sup>, (1)Neurosciences, University of California San Diego, San Diego, CA, (2)Autism Center of Excellence, UCSD, San Diego, CA, (3)Neurosciences, University of California, San Diego, La Jolla, CA*

#### Background:

With a 4:1 male-to-female ratio (Maenner et al. 2020) Autism Spectrum Disorder (ASD) has been classically regarded as a male condition. However, epidemiological, and population-based studies challenge these numbers and report much more balanced ratios (Kim et al. 2011; Mattila et al. 2011), suggesting that females with ASD are underdiagnosed. A proposed explanation for the difficulties identifying females on the spectrum is that they often “mask” symptoms with superior social and language abilities (for a review see Hull et al. 2020). Yet, studies on sex differences in ASD are scarce and have small sample sizes.

#### Objectives:

The present study aimed at elucidating the presence of fundamental sex differences in the behavioral presentation of ASD within social, communicative, cognitive, motor, and adaptive skills in a large sample of toddlers with and without ASD.

#### Methods:

A total of 1373 toddlers diagnosed with ASD ( $F=294$ ,  $M=1079$ ; mean age  $F=24.9$  months,  $M=25.8$  months) and 694 typically developing toddlers ( $F=277$ ,  $M=417$ ; mean age  $F=20.3$  months,  $M=19.1$  months) participated. Scores of the Autism Diagnostic Observation Schedule (ADOS-2), the Communication and Symbolic Behavior Scales Developmental Profile (CSBS-DP), the Mullen Scales of Early Learning (MSEL) and the Vineland Adaptive Behavior Scales (VABS-3) were selected as measures of social, communicative, cognitive, motor, and adaptive skills. Sex differences were examined using T-tests, and the Benjamini-Hochberg (B-H) procedure was applied to correct for multiple comparisons.

#### Results:

While no statistically significant sex differences were found in the ASD group, boys and girls in the typically developing (TD) group displayed significantly different profiles in all the domains of the ADOS-2 [Communication & Social interaction ( $t = -3.196$ ,  $p = 0.002$ ), Restricted & Repetitive Behavior ( $t = -3.669$ ,  $p = 0.002$ ), Overall Total ( $t = -3.925$ ,  $p = 0.002$ )], the MSEL [Visual Reception ( $t = 2.255$ ,  $p = 0.029$ ), Fine Motor ( $t = 2.156$ ,  $p = 0.032$ ), Receptive Language ( $t = 3.858$ ,  $p = 0.002$ ), Expressive Language ( $t = 2.751$ ,  $p = 0.009$ ), Early Learning Composite ( $t = 3.577$ ,  $p = 0.002$ )] and the CSBS-DP [Social ( $t = 2.605$ ,  $p = 0.011$ ), Expressive ( $t = 2.770$ ,  $p = 0.009$ ), Symbolic ( $t = 2.159$ ,  $p = 0.032$ ), Total Score ( $t = 2.817$ ,  $p = 0.009$ )] and the VABS-3 [Communication ( $t = 3.744$ ,  $p = 0.002$ ), Daily Living Skills ( $t = 3.413$ ,  $p = 0.002$ ), Socialization ( $t = 2.688$ ,  $p = 0.009$ ), Adaptive Behavior Composite ( $t = 3.347$ ,  $p = 0.002$ )] except for Motor Skills domain. Girls outperformed boys in all measures except for Restricted & Repetitive Behavior in the ADOS-2, and the Social and Total Score in the CSBS-DP. All reported p-values were corrected with B-H. See figures for example.

#### Conclusions:

Our results show that in TD toddlers, sex differences in social, language, and cognitive skills are common, with females generally scoring higher than males during this young age period. Yet, boys and girls with autism perform similarly, even in the ADOS-2. These findings challenge the prevailing theory of fundamental sex differences in ASD at this young age.

**423.027 (Poster)** Expanding Social Attention and Communication Surveillance into Preschool (SACS-PR): An Additional Checklist of the SACS-Revised for Early Autism Detection

**J. Barbaro<sup>1</sup>**, **N. Sadka<sup>1</sup>**, **M. Gilbert<sup>2</sup>**, **L. Ridgway<sup>3</sup>** and **C. Dissanayake<sup>1</sup>**, (1)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (2)Olga Tennison Autism Research Centre, Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (3)Judith Lumley Centre, La Trobe University, Melbourne, VIC, Australia

---

**Background:** A universal, developmental surveillance tool for autism, Social Attention and Communication Surveillance-Revised (SACS-R), was developed for use in 11-30-month-old children, with very strong psychometric properties (83% positive predictive value, PPV; 99% negative predictive value, NPV; 72% sensitivity, 99.5% specificity; Barbaro et al., under review). Although the SACS-R's sensitivity was sufficient, we wanted to investigate whether we could improve its sensitivity whilst maintaining sufficient accuracy.

**Objectives:** The objective of this study was to improve the SACS-R's sensitivity by adding a preschool checklist (SACS-PR) at 42-months of age at children's free, routine, community-based health-checks.

**Methods:** The SACS-R and SACS-PR comprise brief checklists to monitor developmentally appropriate social-attention and communication behaviours at 12-, 18-, 24-, and 42-months-of-age. A total of 126 Maternal and Child Health (MCH) nurses were trained to utilise these checklists during routine child health-checks, with 13,511 children monitored with the SACS-R between 11- and 30-months, and 8,233 with the SACS-PR at 42-months. All children identified at 'high likelihood' for autism were referred for a University developmental assessment. Furthermore, children identified at 'low likelihood' on SACS-PR who had *any* developmental concerns, or had a community-based diagnosis of autism, were also referred for a University assessment to determine false negatives. Gold-standard assessment tools were utilised (ADOS, ADI-R, Mullen Scales of Early Learning) at each age.

**Results:** A total of 270 children on the spectrum were identified by the SACS-R between 11- and 30-months of age. The MCH nurses identified an additional 168 children at 'high likelihood' for autism using the SACS-PR at 42 months who had not previously been identified by the SACS-R. An additional 11 children on the spectrum were identified that were 'low likelihood' on both tools (i.e., false negatives). The psychometrics of the SACS-PR as a stand-alone tool was 89.6% sensitivity, 99.1% specificity, 56.5% PPV, and 99.9% NPV. However, when used as intended – as a developmental surveillance tool combined with the SACS-R, the PPV increased significantly to 73.7%, with 97.7% sensitivity, 99% specificity, and 99.9% NPV.

As with the SACS-R, no "true" false positives (typically developing children) were identified using the SACS-PR, with all children identified as either on the spectrum or having developmental/language delays. Autism prevalence was 1.99% (1 in 50) between 11- and 30-months and rose to 2.78% (1 in 36) when the children identified at 42-months were included.

**Conclusions:** The addition of the SACS-PR as a 42-month follow-up checklist to the SACS-R significantly increased sensitivity from 72% to 97%, stressing the importance of a developmental surveillance model where children are repeatedly monitored across time for autism. Had a preschool checklist not been utilised, >160 children on the spectrum would have missed the opportunity to be identified, diagnosed, and enrolled into early intervention services prior to school entry. Thus, it is imperative that early screening/developmental surveillance tools include a preschool check to identify a significant proportion of children who will not be identified very early in life. Used together, the SACS-R/PR continues to be the most robust early developmental surveillance tool for autism.

**423.028 (Poster)** Explaining the Gap: Executive Functioning Predicts the Discrepancy between Cognitive and Adaptive Functioning in Toddlers with ASD

**S. R. Edmunds<sup>1</sup>**, **Y. Braverman<sup>2</sup>**, **I. Hastedt<sup>2</sup>** and **S. Faja<sup>2</sup>**, (1)Psychology, University of South Carolina, Columbia, SC, (2)Boston Children's Hospital, Boston, MA

---

**Background:** Autism spectrum disorder (ASD) is associated with poor adaptive functioning (AF), even in the absence of cognitive delays. For school age autistic children, the gap between IQ and age-expected AF increases with age, such that AF lags behind IQ (Pugliese et al., 2015). Executive functioning (EF) and AF are correlated in ASD (Pugliese et al., 2016), although results are mixed regarding which aspects of EF and AF are linked. No study has examined the association between EF and the gap between cognitive ability and AF in autistic toddlers and young children.

**Objectives:** We evaluated whether: (a) toddlers' AF decreases with age relative to age norms; (b) the gap between cognition and AF increases with age; (c) EF is associated with AF; and, (d) EF predicts the cognition-AF gap.

**Methods:** Parents of children with ASD without cognitive delays (i.e., nonverbal developmental quotient  $\geq 70$ ) ages 25-36 and 48-60 months (N=61, 66% boys, 69% white) completed the Vineland Adaptive Behavior Scales (VABS-III) and the Behavior Rating Inventory of Executive Functioning, Preschool Edition (BRIEF-P). Multiple regressions examined whether: age (months) predicted (a) VABS domain scores beyond cognition, (b) the gap between cognition and VABS; and BRIEF-P Global Executive Composite (GEC) predicted (c) VABS domain scores beyond age and cognition and (d) the gap between cognition and VABS domains beyond age. Caregiver income and education were not significant predictors of AF or EF and were removed from final models.

Results: For 2- and 4-year-olds, age was not related to VABS Composite, Communication, Daily Living Skills, or Socialization domains ( $-.15 < \beta s < .10$ ,  $.22 < ps < .71$ ). Similarly, age did not predict the gap between cognition and AF ( $.04 < \beta s < .19$ ,  $.31 < ps < .78$ ). While cognition-AF gaps exist, ANCOVAs yielded no effect of age or domain. For 2-year-olds, EF skills predicted adaptive Composite ( $\beta = -.46$ ,  $p = .02$ ) and Socialization ( $\beta = -.59$ ,  $p < .001$ ) domains. For 4-year-olds, EF skills predicted VABS Composite ( $\beta = -.43$ ,  $p < .01$ ), Socialization ( $\beta = -.56$ ,  $p < .001$ ), and Daily Living ( $\beta = -.43$ ,  $p < .01$ ) domains. Overall, as EF problems increased, AF decreased. EF was not associated with Communication domain scores ( $-.28 < \beta s < .07$ ,  $.17 < ps < .68$ ). For 2-year-olds, EF problems predicted the gap between cognition and Socialization only ( $\beta = .51$ ,  $p < .01$ ), whereas for 4-year-olds, EF problems predicted the gap between cognition and Composite ( $\beta = .35$ ,  $p = .03$ ), Socialization ( $\beta = .48$ ,  $p = .002$ ) and Daily Living skills ( $\beta = .32$ ,  $p = .047$ ). Overall, as EF problems increased, the degree to which AF lagged cognition increased.

Conclusions: For autistic 2- and 4-year-olds without cognitive delays, no decline in adaptive functioning (AF) relative to same-aged peers or increase in the gap between cognition and AF was observed. Plateauing of AF likely begins later in development (Pugliese et al., 2015; Braverman et al., in prep). However, as early as 2 years, children's executive functioning (EF) skills predict both concurrent socialization skills and the gap between cognition and socialization skills. By 4 years, EF also predicts daily living skills and the gap between cognition and daily living skills. Everyday communication skills may track more closely with factors other than EF (e.g., cognition) in preschool. These findings demonstrate the potential importance of EF interventions in toddlerhood to support adaptive development.

**423.029 (Poster)** Eye-Tracking and NIRS Measures of Familiar Face Processing in Infants with and without an Older Sibling with Autism  
J. B. Wagner<sup>1,2</sup>, M. Pecukonis<sup>1</sup>, S. R. Scarano<sup>1</sup>, C. Martinez<sup>2</sup>, H. Tager-Flusberg<sup>1</sup> and C. A. Nelson<sup>1</sup>, (1)Department of Psychology, College of Staten Island, City University of New York, Staten Island, NY, (2)Department of Psychology, The Graduate Center, City University of New York, New York, NY, (3)Department of Psychological and Brain Sciences, Boston University, Boston, MA, (4)Department of Developmental Medicine, Boston Children's Hospital, Boston, MA

Background: Differences in attentional and neural responses to faces have been found between individuals with and without autism (e.g., Pelphrey et al., 2002; Webb et al. 2006). These differences have also been examined in first-degree relatives, including infants who have an older sibling diagnosed with autism (Sibs-ASD; e.g., Lloyd-Fox et al., 2013; Wagner et al., 2018), but little work has explored attentional and neural responses within the same sample and asked how these responses might be associated.

Objectives: In the current study, we examined attentional and neural responses to faces in Sibs-ASD and a comparison group with no family history of autism (Sibs-Comp).

Methods: Sibs-ASD ( $n = 14$ ) and Sibs-Comp ( $n = 35$ ) were tested at 12 months with a Tobii T-120 eye-tracker and a 24-channel Hitachi ETG-4000 NIRS system simultaneously recording responses to 16s videos of the infant's mother or a stranger talking with a neutral expression (sound removed). Analysis of attention focused on the proportion of time on eyes and mouth (divided by time on face). NIRS recordings were collected from frontal and right lateral regions. Oxyhemoglobin concentration (oxyHb) was averaged from 6s to 16s after stimulus onset. Infants who contributed  $\geq 2$  trials for both mother and stranger for eye-tracking and/or NIRS were included in the current analyses.

Results: For eye-tracking, a 2 (Identity: Mother, Stranger)  $\times$  2 (Group: Sibs-ASD, Sibs-Comp)  $\times$  2 (Region: Eyes, Mouth) mixed model ANOVA analyzed visual attention, and a Group  $\times$  Region interaction was found ( $p = .014$ ). Post hoc tests revealed that Sibs-Comp showed a greater proportion of time on the mouth than the eyes ( $p = .004$ ), but Sibs-ASD showed no difference in attention to these two regions ( $p = .29$ ; Figure 1). For NIRS, a 2 (Identity: Mother, Stranger)  $\times$  2 (Group: Sibs-ASD, Sibs-Comp)  $\times$  2 (Region: Frontal, Right Lateral) mixed model ANOVA analyzed mean oxyHb responses, and a Group  $\times$  Identity interaction was found ( $p = .013$ ), with Sibs-ASD responding significantly more to mother than stranger ( $p = .026$ ) and Sibs-Comp showing no difference ( $p = .38$ ). An exploratory analysis looked at correlations between eye-tracking and NIRS responses and found that decreased attention to the mouth was associated with increased frontal neural responses ( $r = -.38$ ,  $p = .026$ ; Figure 2), and this was driven by the Sibs-Comp group ( $r = -.51$ ,  $p = .008$ ). Sibs-Comp also showed a trend towards increased attention to the eyes relating to increased frontal neural responses ( $r = .39$ ,  $p = .05$ ).

Conclusions: The current study found interactions with group for both eye-tracking and NIRS measures and relations between attentional and neural responses. For eye-tracking, Sibs-Comp showed increased attention to the mouth relative to the eyes, while Sibs-ASD looked similarly to the two face regions. Across frontal and right lateral brain regions, Sibs-ASD showed greater neural responses to mother than stranger, but Sibs-Comp showed no difference based on identity. Together, this work suggests that differential patterns of attentional and neural responses could underlie face processing in Sibs-ASD and Sibs-Comp in the first year.

**423.030 (Poster)** Impact of Co-Occurring Gestures on Social Visual Engagement to Caregivers in Infants with and without Autism Spectrum Disorder  
C. Nicholson<sup>1,2,3</sup>, N. Fram<sup>4</sup>, M. K. Sahoo<sup>5</sup>, M. Hines-Wilson<sup>1</sup>, A. Klin<sup>6</sup>, W. Jones<sup>6</sup>, M. D. Lense<sup>7</sup> and L. A. Edwards<sup>1</sup>, (1)Marcus Autism Center, Atlanta, GA, (2)Emory University School of Medicine, Atlanta, GA, (3)Children's Healthcare of Atlanta, Atlanta, GA, (4)Stanford University, Stanford, CA, (5)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (6)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (7)Vanderbilt University Medical Center, Nashville, TN

**Background:** Communication to infants occurs multimodally through speech, gesture, and facial expressions. Parents' use of co-occurring gestures with speech facilitates language development, including in children at risk for autism spectrum disorder (ASD). Children with ASD have impairments in both gesture and language development. Using gestures and teaching gesture imitation skills through natural play opportunities may be important for supporting social interaction and may have downstream impacts on child language/communication skills. However, little is known

about how the use of gesture during interactions impacts how infants allocate their visual engagement and if this relates to their later development. We investigated visual engagement in infants with and without ASD within two common contexts that frequently involve co-occurring gestures: infant-directed speech and song.

**Objectives:** Explore the impact of co-occurring gestures on patterns of social visual engagement (SVE) in naturalistic social scenes of infant-directed speech and song in both typically-developing (TD) infants and infants that later develop ASD.

**Methods:** Eye-tracking measures of SVE were collected from infants while they watched videos of a caregiver engaging them naturalistically, using either infant-directed speech (with and without gestures) or song (with and without gestures). Infants were eye-tracked at 12 months (Speech:  $n_{TD}=72$ ,  $n_{ASD}=19$ ; Song:  $n_{TD}=137$ ,  $n_{ASD}=33$ ) and 24 months (Speech:  $n_{TD}=118$ ,  $n_{ASD}=22$ ; Song:  $n_{TD}=159$ ,  $n_{ASD}=41$ ). Data were quantified as the percentage of time infants spent fixated on regions of interest within videos (i.e. eyes, mouth, body, and object). Infants were evaluated for ASD at 24 months by expert clinicians using gold-standard assessments.

**Results:** Patterns of SVE were significantly different between clips with and without gestures in both the speech and song conditions, at both 12 and 24 months, in infants with and without ASD (all  $p$ -values $<0.01$ ). At both 12 and 24 months of age, infants with and without ASD fixated more on the caregiver's body when she used co-occurring gestures in speech or song ( $p$ 's $<0.001$ ). In addition to the main effect of gestures on body-looking, at 24 months, there was a significant interaction with diagnosis in both the speech ( $p<0.001$ ) and song ( $p<0.01$ ) conditions. At 24 months of age, ASD infants fixated more on bodies during videos where the caregiver engaged them with gestures than TD infants, but not in videos without gestures.

**Conclusions:** Co-occurring gestures modulate social visual engagement to caregivers in infants with and without ASD, during both infant-directed speech and song. By 24 months, infants with and without ASD also diverge in their patterns of visual engagement to speech and song with and without gestures. This may reflect differences in children's symbolic development and the communicative value of different components of multimodal, social-communicative signals by this age. Future analyses will explore the adaptive value of SVE to gestures in speech and song contexts for clinical outcomes. This work has implications for interaction strategies that incorporate using animated and exaggerate gestures to modulate SVE in children with ASD.

Pierce<sup>9</sup>, (1)Southwest Autism Research & Resource Center, Phoenix, AZ, (2)Arizona Autism United, Phoenix, AZ, (3)Carolina Psychological Associates, Greensboro, NC, (4)SARRC, Phoenix, AZ, (5)Mountain Park, Phoenix, AZ, (6)University of California, San Diego, La Jolla, CA, (7)Neurosciences, University of California, San Diego, La Jolla, CA, (8)Rady Children's Hospital, San Diego, CA, (9)UCSD Autism Center of Excellence, La Jolla, CA

#### **Background:**

Despite research indicating that symptoms of autism are present as early as 12-months in many cases (Miller et al., 2017; Ozonoff et al., 2010; Pierce et al., 2011, 2019; Wan et al., 2013; Zwaigenbaum et al., 2015), and that autism can be diagnosed soon thereafter (Lord, et al., 2006; Pierce et al., 2019), the current median age of diagnosis is 51 months (Maenner et al., 2020) and in many states, it is even older. Various reasons exist for late diagnosis, including limited understanding of early warning signs among healthcare professionals and parents, and limited access to diagnostic evaluations (Crais et al., 2014; Daniels & Mandell, 2014). Since diagnosis enables access to early intensive intervention, which improves long-term outcomes (Anderson, Oti, Lord, & Welch, 2009; Dawson, 2008; Dawson et al., 2012; Reichow, 2018), effective screening practices are critical.

**Objectives:** The goal of the present study was to implement a validated early detection program, *Get SET Early*, which results in a mean age of diagnosis of 19 months when mediated through a university research program, in a community clinic setting.

**Methods:** Following *Get SET Early* guidelines, licensed psychologists were trained to provide diagnostic evaluations to toddlers as young as 12 months. Next, 109 primary healthcare providers (PHP) joined the screening network and completed a survey at both baseline and 2 years into the program. PHPs administered the CSBS-IT Checklist at 12-, 18- and 24-month well-baby visits and referred toddlers whose scores fell into the range of concern for a developmental evaluation. For comparison, 18 providers that were not part of the screening network completed a blinded survey to document the use of a screening tool at the same well-baby visit schedule. Mean age of diagnosis was compared to current population rates.

**Results:** PHP screening improved after *Get SET Early* program implementation. Across a 4-year period, 45,504 screens were administered at well-baby visits and 648 children were evaluated at least one time. The median age for ASD diagnosis overall was 22 months, significantly lower than the median age reported by the CDC (57 months). For children screened at 12 months, the age of first diagnosis was significantly lower at 15 months. Of the 350 children who completed at least one follow up evaluation, 323 were diagnosed with ASD or another delay, and 239 (74%) were enrolled in a treatment program.

**Conclusions:** Overall, the *Get SET Early* model was successfully implemented in a community-based center and led to positive changes in pediatrician attitudes and behavior regarding early developmental screening. Toddlers with ASD were diagnosed nearly 3 years earlier than the most recent CDC report for a similar region, which allowed most children to start a treatment program by 36 months. Overall, the *Get SET Early* model was an effective strategy for improving the current approach to screening, evaluation, and treatment referral for toddlers with ASD. Efforts to demonstrate sustainability and scalability are underway.

#### **423.032 (Poster)** Increased Feminine Gender Markers in Toddler Girls with and without Autism Spectrum Disorder

#### Background:

Autism Spectrum Disorders (ASD) has traditionally been considered a predominantly male disorder with a 4:1 ratio. Until recently the majority of research recruited male-skewed samples, leading to a potential self-reinforcing male-biased understanding of the syndrome. Underrepresentation of females and lack of knowledge about female presentation may contribute to delayed or misdiagnosis of girls, despite similarities in symptoms, timing and type of parental concerns. As long as ASD remains a behaviorally-defined disorder it is necessary to address clinicians' sex/gender biases and raise awareness about female phenotypes and women's experiences with ASD. This study aimed to explore the particular phenomenon of Gender-Appearance-Rigidity (GAR; i.e., gender-specific marking) as a potential factor for clinicians' biased expectations and diagnoses. Following research showing that child's sex/gender (e.g., clothing, hair) influences teachers' appraisals of children's behavior and performance, we investigated whether girls with ASD referred for neurodevelopmental assessment exhibit enhanced feminine appearance compared to girls without ASD.

#### Objectives:

(1) Develop and validate a video coding scheme to quantify gender markers in toddler girls; (2) Use the scoring to compare feminine genderness between toddler girls with and without ASD.

#### Methods:

Participants included two age-matched groups of girls, 41 with ASD (mean age: 45.3 months) and 21 without ASD (mean age: 45.2 months). Girls with ASD were recruited from a neurodevelopmental clinic and received a formal diagnosis. Girls without ASD included those who did not receive the diagnosis, as well as 10 typically developing (TD) girls recruited from a mainstream nursery school in the same area. We developed and validated ( $\kappa = 0.82, p < 0.001$ ) a modified coding scheme for GAR by Halim et al. (2018). Four coders, blinded to diagnosis, scored GAR from full-body images extracted from videos. The GAR scoring included markers of gender appearance rigidity in choices of color, texture, and style (i.e., pink/purple, sequins/sparkles, ruffles/frills, dresses/skirts). One point was given for each gender-rigid characteristic.

#### Results:

Differences in GAR scores between girls with and without formal ASD diagnosis were analyzed using the nonparametric Wilcoxon rank-sum test. Total GAR scores did not differ, however compared to girls without ASD, girls with ASD scored higher in stereotypically feminine items. Specifically, they wore more dresses or skirts ( $W = 581.5, p < 0.01$ ) with more gender-rigid accents such as ruffles, frills, or lace ( $W = 537.5, p < 0.05$ ).

#### Conclusions:

This study examines GAR in toddler girls with and without ASD. Based on our modified scoring system (Halim et al., 2018), we found more gender-specific items (i.e., pink, dresses/skirts, ruffles/frills) in girls who received a formal diagnosis of ASD, compared to age-matched girls without ASD and the sample of TD girls. These results suggest that in addition to IQ and behavioral symptoms, increased genderness may contribute to clinicians' best-estimate ASD diagnoses. Furthermore, since toddler girls' clothing is likely based on parents' cultural and socioeconomic background, future studies will determine the importance of social impairment in girls as the basis for parents from diverse backgrounds to use hyperfeminine markers at the time of the diagnostic evaluation.

#### **423.033 (Poster) Infant Sibling's Temperament Associate with Proband Traits of ASD and ADHD**

**H. Halkola<sup>1</sup>, A. Pickles<sup>2</sup>, J. Begum Ali<sup>3</sup>, A. Gui<sup>4</sup>, G. Pasco<sup>5</sup>, M. H. Johnson<sup>6</sup>, T. Charman<sup>3</sup>, E. J. Jones<sup>4</sup> and &. The BASIS-STAARS Team<sup>6</sup>,** (1)Institute of Psychiatry, Psychology and Neuroscience, Department of Psychology, King's College London, London, United Kingdom, (2)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (4)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (5)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

---

#### Background:

Autism spectrum disorder (ASD) and attention deficit/hyperactivity disorder (ADHD) are both highly heritable neurodevelopmental conditions. Having an older sibling (proband) with ASD increases the likelihood of developing ASD symptoms. Dimensional variation of proband symptomology has been shown to predict likelihood of familial ASD recurrence. Likewise, having a family member with ADHD increases the likelihood of developing ADHD. Previous prospective studies have shown associations between fear/shyness to later development of ASD traits, while activity level and attentional measures show similar pattern for later ADHD trait development. However, few previous studies have investigated how proband traits of ASD and ADHD associate with early infant temperament traits in their younger siblings.

#### Objectives:

To investigate how elevated likelihood of developmental disorders and older siblings' ASD and ADHD traits associate with early childhood predictors of ASD and ADHD in infant siblings.

#### Methods:

The study included 411 infant participants (male=213, female=198) and their older siblings with ASD (n=250), ADHD (n=31), both (n=21) or neither (n=106) from the British Autism Study of Infant Siblings (BASIS) and Studying Autism and ADHD Risks (STAARS) studies. A combined group variable was made combining all elevated likelihood children into one category (n=302). For infant temperament, parents completed the Infant Behavior Questionnaire (IBQ) at 8-months and 14-months and the Early Childhood Behavior Questionnaire (ECBQ) at 24-months. Fear/shyness was used as possible early predictors of ASD, while activity level, duration of orientation and attentional shifting/focus were used for ADHD. For proband ASD traits, parents completed Social Communication Questionnaire (SCQ) Lifetime version (n=329). Conners 3 parent questionnaire was used for ADHD traits from which a mean variable was derived using the subscales for inattention and hyperactivity/impulsivity. Latent growth curve models with maximum likelihood method were used for statistical analysis.

#### Results:

Infants with older siblings with more ASD symptoms had higher levels of initial fear/shyness with the effect carrying over all timepoints (figure 1). Neither group nor ADHD traits were significantly associated with fear/shyness. Infants whose siblings had more ADHD traits had higher scores in initial attention and lesser change over time (figure 2). On the other hand, being in an elevated likelihood group was associated with lower initial attention and higher level of change over time. Proband ASD traits were not associated with attention. Higher ADHD traits in older sibling was also associated with increased initial level of activity in infant siblings ( $\beta=.21$ ,  $p=.038$ ) with the effect carrying across all timepoints, while group and ASD traits showed no significant association. There were no associations between the change in activity level over time and proband traits or group.

#### Conclusions:

This is one of few studies investigating how older siblings' traits associate with the development of temperament in their infant siblings. The results show that older siblings' ADHD and ASD traits associate with the temperament trajectories of their infant sibling in a distinctive manner, differentiating across different constructs. Future studies should explore possible connection with later emergence of ASD and ADHD, as temperament traits might be early predictors of later neurodevelopmental disorders.

**423.034 (Poster)** Infant's Visual Attention to Faces and Temporal Frequency: A Prospective Longitudinal Autism and ADHD Study  
**M. A. Agyapong<sup>1</sup>**, M. H. Johnson<sup>2</sup>, T. Charman<sup>3</sup>, E. J. Jones<sup>4</sup> and & The BASIS-STAARS Team<sup>1</sup>, (1)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (2)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (3)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (4)Department of Psychology, Institute of Psychiatry, Psychology & Neuroscience, King's College London, London, United Kingdom

#### Background:

Neurodevelopmental conditions like autism spectrum disorder (ASD) and attention deficit hyperactivity disorder (ADHD) are diagnosed in early childhood and frequently co-occur. It is important to understand the early mechanisms that could contribute to later difficulties in these neurodevelopmental conditions through prospective studies. Throughout infancy, there are developmental changes in infant's face-scanning patterns, which shapes and reflects their processing of social information like language. Another important component in early learning is how temporal structure of events influences attention. Syllabic speech occurs at 6Hz frequency, but it is unclear how mouths moving at different frequencies affects visual attention. Here we explore looking patterns to faces at various temporal frequencies, in infants with and without autistic and/or ADHD first-degree relatives.

#### Objectives:

To investigate attention to eyes, mouth and temporal structure (i.e. information presented at different frequencies), in infants at typical-likelihood (TL) and elevated-likelihood (EL) of ASD and/or ADHD.

#### Methods:

This prospective study included 161 infants (70 females) from the Studying Autism and ADHD Risks Study (STAARS; [www.staars.org](http://www.staars.org)). At 5- 10- and 14-month timepoints, 29 TL controls, 80 EL-ASD, 31 EL-ADHD and 21 EL-ASD+ADHD infants completed an eye-tracking paradigm ('Frequency Task'). Three 10-second videos of face pairs were presented to the infants (Figure 1A). Each stimulus in the pair displayed the mouth opening and closing at low, mid or high frequencies. An eye-mouth index (EMI; see Figure 1B) was calculated as: upper-face-looking time/(upper-face-looking time + lower-face-looking time).

#### Results:

A Linear Mixed Model was used to investigate the main effects and interactions of likelihood groups, frequency, and age (in months) on EMI. Side of stimulus presentation was a significant predictor, and therefore included as a covariate. Meanwhile, age and participant-ID were included as

random effects. There were no TL or EL group differences in EMI ( $ps > .47$ ), and no effect of frequency ( $ps > .06$ ). However, the main effect of age was significant;  $t(1910) = -5.38$ ,  $p < .001$ ,  $d = 0.69$ ), showing that EMI decreased with age; see Figure 2. Interactions did not reach significance.

## Conclusions:

Typical-likelihood and elevated-likelihood for ASD and/or ADHD infants showed similar patterns of looking to the eyes and mouth. Temporal frequency did not modulate infant's visual attention, suggesting no preference for stimuli presented at the rate of human syllabic speech. As they got older, infants across groups looked more at the mouth than the eyes. This provides support for the primary developmental shift from looking at the eyes towards looking at the mouth, consistent with the age of language emergence. The present study contributes to the developmental literature of infant's face scanning patterns by investigating EMI in EL-ADHD and EL-ASD+ADHD populations. Future work will explore the relation between EMI, later language abilities and ASD outcomes in these infants.

### 423.035 (Poster) Internalizing and Externalizing Symptoms Are Elevated in 3-Year-Olds with ASD and Are Predicted By Temperamental Features at Age 2.

**S. Macari<sup>1</sup>**, **K. K. Powell<sup>1</sup>**, **E. Diamond<sup>2</sup>**, **E. Brennan-Wydra<sup>1</sup>**, **A. Verneti<sup>1</sup>** and **K. Chawarska<sup>1</sup>**, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale University, New Haven, CT

#### Background:

Internalizing symptoms (e.g., anxiety, depression) and externalizing symptoms (e.g., aggression, oppositional behavior) occur in children with ASD at rates several times higher than in the general population (Salazar et al., 2015), resulting in greater functional impairments and additional challenging behaviors (Brookman-Frazee et al., 2018). Preschoolers with ASD experience more internalizing and externalizing (I/E) symptoms compared to typically-developing (TD) peers (Li et al., 2019) with a subgroup exhibiting high levels of I/E symptoms during preschool- and school-age (Vaillancourt et al., 2017). Models of the emergence of I/E symptoms stress the role of early temperament, particularly Negative Affectivity (NA) and Surgency (SU) (Behrendt et al., 2020; Colder et al., 2002; Putnam & Stifter, 2005; Rothbart, Posner & Hershey, 1995) but little is known about these predictors in children with ASD.

#### Objectives:

Determine 1) if 3-year-old toddlers with ASD differ from non-ASD toddlers on I/E symptoms, and 2) if parent-reported temperament (NA, SU) at age 2 predicts I/E symptoms at age 3.

#### Methods:

Participants included age-matched toddlers with ASD ( $n=67$ ; 81% male) and without ASD ( $n=81$ ; 58% male; with atypical development, TD, and unaffected siblings of children with ASD) during their first visit (Time1;  $M_{age}=21.35m$ ,  $SD=3.38$ ), at which time parents completed the Early Childhood Behavior Questionnaire (ECBQ; Putnam et al., 2006). Negative Affectivity (NA) and Surgency (SU) scores were computed. Approximately one year later (Time2;  $M_{age}=39.16m$ ,  $SD=3.67$ ), parents completed the Early Childhood Inventory-5 (ECI-5; Sprafkin & Gadow, 2014); Internalizing and Externalizing (I/E) composites were derived. Group differences in I/E scores were assessed using group (2) by sex (2) general linear models. Multiple regressions evaluated contributions of Time1 temperament (NA, SU), severity of autism symptoms (ADOS), and cognitive abilities (Mullen Scales: VerbalDQ, NonverbalDQ) to Time2 I/E symptoms.

#### Results:

GLM analyses resulted in significant main effects of group for both ECI-5 Internalizing ( $p<.001$ ) and Externalizing ( $p<.05$ ) but, in both analyses, no effect of sex ( $ps>.694$ ) or group by sex interaction ( $ps>.107$ ). Contributions of NonverbalDQ were not significant in either model ( $ps>=.413$ ) nor was VerbalDQ for Internalizing ( $p=.266$ ), although marginally significant for Externalizing ( $p=.060$ ). Planned contrasts indicated that toddlers with ASD had significantly more severe Internalizing symptoms ( $p<.001$ ,  $d=.996$ ) and Externalizing symptoms ( $p<.05$ ,  $d=.682$ ) than non-ASD toddlers. In the ASD group, multiple regression indicated that among all T1 predictors, ECBQ NA alone was significant and explained 23.4% of the variance ( $R^2=.234$ ,  $p<.001$ ) in age 3 Internalizing symptoms ( $\beta=.483$ ,  $p<.001$ ). Similarly, multiple regression indicated that ECBQ NA explained 18.9% of the variance ( $R^2=.189$ ,  $p<.001$ ) in later Externalizing symptoms ( $\beta=.434$ ,  $p<.001$ ).

#### Conclusions:

By 3 years of age, significant vulnerabilities in internalizing and externalizing symptoms occur in children with ASD compared to peers. As in the general population, both classes of symptoms are predicted by negative temperament assessed a year earlier. Given the relationships between NA and I/E symptoms by late toddlerhood, high negative affectivity in toddlers with ASD should be identified as a potential risk factor for later emotional/behavior problems, which are likely to affect quality of life for children as well as their families.

### 423.036 (Poster) Investigating Discrepancies between Eye-Tracking Measures and Expert Clinician Evaluation of ASD: Discrepancies Reflect Less Diagnostically-Clear Cases

**H. Tokish<sup>1</sup>**, **S. Sivathanan<sup>1</sup>**, **E. McQueen<sup>1</sup>**, **C. Klaiman<sup>2</sup>**, **H. Walum<sup>1</sup>**, **A. Klin<sup>1</sup>** and **W. Jones<sup>1</sup>**, (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Marcus Autism Center, Emory University, Atlanta, GA

**Background:** To increase access to timely expert clinical assessment for autism spectrum disorder (ASD), eye-tracking technologies show promise for objectively quantifying biomarkers of atypical social visual engagement (SVE)—a core feature of ASD—and may serve as an effective tool to aid early identification and diagnosis. To that end, an in-depth examination comparing discrepant and concordant cases between eye-tracking and reference-standard clinician best estimate (CBE) diagnosis can help inform that development.

**Objectives:** To examine quantitative differences in profiles of clinically-referred children between 16-45 months for whom eye-tracking and reference-standard CBE of ASD were concordant versus discrepant.

**Methods:** Eye-tracking and clinician assessments were completed concurrently in a large sample of patients referred to a specialty center for evaluation ( $N=243$ ,  $M_{\text{age(months)}}=28.7$ ). Expert clinicians blind to eye-tracking results completed standard-of-care diagnostic evaluations using the *Mullen Scales of Early Learning (MSEL)* and the *Autism Diagnostic Observation Schedule (ADOS-2)* to obtain a CBE diagnosis. Clinicians also rated their level of diagnostic certainty. True Positive (TP) and True Negative (TN) status was assigned based on concordant eye-tracking to CBE. False Positive (FP) and False Negative (FN) status was assigned when eye-tracking was discrepant with CBE. Data were analyzed according to two distinct pairings: FP versus TN (i.e., non-ASD) cases and FN versus TP (i.e., ASD) cases.

**Results:** Paired groups did not differ on age or sex. TN versus FP: Compared to TN ( $n=47$ ) cases, FP ( $n=20$ ) cases had higher ADOS-2 Restricted and Repetitive Behavior (RRB) scores ( $p=0.03$ ,  $d=0.59$ ), but no differences in Total ( $p=0.06$ ,  $d=0.52$ ), Social Affect (SA) ( $p=0.28$ ,  $d=0.29$ ) or MSEL scores ( $ps>0.05$ ). There were no significant differences in diagnostic certainty ( $p=0.99$ ). Notably, 80% of FP and 64% of TN were diagnosed with non-ASD developmental delays or subthreshold ASD traits. TP versus FN: Compared to TP ( $n=148$ ) cases, FN ( $n=28$ ) cases had lower ADOS-2 Total ( $p<0.001$ ,  $d=1.11$ ), SA ( $p<0.001$ ,  $d=1.10$ ), and RRB scores ( $p=0.02$ ,  $d=0.48$ ). The FN group also had higher MSEL verbal ( $p<0.001$ ,  $d=0.74$ ) and nonverbal ( $p=0.02$ ,  $d=0.47$ ) age equivalent scores than the TP group. Clinicians indicated greater diagnostic certainty ( $>80\%$ ) for children in the TP versus FN group ( $p=0.03$ ).

**Conclusions:** Overall, our findings reveal quantitative differences in profiles of children classified concordantly and discrepantly between eye-tracking measures of atypical SVE and a reference-standard CBE diagnosis of ASD. The majority of children for whom eye-tracking indicated ASD but the clinician did not (i.e., FP) received other diagnoses and had higher RRB scores than the TN cases, but otherwise demonstrated comparable developmental and social abilities. This suggests that eye-tracking identified children with more atypical behavioral symptoms. Children for whom eye-tracking did not indicate ASD while the clinician did (i.e., FN) had greater developmental and social abilities than TP cases, suggesting that these children demonstrated fewer or more subtle observable symptoms. Clinicians were less diagnostically certain of children classified as FN. As such, findings provide preliminary evidence that eye-tracking may detect children who display potentially more complex or less diagnostically clear symptom presentations, and who may benefit from additional monitoring and follow-up.

#### **423.037 (Poster)** Multimodal Investigation of Brain Morphology and Local Activity and Connectivity in Young Children with ASD

**B. Chen<sup>1</sup>**, A. C. Linke<sup>2</sup>, L. Olson<sup>3</sup>, J. S. Kohli<sup>2</sup>, M. C. Arcadio Arce<sup>2</sup>, S. R. Peña<sup>2</sup>, A. Andriasyan<sup>2</sup>, E. Mendez<sup>2</sup>, R. A. Müller<sup>2</sup>, R. A. Carper<sup>2</sup> and I. Fishman<sup>2</sup>, (1)San Diego State University, San Diego, CA, (2)Brain Development Imaging Laboratories, San Diego State University, San Diego, CA, (3)Joint Doctoral Program in Clinical Psychology, SDSU/UC San Diego, San Diego, CA

**Background:** Previous studies have examined early brain structural abnormalities and functional connectivity in young children with ASD (Wolff et al., 2017). However, little is known about regional brain activity and connectivity in the first years of life in autism. In particular, it is unknown if regions with aberrant neuroanatomy (e.g., morphometric features such as cortical thickness or surface area) also show atypical brain function in young children with ASD. A multimodal investigation examining both structural and functional brain patterns can provide clues about the underlying neurobiology and neurodevelopment in ASD.

**Objectives:** (i) To identify regions with atypical brain morphometry, by investigating the effects of ASD diagnosis, age, and their interactions on surface area (SA) and cortical thickness (CT), and (ii) to examine local activity and functional connectivity in the same regions in young children with ASD, as compared to typically developing (TD) peers.

**Methods:** Participants were young children with ASD (mean age:  $45\pm15$  months) and TD children (mean age:  $44\pm14$  months) enrolled in a longitudinal study of early brain markers of autism. Data from 69 participants (38 ASD, 31 TD) for whom both T1-weighted structural and functional MRI (fMRI) scans were successfully acquired during natural sleep were included. SA and CT measures were extracted from 34 regions of interest (ROIs) per hemisphere using the Desikan-Killiany atlas. To reduce the number of comparisons, Principal Component Analysis (PCA) was carried out, separately for SA and CT, and PCA loadings guided the selection of ROIs for subsequent analyses. The fractional amplitude of low frequency fluctuation (fALFF) and the local correlation index (LCOR) as indices of local activity and connectivity were extracted from the fMRI data, in the ROIs identified through PCA of the neuroanatomical data. Linear regression models were employed with SA, CT, fALFF, and LCOR as outcome variables, and age, diagnostic group, and age by group interaction as predictors (with gray/white contrast-to-noise ratio and head motion indexed by root mean square of displacement as covariates in structural and functional analyses, respectively).

**Results:** PCA revealed an SA component encompassing the pars triangularis subdivision of the inferior frontal gyrus (IFG<sub>p.tri</sub>) and a CT component encompassing the medial and lateral orbitofrontal cortex (OFC). Linear regression analyses revealed no effect of diagnosis, but a main effect of age on IFG<sub>p.tri</sub> SA (positive; Fig. 1a), OFC CT (negative; Fig. 1b,c), and OFC fALFF (negative; see Fig. 2c). An age by diagnostic group interaction effect on IFG<sub>p.tri</sub> fALFF and LCOR was identified ( $p = 0.01$  and  $0.005$ , respectively), with fALFF and LCOR increasing with age in TD children but not in the ASD group (Fig. 2a,b).

Conclusions: Although we found no main effect of diagnosis on brain morphometry in the brain regions showing age-related SA expansion and cortical thinning (cross-sectionally), a lack of neurotypical age-related increase in local activity and connectivity was identified in IFG, pars triangularis among children with ASD. These results suggest that multi-modal investigations of structural and functional brain indices may reveal complementary information on early neurodevelopment in ASD.

**423.038 (Poster)** Pre-Emptive Interventions for Infants and Toddlers at Risk for Autism: A Systematic Review and Meta-Analysis

**E. Rodríguez<sup>1</sup>** and **L. H. Hampton<sup>2</sup>**, (1)Special Education, The University of Texas at Austin, Austin, TX, (2)The University of Texas at Austin, Austin, TX

---

Background: Caregivers may observe early indications of delays related to autism before a child reaches one year old; however, deficits become apparent when the child reaches school-aged (American Psychiatric Association, 2013). Risk factors should be evaluated to reduce the severity of autism, and earlier identification should be prioritized (Fulsberg, 2016). A key indicator of development is language; however, development is tough to assess in children at risk for autism. The receptive language performance of a child at an early age predicts long-term development. Nevertheless, researchers rely heavily on linguistic and phonetic milestones as the primary makers of development (Moharir et al., 2014). Emphasis on the receptive domain is critical as all parts of language a child is exposed to play a role in how significant the receptive-expressive language gap is later (Gibson et al., 2014). One option is to evaluate parent-mediated interventions on receptive language. Hampton et al. (2017) observed that young children with receptive and expressive language delays profited from parent-mediated early intervention. Children with expressive language only delay indicated skill increase despite the group they were assigned. This proposal evaluates the receptive domain and provides recommendations for future research to improve the expressive-receptive gap in toddlers at risk for autism.

Objectives: This systematic review and meta-analysis observed the impact of preemptive autism interventions on siblings' receptive language outcomes.

Methods: Criteria for this study included toddlers under 36 months who were "at-risk" for autism, a behavior intervention, child development outcomes, an intervention, and a non-intervention group. The studies had to be completed in English and published after 2009. PsychInfo, PsycArticles, Academic Search Complete, ERIC, and PubMed databases were reviewed. Dissertations, peer-reviewed publications, and conferences were also examined for content. In the end, 16 records representative of 13 studies were reviewed.

Results: Receptive assessments included the Mullen Scale for Early Learning, Vineland Adaptive Behavior Scale, and Clinical Assessment of Speech Perception for Infants and Toddlers. Additional assessments included MacArthur-Bates Communication Development Inventories. Event-related potentials (ERPs) measurement (ERPs) receptive language were compared to test perception. Results showed little effect on receptive language ( $g = -.021$ ,  $se = .173$ ).

Conclusions: Research indicates that early childhood intervention before two can lead to higher gains in development while the brain is still developing (Whitehouse et al., 2021). This finding provides a foundation for future research into high-risk siblings as the severity of autism symptoms may decrease with intervention. Despite the small effect of receptive language outcomes in this study, it plays a vital role in long-term child outcomes. Large-scale diagnoses result in long-term societal and financial burdens on the early childhood education system; therefore, addressing the expressive-receptive language gap is an urgent public health issue. Future research should consider the validity of parent surveys as measures of child outcomes and instead contemplate integrating standardized measures of language for robustness—comparisons in future meta-analyses. Researchers should identify early language markers of both the child and their autistic sibling as potential risk factors.

**423.039 (Poster)** Qualitative and Quantitative Analyses of Early Vocal Productions of 6 Months Old Infants with High-Likelihood of ASD

**M. Weyland, P. Maes and M. Kissine, ACTE — Center of research in Linguistics — ULB Neuroscience Institute, Université libre de Bruxelles, Brussels, Belgium**

---

Background: The estimates of recurrence of autism within siblings ranges from 10 to 25% and the probability that they have a history of language delays is three to four times higher than siblings of non-autistic children, viz. with a low likelihood of autism; LL-ASD. Beyond investigations into early markers of ASD, conducting observations of HL-ASD infants could also help delineate early signs of atypical language development. Canonical babbling, emerging around 6-months old represent the first typical pre-speech-language milestones. At that young age, this mix of early vocalizations and canonical babbling can be regarded as the pre-linguistic output made available for researchers.

Objectives: The present study, exploratory in nature, tested if at 6 months, significant differences already emerging between infants with higher likelihood of ASD and infants with lower risk of autism in term of volubility (amount total of productions) and of representation of type of productions, consonant inventory and vocalic inventory. We are wondering if infants with HL-ASD will demonstrate significantly more restricted and less diversified consonant repertoire compared to LL-ASD infants and if type and diversity of vocalizations will be correlated with the VABS-II score.

Methods: This corpus is part of the sample of a longitudinal study following infants between 6 and 36-months with HL and LL of ASD. The sample of the present study is composed of 8 males and 9 females HL-ASD and 12 males and 5 females LL-ASD. Manual transcription of infants' productions were made on a daylong recording at 6-months, at home. The entire coding procedure is included in a OSF project co-authored [https://osf.io/y2jxm/?view\\_only=998df871579f445283cb54b89e91ff75](https://osf.io/y2jxm/?view_only=998df871579f445283cb54b89e91ff75). General Logistic Models (Poisson family) were used to investigate both group differences on total amount of productions and on amount of each type of productions (non-vocalic preverbal productions, vocalic preverbal production, proto-word and word).

Results: Results showed a significant effect of group on total production counts ( $\chi^2(1) = 10.82, p = .001$ ) with HL-ASD producing more than LL-ASD ( $\beta = -0.07, z = -3.29, p < .001$ ). Additionally, result also showed a significant group x type interaction on production counts ( $\chi^2(4) = 69.3, p < .001$ ). Further analyses showed that groups did not differ in the production of proto-words and words (both  $p > .97$ ). However, HL-ASD produced more non-vocalics ( $\beta = 0.31, z = 4.37, p < .001$ ) and vocalic ( $\beta = 0.12, z = 5.2, p < .001$ ) pre-verbal productions than LL-ASD. On the other hand, LL-ASD used more syllabic productions than HL-ASD ( $\beta = -0.24, z = -5.2, p < .001$ ).

Conclusions: Preliminary results shown that quantitative and qualitative differences of infant's productions are already measurable at 6-months old between infants with higher likelihood of ASD and infants with lower risk of autism. Further analyses will focus on qualitative differences in term of consonant and vocalic inventories and the relation between early vocal and verbal productions and VABS-II scores.

**423.040 (Poster)** Racial/Ethnic and Socioeconomic Disparities in Identification and Diagnosis of Autism Spectrum Disorder

**C. Jiang<sup>a</sup>, J. Shenouda<sup>a</sup>, K. Sidwell<sup>b</sup> and W. Zahorodny<sup>a</sup>,** (1)Rutgers New Jersey Medical School, Newark, NJ, (2)Department of Pediatrics, Rutgers University, Newark, NJ, (3)Department of Pediatrics, Rutgers New Jersey Medical School, Newark, NJ, (4)Department of Pediatrics, Rutgers--New Jersey Medical School, Newark, NJ

---

Background: Multiple studies have documented disparities in the identification and treatment of Autism Spectrum Disorder (ASD) by race/ethnicity and socioeconomic status (SES). Previous studies have shown that the median age at diagnosis among children with ASD was still higher in Black than White children (48 months vs. 42 months) [1]. Potential barriers to identification of ASD include: lack of healthcare services due to non-citizenship or low-income, a non-English primary language, lack of awareness about ASD, and stigma. A delay in diagnosis can have significant consequences in delaying access to early intensive behavioral interventions such as Early Intervention Programs that have been shown to improve clinical outcomes in children with ASD [1]. Recent studies have begun to show equalizing prevalence among non-Hispanic White, non-Hispanic Black and Hispanic children indicating improvement in identification among minorities and in underserved regions.

Objectives: In this study, we estimated the proportion of children identified with ASD between 2000 and 2016 in New Jersey that received their first professional evaluation by age 36 months of age. Data was further stratified by sociodemographic factors (sex, race/ethnicity, SES) to assess if disparities exist in identification of ASD.

Methods: Data from seven surveillance cycles of active ASD surveillance from New Jersey (NJ ADDM) were utilized. Data collected by the surveillance includes demographic and clinical information obtained from professional evaluations. Age of first evaluation was based on first evaluation abstracted for each ASD case.

Results: Between 2000 and 2016, across seven ASD surveillance cycles, 4,661 children were identified with ASD. Prevalence estimates increased from 1% in the initial 2020 surveillance cycle to 3.1% in the 2016 surveillance cycle. The analysis was restricted to children identified with ASD and born in NJ,  $n = 3,807$  (82%). Overall, 42% ( $n = 1612$ ) of children with ASD received their first evaluation by age 36 months. While there was no difference by sex, bivariate analysis identified differences by race/ethnicity, SES, and intellectual ability. Multivariate analysis showed that no significant differences by race/ethnicity remained when we controlled for SES. Overall, children from high SES areas were twice as likely to receive an evaluation by age 36 months when controlling for sex, race/ethnicity, intellectual ability and birth cohort. We did not identify any improvement or increase in the number of children receiving their first evaluation by 36 months over a 16-year period of ASD surveillance.

Conclusions: Consistent with previous findings, our analysis showed disparities in the first age of identification of ASD. While race/ethnicity is a well-documented factor in receipt of services, our findings indicate that SES is a stronger predictor of receipt of services. Our findings highlight that in a 16-year period the proportion of children with ASD identified early has remained static, highlighting the need for new strategies for early identification of ASD, especially of children from low SES communities.

**423.041 (Poster)** Relationship between Caregiver-Reported Autism Symptoms and Age, Cognitive Level, and Language Abilities.

**K. L. Coulter<sup>a</sup>, M. Frisch<sup>a</sup>, M. Barton<sup>a</sup>, D. L. Robins<sup>a</sup> and D. A. Berger<sup>a</sup>,** (1)Psychological Sciences, University of Connecticut, Storrs, CT, (2)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

---

Background: Autism is a neurodevelopmental disorder that emerges in the first few years of life, a dynamic period in which significant growth across a range of domains occurs. Over this time period, children with autism or other developmental delays gradually demonstrate skills that diverge from those of their typically developing peers. Accurate assessment of autism therefore requires careful consideration of the impacts of emerging language and cognitive abilities. The Toddler Autism Symptom Inventory (TASI) is a novel caregiver interview for use in diagnostic evaluations of children 12-36 months of age. While the validity and reliability of the TASI has been demonstrated (Coulter et al., 2021), the contributions of cognitive abilities, age, and language level to the total TASI score have not yet been determined. Given the dynamic development that occurs between 12 and 36 months, investigation of the contributions of these factors is necessary.

Objectives: To examine the impact of age, cognitive skills, and language level on the total score of the TASI.

Methods: Data were obtained during diagnostic evaluations of young children identified as having concerns for autism by screener or provider concern. Diagnostic evaluations included the Autism Diagnostic Observation Schedule (ADOS-2), TASI, Mullen Scales of Early Learning (MSEL),

and developmental history, and clinical best-estimate diagnoses (CBE) were assigned. Children were diagnosed with autism (ASD;  $n=72$ ), another developmental delay (DD;  $n=131$ ), or typical development (TD;  $n=91$ ).

Multiple linear regression was conducted in order to examine the relationship of these factors with TASI total score, above and beyond diagnosis (dummy coded). Child age in months and MSEL expressive language, receptive language, and visual reception age equivalents (MSEL EL ae, RL ae, and VR ae) were included in the model.

Results: Diagnosis, age, and receptive and expressive language abilities were significant predictors of total TASI score. Older age and lower language abilities were associated with higher TASI scores. Nonverbal cognition (MSEL VR ae) was not significantly related to TASI total score. Overall, the model predicted 51% of the variance in TASI total score ( $R^2=.52$ ). Even when accounting for the effect of age and visual reception, expressive language, and receptive language age equivalents, diagnosis remains the most influential contributor to TASI total score.

Conclusions: Results suggest that total TASI score is associated with a child's diagnostic status, as well as their age and receptive and expressive language skills. Total TASI score was not found to be related to visual reception skills. Overall, a child's diagnosis has the strongest relationship with TASI total score. However, the significant contributions of a child's age and language level to the model suggest that these are factors that clinicians must consider carefully when conducting diagnostic evaluations of young children.

#### **423.042 (Poster)** Sleep Challenges and Temperament Among Infants with Autistic Siblings

**M. Foster and J. Bradshaw, University of South Carolina, Columbia, SC**

##### **Background:**

Subtle indicators of atypical neurodevelopment exist among children with ASD before hallmark symptoms emerge. For example, autistic infants have been observed to experience difficulties with falling asleep in addition to difficult temperament, such as reduced surgency, increased negative affect, and lower regulatory capacity (MacDuffie et al., 2020; Macari et al., 2017). Among neurotypical infants, researchers have found associations between shorter sleep duration and frequent nighttime awakenings with high negative affectivity and reduced regulatory capacity (Mindell et al., 2017). The link between surgency and sleep difficulties is less apparent as some suggest that higher surgency is related to better sleep while others found the opposite (Jian & Teti, 2016). It remains unclear how these two developmental indicators interact and reflect neurological mechanisms underlying ASD.

##### **Objectives:**

The current study uses parent report in a prospective longitudinal design to examine the relationship between early sleep difficulties and temperament among infants with an older sibling diagnosed with ASD (elevated likelihood, EL) and those with no familial history of ASD (low likelihood, LL).

##### **Methods:**

Participants ( $n = 39$ ; EL,  $n = 10$ ; LL,  $n = 29$ ) were enrolled in a prospective longitudinal study on early autism symptoms. At 6 and 12 months, caregivers completed the Short Form of the Infant Behavior Questionnaire-Revised (IBQ-R) (Putnam et al., 2014). To understand how sleep difficulties are related to temperament, a new scale of Sleep Challenges was created with items related to falling and staying asleep as had previously been done with the Very Short Form (Macduffie et al., 2020). We investigated trajectories of sleep difficulties between EL and LL groups with linear mixed-effects models. In addition, associations between early sleep difficulties and IBQ-R scales were examined.

##### **Results:**

As expected, sleep difficulties were significantly higher in the EL group than in the LL group ( $F(1, 37) = 6.94, p = .01$ ), but sleep difficulties did not decrease over time for either group. Significant positive associations among Sleep Challenges and Smiling and Laughter ( $r = .68, p = .03$ ) were found in the EL group at 6 months. Within the LL group, Sleep Challenges were negatively correlated with Perceptual Sensitivity ( $r = -.43, p = .02$ ) at 6 months and positively associated with Approach ( $r = .59, p = .01$ ) and High Pleasure at 12 months ( $r = .51, p = .02$ ).

##### **Conclusions:**

The results of this preliminary study suggest that sleep difficulties are significantly higher among children with autistic siblings and this trend remains stable between 6 months to 12 months of life. Sleep difficulties were not significantly associated with regulation/orientation as previously considered, but instead with various aspects of surgency in both groups. Findings of this study point to the possibility that early predictors of sociability are related to temperamental challenges of falling and staying asleep. Additional research is needed to examine objective measures of sleep alongside temperamental measures and its relationship to clinical outcomes.

#### **423.043 (Poster)** Symptoms of Executive Dysfunction and ADHD Are Linked with Poorer Adaptive Functioning in 3-Year-Olds with ASD

**K. K. Powell<sup>1</sup>, S. Macari<sup>1</sup>, E. Brennan-Wydra<sup>1</sup>, H. Feiner<sup>1</sup>, M. Butler<sup>1</sup>, D. M. Goncalves Fortes<sup>1</sup>, A. Boxberger<sup>1</sup>, C. Morgan<sup>2</sup>, M. Lyons<sup>1</sup>, M. S. Torres-Viso<sup>2</sup> and K. Chawarska<sup>1</sup>, (1)Child Study Center, Yale University School of Medicine, New Haven, CT, (2)Yale, New Haven, CT, (3)Yale Child Study Center, New Haven, CT**

**Background:** Executive functioning (EF) deficits and attentional problems co-occur frequently with autism spectrum disorder (ASD) and have a long-term detrimental impact on the quality of life for affected children and their families (Rosenthal et al., 2013; Simonoff et al., 2008). Elevated symptoms of EF impairments and attention deficit-hyperactivity disorder (ADHD) are already present in preschool-aged children with ASD, although it is not clear when they first begin to manifest at clinically relevant levels (Smithson et al., 2013; McLean et al., 2014). Timely identification of regulatory and attentional problems may hasten access to early intervention and alleviate their long-term consequences.

**Objectives:** Determine (1) if EF deficits and ADHD symptoms are elevated in 3-year-olds with ASD compared to siblings of children with ASD, typically developing (TD) toddlers, and toddlers with atypical development; and (2) if the co-occurring symptoms have negative effects on adaptive functioning in ASD.

**Methods:** Participants included 73 toddlers with ASD, 34 unaffected siblings of children with ASD (SIB), 36 toddlers with atypical developmental features (ATP), and 30 TD toddlers (TYP) matched on age ( $M = 38.97$  months,  $SD = 3.09$ ). EF deficits and ADHD symptoms were measured using parent report on the Behavior Rating Inventory of Executive Function – Preschool Version (BRIEF-P; Gioia et al., 2003) and Early Childhood Inventory-5 (ECI-5; Sprafkin & Gadow, 2014), respectively. Adaptive skills were measured using the Vineland Adaptive Behavior Scales-II (VABS-II; Sparrow et al., 2005). Group differences in EF and ADHD scores were assessed using group (4) x sex (2) general linear models (GLM). Multiple regression was used to assess relationships between EF deficits, ADHD symptoms, and adaptive skills in the ASD group. Whenever appropriate, analyses controlled for developmental level using the Mullen Scales of Early Learning (MSEL, 1995), autism severity using the Autism Diagnostic Observation Schedule-2 (ADOS2; Lord et al., 2012), and sex.

**Results:** GLM analysis indicated main effects of group in both BRIEF-P Global Executive Composite (GEC) and ECI-5 ADHD-Combined (ADHD-C) scores. Planned comparisons revealed that the ASD group had significantly higher mean GEC and ADHD-C scores compared to each of the three comparison groups (all  $p < .002$ , Cohen's  $d$  0.68-1.34, **Figure 1**). Regression analysis revealed that higher GEC and ADHD-C scores were each associated with lower VABS-II scores across social, communication, and daily living skills domains. Importantly, neither severity of EF deficits nor ADHD scores correlated with autism symptom severity ( $r = .09$  and  $r = .15$ , respectively).

**Conclusions:** By the age of 3, children with ASD exhibit marked challenges in executive functioning and attention/hyperactivity compared to toddlers at increased likelihood for ASD due to familial factors, those with other developmental challenges, and TD peers. Further, greater severity of co-occurring conditions was associated with lower adaptive skills in ASD. These differences can be detected using parent-based questionnaires. Considering the links with adaptive skills, EF and attentional deficits should be targeted for intervention early on to ameliorate their cascading effects on long-term outcomes and quality of life of children and their families.

#### **423.044 (Poster)** Temperament in Infancy in Relation to Symptom Load of ASD and ADHD in Older Siblings

**L. Andersson Konke<sup>1</sup>, T. Falck-Ytter<sup>2</sup>, E. J. Jones<sup>3</sup>, A. Goodwin<sup>4</sup> and K. Brocki<sup>5</sup>,** (1)Uppsala University, Uppsala, Sweden, (2)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden, (3)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (4)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (5)Department of Psychology, Uppsala University, Uppsala, Sweden

#### **Background:**

ASD is a highly heterogeneous condition with many affected children showing co-occurring symptoms of ADHD. However, it remains unclear whether early emerging phenotypic markers for ASD and ADHD are shared or distinct. Infant sibling studies have several advantages in order to understand the early development of later diagnostic outcome (Johnsson et al., 2016). However, certain features or behaviors might not necessarily be predictive of later symptoms or outcome but still be important liabilities that contribute to elevated likelihood for ASD and ADHD (Constantino, 2018; 2021). We reason that by using a *between* sibling design we might be able to reduce factors that may modify or alter developmental trajectories. Thus, a valuable way to study the early expression of elevated likelihood independent of outcome is to explore associations to symptoms in the proband.

#### **Objectives:**

To explore early specific and/or common temperamental markers of co-occurring ASD and ADHD by examining phenotypic associations *between* sibling behaviors. We use proband symptoms of either ASD or ADHD as a proxy for familial likelihood for these conditions.

#### **Methods:**

The sample consisted of 214 infants at elevated likelihood of ASD between 7 to 12 months of age ( $M = 9.39$  months,  $SD = 1.03$ ), and a respective older sibling diagnosed with ASD ( $M = 7.06$  years,  $SD = 2.63$ ). We used the Infant Behavior Questionnaire Revised (IBQ-R; Gartstein & Rothbart, 2003) to assess infant temperament. In terms of symptoms of ASD and ADHD in the older sibling, we used the Social Communication Questionnaire (SCQ; Rutter, Bailey, & Lord, 2003) and the Conner's Rating Scale- 3 (CRS-3; Conners, 1989, 2008), respectively.

#### **Results:**

We found distinct as well as common relations between infant temperament and the sibling symptoms of ASD and ADHD. First, poor approach behavior and low cuddliness was specifically related to higher sibling symptoms of ASD. Second, high levels of infant activity were specifically related to higher levels of ADHD symptoms in the older sibling. Lower infant soothability was related to higher levels of ASD and ADHD symptoms in the older sibling.

#### Conclusions:

This explorative study shows distinct but also common phenotypic profiles of likelihood for ASD and ADHD which can be detected from 10 months of age by dimensional proband phenotyping. By furthering our understanding of how early developmental liabilities spread across family members we might improve our understanding of the heterogeneity of these disorders. Finally, we reason that these traits might constitute early liability that contribute to elevated likelihood for ASD and ADHD and might serve as part of early intervention strategies to alleviate later difficulties.

#### **423.045 (Poster)** The Role of Predictability in Social Rhythmic Entrainment in TD and ASD Toddlers

*S. Chawla<sup>1</sup>, Y. Wang<sup>2</sup>, W. Jones<sup>1</sup>, L. A. Edwards<sup>1</sup> and M. D. Lense<sup>2</sup>, (1)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (2)Vanderbilt University Medical Center, Nashville, TN, (3)Marcus Autism Center, Atlanta, GA*

---

#### Background:

Typically developing (TD) children are sensitive to the rhythm and timing of social engagement from infancy (Beebe et al., 2016). In contrast, children with Autism Spectrum Disorder (ASD) have impairments in social timing and coordination (Ozonoff et al., 2010). However, in our recent work using child-directed singing, a naturally-occurring, rhythmic, social interactive behavior, both TD and ASD toddlers rhythmically modulated their social visual engagement, as observed by increased looking to the eyes of a singing caregiver, time-locked to the song beats (Chawla et al., INSAR 2021). As rhythmically important moments, beats are temporally predictable and associated with meaningful social-communicative cues such as caregivers' wide-eyed, positive facial expressions, which may potentiate rhythmically entrained eye-looking in toddlers. Given the critical importance of eye-looking for understanding social information, we examined whether time-locked attention to eyes is modulated by the temporal predictability of the social information.

#### Objectives:

To examine the role of rhythmic predictability on entrainment of eye-looking during child-directed singing in TD and ASD toddlers.

#### Methods:

Thirty-two age- and sex-matched TD (n=16) and ASD (n=16) toddlers (18-37 months) watched videos of an actress engaging them with child-directed singing while eye-tracking data were collected. Stimuli videos included natural rhythmic versions of songs as well as experimentally-manipulated versions in which the rhythmic structure was disrupted by randomly jittering inter-beat intervals (duration of all intervals randomly expanded or contracted up to 50%). Eye-looking was quantified as the amount and timing of toddlers' fixations on actresses' eyes. We measured whether changes in looking to the eyes of actresses were time-locked to the beats using permutation testing of crosscorrelograms compared with chance rates of eye-looking.

#### Results:

Both TD and ASD toddlers demonstrated significant rhythmically-entrained eye-looking during the original singing ( $p < 0.05$ , by permutation testing), albeit with peak magnitudes of increase that were numerically reduced in ASD versus TD toddlers: 5.3% ASD versus 9.0% TD (non-significant difference in this initial sample). When experimentally-manipulated, reduced-predictability singing was presented, both TD and ASD groups showed less entrained eye-looking than for the original, rhythmically-predictable singing (6.5% TD,  $p < 0.05$ ; 4.4% ASD,  $p > 0.05$ ). Notably, during the reduced-predictability singing, change in ASD eye-looking was no longer significantly different from chance for the ASD toddlers (Figure 1), although in TD toddlers there remained a small increase over levels expected by chance alone.

#### Conclusions:

These findings suggest that rhythm is an important structuring mechanism for social behavior during early childhood. Rhythmic predictability may serve as a structuring mechanism to help children coordinate their behavior to important moments of social-communicative signaling. Decreased predictability may be particularly detrimental for toddlers with ASD, who may be less able to flexibly accommodate such unpredictable cueing. Future work will further analyze effects of rhythmic predictability in a larger sample and examine how different social cues combine to scaffold toddlers' looking behaviors. These results have implications for the use of rhythmic predictability during natural social interactions to scaffold social behavior.

#### **423.046 (Poster)** Trajectories of Language Development in Young Children with and without Autism Spectrum Disorder in Taiwan

*C. C. Wu and P. Y. Yao, Department of Psychology, Kaohsiung Medical University, Kaohsiung, Taiwan*

---

**Background:** Language development is an important issue and plays a critical role in outcomes in young children with developmental disabilities (DD), including autism spectrum disorder (ASD) and non-ASD delays (e.g., language delay, developmental delays). However, few studies have explored the trajectories of language development in young children with and without ASD.

**Objectives:** This study aimed to investigate the trajectories of receptive and expressive language development in young children DD, including ASD and non-ASD delays, across 3 years by a longitudinal study. Besides, further exploring the relations between trajectory class assignment and diagnostic outcomes 3 years later, and the characteristics of early abilities among trajectory classes to provide implications to early intervention.

**Methods:** One hundred and one young children with DD in a rural county in Taiwan were recruited at the mean age of 21.88 months old (Time 1). Receptive and expressive language abilities were assessed by the Mullen Scales of Early Learning (MSEL) and were followed up 1.5 (Time 2) and 3 years (Time 3) after the first assessment. Based on information at Time 3, participants were divided into ASD (n = 54) and non-ASD delays (n = 47) group. Growth mixture modeling analyses were respectively conducted to receptive language developmental quotients (RLDQ) and expressive language developmental quotients (ELDQ) assessed over three time points for investigating the trajectory classes.

**Results:** The results showed that receptive language development in young children with DD could be identified with three trajectory classes: age-expected, delay catch-up, and delayed trajectory class. While expressive language development could only be identified with two trajectory classes: delay catch-up and delayed trajectory class. The trajectory class assignments in receptive and expressive language development were respectively related to diagnostic outcomes three years later. A majority of young children with ASD were assigned in trajectory classes of receptive and expressive language development with worse outcomes. In addition, children with better ability levels in receptive or expressive language development showed better performances on their early nonverbal developmental quotients (NVDQ), developmental quotients (DQ), social-communication skills, and autistic symptom severity. However, early adaptive functioning did not show significant differences among those children assigned in the two trajectory classes of expressive language development.

**Conclusions:** Trajectories of receptive and expressive language development in young children with DD are heterogeneous. The trajectory class assignment in receptive and expressive language development were related to the diagnostic outcomes. Besides, children with better outcomes on language development showed better performances on most early abilities. Findings of the current study provides implications for clinicians to plan suitable early intervention to young children with DD based on individuals' developmental characteristics.

**423.047 (Poster)** Trajectories of Visual Attention to the Mouth during Infant-Directed Speech and Song in Infants with and without ASD over the First Year of Life

**M. K. Sahoo<sup>1</sup>, M. Hines-Wilson<sup>2</sup>, C. Nicholson<sup>2</sup>, D. Parmaksiz<sup>2</sup>, A. Klin<sup>3</sup>, W. Jones<sup>3</sup>, L. A. Edwards<sup>2</sup> and M. D. Lense<sup>4</sup>,** (1)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (2)Marcus Autism Center, Atlanta, GA, (3)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (4)Vanderbilt University Medical Center, Nashville, TN

**Background:** Infant directed speech (ID-speech) is a universal form of communication by which caregivers engage with their infants. In comparison to adult-directed speech, ID-speech is characterized by notable rhythmicity, increased pitch variability, and exaggerated and repetitive frequency contours (Fernald 1992). These characteristics increase the perceptual saliency of speech to capture and maintain infants' attention. Over the first year of life, when engaged with ID-speech, infants gradually shift their gaze from the eye region to the mouth region of the caregiver, as the mouth region provides synchronous visual cues to support language development (Tenenbaum et al. 2015). Another form of communication, infant-directed song (ID-song), exaggerates the characteristics of ID-speech through increased rhythmic predictability, repetition, and audiovisual synchrony. The multimodal cues of ID-song maintain infant attention longer than ID-speech (Tsang et al. 2017). Infants with ASD also attend to the faces of singers for longer durations, and for similar durations as typically developing infants, than to faces of speakers (Macari et al. 2020; Thompson & Abel 2018). However, how infants with and without ASD allocate visual attention to the face during ID-song, and whether this differs from ID-speech, is unknown.

**Objectives:** Examine visual fixations to the mouth over the first year of life (3-12 months of age), across ID-speech and ID-song conditions, in typically developing (TD) infants and those later diagnosed with autism spectrum disorder (ASD).

**Methods:** TD infants (N = 351) and those later diagnosed with ASD (N = 61) were eye-tracked at 3, 4, 5, 6, 9, and 12 months of age, while watching videos of caregivers singing a song (ID-song) or speaking (ID-speech). Eye-tracking data was quantified as the proportion of face-looking time (PFLT) spent on the caregivers' mouth (i.e. number of fixations to mouth region/number of fixations to face (mouth and eyes); PFLT-mouth). A linear mixed model assessed changes in mouth-looking (PFLT-mouth) by age, condition (ID-speech vs. ID-song), and diagnosis.

**Results:** Across diagnostic groups, a significant main effect of age indicated that PFLT-mouth significantly increased with age ( $\beta = .033$ ,  $p < .001$ ). Infants also exhibited greater PFLT-mouth in ID-song compared to ID-speech ( $\beta = -.052$ ,  $p = .005$ ). A significant interaction between age and condition indicated that PFLT-mouth increased at a faster rate for ID-song than ID-speech ( $\beta = -.009$ ,  $p < .001$ ; Figure 1).

**Conclusions:** Over the first year of life, infants with and without ASD allocate more facial visual attention to the mouth. This effect is greater during ID-song compared to ID-speech potentially due to the increased rhythmicity and audiovisual synchrony provided during song. Next steps will explore differential adaptive value of attention to the mouth during ID-speech vs. ID-song on language development in TD and ASD infants. These findings may have implications for early interventions aimed at improving language development in infants at risk for ASD, as well as processes that may underlie differential attention to ID-song and ID-speech.

**Figure 1:** Proportion of mouth fixation (mouth/face fixation) vs age in ASD and TD infants during ID-Song and ID-Speech.

#### **423.048** (Poster) Trends in Regressive Autism between 2000 and 2016

**M. Palmeri<sup>1</sup>, R. Krishnaraj<sup>1</sup>, J. Shenouda<sup>2</sup>, K. Sidwell<sup>3</sup> and W. Zahorodny<sup>4</sup>,** (1)*Rutgers New Jersey Medical School, Newark, NJ,* (2)*Department of Pediatrics, Rutgers University, Newark, NJ,* (3)*Department of Pediatrics, Rutgers New Jersey Medical School, Newark, NJ,* (4)*Department of Pediatrics, Rutgers--New Jersey Medical School, Newark, NJ*

---

##### **Background:**

Autism Spectrum Disorder (ASD) is a neuro-developmental disorder characterized by restricted, repetitive patterns of behavior and limited social and communication skills. ASD is often diagnosed in early childhood and may be classified as regressive or non-regressive. Published research suggests that regression in ASD occurs in 10-30% of children who are diagnosed with ASD and is characterized by initial attainment of developmental milestones in year one, followed by loss of language and social skills between the ages of 18 to 30 months. The definition and parameters of regressive autism are controversial. In the past, loss of language skills, which is often the factor most readily identified by parents, has been used as the sole factor in defining regression. To date, few studies have reported on the prevalence and expression of regressive ASD from population-based studies.

##### **Objectives:**

The objective of this study is to report on trends in the prevalence of regressive ASD across a 16-year-period, from 2000 to 2016.

##### **Methods:**

ASD cases were identified and characterized through the New Jersey Autism Study, a longstanding Autism and Developmental Disabilities Monitoring (ADDM) Network site. The ADDM surveillance method utilizes a two-phase process based on review, scoring and analysis of information contained in educational and health evaluations. Regressive ASD was defined as documented indication in professional evaluations, by either parent report and/or by a qualified professional, noting loss of skills in either language and/or social ability, before the age of 36 months. The definition and scoring of regressive ASD was maintained across all 7 surveillance cycles from 2000 to 2016 in the New Jersey surveillance region.

##### **Results:**

Across seven cycles of ASD surveillance, 4,661 8-year-old children with ASD were identified. Among those, 690 cases (15%) satisfied the case definition of regressive ASD. Regressive ASD prevalence ranged from 1.4 per 1,000 (95% CI:1.0-1.8) in 2000 to 4.6 per 1,000 (95% CI:3.9-5.4) in 2016, a 3.3-fold increase over the period. Overall, regressive ASD ranged from 6.1% in 2000 to 22.2% in 2016 of ASD cases across the surveillance cycles. Regressive ASD increased 4.2-fold among males and 2.2-fold among females. Among Hispanic children, regressive ASD increased from 0.64 per 1000 in 2000 to 5.3 per 1,000 in 2016, which was the highest rate of regressive ASD prevalence. The median age of the onset of regression was 20 months. Overall, children with regressive ASD were more likely to be categorized with severe impairment and to have higher rates of intellectual disability compared to children with non-regressive ASD. Children with regressive ASD were highly likely to have an ASD diagnosis before 8-years.

##### **Conclusions:**

This study indicates that 1 in 7 children with ASD experience developmental regression. Our findings also show that increases in ASD prevalence have occurred broadly, including for children with the regressive ASD subtype and that children with regressive ASD are more likely to have severe impairment.

#### **423.049** (Poster) Unique Pathway to Social Communication Intervention with or without an Autism Spectrum Disorders (ASD) Diagnosis

**N. Brane<sup>1</sup>, K. Ulven<sup>1</sup>, G. Binion<sup>2</sup>, K. Pickard<sup>3</sup> and N. M. Hendrix<sup>2</sup>,** (1)*Marcus Autism Center, Atlanta, GA,* (2)*Marcus Autism Center, Emory University School of Medicine, Atlanta, GA,* (3)*Emory University School of Medicine, Marcus Autism Center, Atlanta, GA*

---

##### **Background:**

Autism Spectrum Disorders (ASD) are among the most prevalent developmental disabilities among children with a current prevalence of one in 54 (Maenner et al., 2020). A number of factors contribute to increased ASD risk, including perinatal and other medical complications (Hyman et al., 2020). These risks can be considerable as preterm and early term births are associated with a three-fold increase in ASD risk (Crump et al., 2021).

The expansion of evidence linking preterm birth and medical complexities to ASD risk highlights the need for creative paths to timely and effective early intervention for high-risk populations who may or may not have a formal diagnosis of ASD. Empirically-validated treatments like Naturalistic Developmental Behavioral Interventions (NDBIs; Schreibman et al., 2015) serve to support social communication in this population by utilizing developmental principles and behavior strategies. Project ImPACT (Ingersoll & Dvortcsak, 2019), one NDBI example, has been found to be efficacious in supporting the imitation and language skills of toddlers at high-risk for ASD due to having an older sibling with ASD (Yoder et al., 2021). Despite its promising support for use with young children with and without a diagnosis of ASD, this model has yet to be examined within other high-risk groups.

##### **Objectives:**

This study sought to: 1) examine the profiles young children with or at heightened-risk for ASD due to medical complexities and/or significant prenatal or perinatal birth complications (including preterm birth and very low birth weight) who were referred to an outpatient clinical program; and 2) assess intervention outcomes following participation in a Project ImPACT parent-mediated treatment model.

#### Methods:

Ten participants (13 to 35 months) and their primary caregivers were referred to an outpatient clinical program targeting social communication deficits in children at or under the age of 36 months (Target: 20 toddlers by 05/2022). Referrals were placed from specialty clinics within a children's hospital in a major metropolitan area. Specialty clinics targeted medically complex children demonstrating neurodevelopmental delays and/or children with significant prenatal and perinatal risks. Five of ten received an ASD diagnosis prior to participating in Project ImPACT. Intervention was delivered once per week for 12 weeks. Outcomes included score change on the *Social Communication Checklist (SCC)* (Wainer et al., 2017) and *Infant Toddler Checklist (ITC)* (Wetherby & Prizant, 2002), progress towards treatment goals made in collaboration with parent, parent satisfaction, and changes in parent sense of competence.

#### Results:

Data collection is ongoing. Preliminary analyses for participants who completed admissions and not actively in treatment ( $n = 2$ ) suggest participants met 75-100% of goals set at week 1. Further, participants' scores on the SCC increased 5-17% over the course of 12 weeks, representing modest increases in social communication skills.

#### Conclusions:

Targeting social communication and play through Project ImPACT for a group of young children at elevated risk for ASD due to perinatal complications and/or medical complexities holds promise. We aim to examine change across a range of measures to describe the program's effectiveness, the differences made in each child's communication profile, and parent satisfaction.

#### **423.050 (Poster) What Are You Looking at? – Gaze Following with and without Target Objects in ASD and TD**

**E. Thorup<sup>1</sup>, P. Nyström<sup>2</sup>, S. Bolte<sup>1</sup> and T. Falck-Ytter<sup>1</sup>, (1)Uppsala universitet, Uppsala, SWEDEN, (2)Uppsala University, Uppsala, Sweden, (3)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, & Stockholm Health Care Services, Region Stockholm, Stockholm, Sweden, (4)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden**

Background: While children with Autism Spectrum Disorder (ASD) are often reported to follow gaze less than typically developing (TD) children in natural settings (e.g. Dawson et. al, 2004), several experimental studies have reported comparable performance across groups (e.g. Akechi et. al., 2011; Parsons et. al., 2019). Previous studies comparing infants at elevated likelihood (EL) of ASD versus TD infants have manipulated aspects relating to the gaze cue (e.g. compared performance in response to eye gaze only versus eye gaze and head movement in conjunction; Thorup et. al., 2016), but the role of the object being attended to by the other is not known.

Objectives: The aim of this study was to assess gaze following when target objects were either present or absent in the direction of an interaction partner's gaze. The study was conducted by the use of live eye tracking, and performance was compared between infants with later ASD and other infants.

Methods: The experiment was conducted at 10, 14 and 18 months. Infants were either at elevated likelihood of ASD (due to having an older sibling with the diagnosis) or TD control infants. All infants went through diagnostic assessment at age three, and were divided into the following groups: EL infants meeting diagnostic criteria for ASD (EL-ASD,  $N = 25$ ), EL infants not meeting diagnostic criteria (EL-no-ASD,  $N = 72$ ) and TD control infants ( $N = 29$ ). During the eye tracking experiment, the infants watched an experimenter gaze in the direction of an area where a target object (doll or stuffed animal) was either present or absent. Dependent measures were gaze following accuracy, looking durations at target and experimenter, and latency to look back at the experimenter after following gaze.

Results: No group differences in terms of gaze following accuracy or looking durations were found. In the latency measure, a group by condition interaction effect emerged,  $p = .030$ . After following gaze, EL-ASD infants looked back at the experimenter faster than TD infants when no target objects were present,  $p = .046$ . There was no difference between groups when target objects were present,  $p = .448$ .

Conclusions: The results add to a number of studies suggesting that gaze following in infants with later ASD is largely typical. However, they also suggest that subtle atypicalities may occur just *after* gaze following. Previous studies have indicated that children with or at elevated likelihood of ASD may be less influenced by others looking behaviors when processing objects in the common attentional focus (e.g. Falck-Ytter et.al., 2015). The current finding that infants with later ASD look back at the experimenter faster than TD infants after following gaze to areas without target objects may be in line with this hypothesis. Compared to many other studies of early gaze following, the current study has the advantage of being performed during live interaction, rather than by the use of pre-recorded stimuli.

#### **423.051 (Poster) Robotese and Mothers: Examining Patterns of Attention Preference in Infants and Toddlers in Eye-Tracking Paradigms**

**G. M. Garcia<sup>1</sup>, M. A. Cox<sup>1</sup>, J. E. Blume<sup>2</sup>, K. Webb<sup>1</sup> and A. Mastergeorge<sup>1</sup>, (1)Human Development and Family Sciences, Texas Tech University, Lubbock, TX, (2)Human Development and Family Sciences, TTU HDFS, Lubbock, TX**

**Background:** Well-established benefits of infant-directed speech (IDS), or “motherese,” for infants and toddlers include learning to respond to joint attention (JA), recognizing emotions, and attending to language input (Filipe et al., 2018; Saint-Georges et al., 2013). Young children typically demonstrate an early preference for IDS, however children with autism spectrum disorder (ASD) risk do not often demonstrate the same social orienting preference (Filipe et al., 2018; Kuhl et al., 2005). In this population, preferential attention patterns include non-social stimuli and non-human social partners such as robots (Anzalone et al., 2018; Boccanfuso et al., 2017; Chevalier et al., 2020; Zheng et al., 2018). For some children, interactions with robots have been characterized by increased turn-taking, more frequent joint attention, and increased language use (David et al., 2020; Chevalier et al., 2020). However, specific aspects of robots that elicit heightened social interest remain to be understood. Thus, directly comparing child social attention to *motherese* versus *robotese* (e.g., the speech and gestural qualities of robots) may yield novel insight regarding such preferences.

**Objectives:** The current study utilizes eye-tracking paradigms to compare visual attention patterns of infants and toddlers to contrasting, dynamic social stimuli that include both *motherese* and *robotese*.

**Methods:** Participants included a sample of ten typically developing infants and toddlers ( $n = 10$ ) age 7-17 months ( $\pm 2$  weeks). Consistent with prior eye-tracking empirical studies with young children, we measured gaze fixation, duration, and total looking time in the context of novel video stimuli (see Figure 1). Child developmental profiles were obtained using the *Mullen Scales of Early Learning* (MSEL; Mullen, 1995) and the *Early Social Communication Scales* (ESCS; Mundy et al., 2013).

**Results:** Preliminary eye-tracking results indicate similar patterns of visual attention for both IDS and robotese conditions. Patterns of heat maps in each stimuli condition indicate that children allocate attention preferentially for faces in both the motherese and robotese conditions (see Figure 1). An exemplar stimuli video clip including social agents providing both IDS and robotese cues simultaneously, gaze plot trends confirm allocation of visual attention in a triadic manner (see Figure 2). This exemplar highlights the finding that young children looked back and forth between the robot, woman, and shared object of interest and indicates that infants respond to the speech and gestural qualities of both social agents similarly.

**Conclusions:** Findings from the current study confirm the preferential attention patterns in young children typically demonstrate in response to IDS/*motherese* are also observable in eye-tracking paradigms. And, these patterns are not exclusive to IDS; children also allocated and sustained similar patterns of visual attention to *robotese*. Given the growing utility and relevance of social robotics as engagement tools for individuals with ASD and autism risk, our results indicate social robotics may also be a potential social attention and engagement tool for very young children. Future studies should investigate visual patterns observed in the current study with neurodiverse samples to examine potential implications for robotics as a tool to facilitate social orienting and to target attention behaviors in early intervention.

**423.052 (Poster)** Visual Attention to the Mouth and Language Acquisition in Infants with and without Autism Spectrum Disorder during the Second Year of Life: Considering Communicative Context

**M. Hines-Wilson<sup>1</sup>, M. K. Sahoo<sup>2</sup>, C. Nicholson<sup>1</sup>, A. Klin<sup>3</sup>, W. Jones<sup>3</sup>, M. D. Lense<sup>4</sup> and L. A. Edwards<sup>1</sup>,** (1)Marcus Autism Center, Atlanta, GA, (2)Emory University School of Medicine, Marcus Autism Center, Atlanta, GA, (3)Marcus Autism Center, Children's Healthcare of Atlanta and Emory University School of Medicine, Atlanta, GA, (4)Vanderbilt University Medical Center, Nashville, TN

**Background:** Infants show shifting patterns of social visual engagement to caregivers' faces over the first two years of life, which is associated with the development of speech and language abilities: typically developing (TD) infants show increases in mouth-looking around the time of first spoken words (Lewkowicz et al., 2012), and this is positively associated with expressive language abilities (Habayeb et al., 2021). In contrast to TD infants, infants later diagnosed with autism spectrum disorder (ASD) exhibit persistent mouth-looking over the first two years of life (Jones&Klin,2008), the adaptive value of which may differ depending on specific child and stimuli characteristics. Prior studies, however, predominantly focus on infant-directed speech (ID-speech), or do not differentiate between ID-speech and infant-directed song (ID-song) contexts. ID-song exaggerates the characteristics of ID-speech through increased rhythmic predictability, repetition, and audiovisual synchrony, which promotes attention to the mouth (Sahoo et al., 2021). Additionally, infants with ASD attend to ID-song for longer durations, and at levels comparable to TD infants, than ID-speech (Macari et al., 2020).

**Objectives:** Investigate the differential adaptive value of visual attention to ID-speech and ID-song on language development in infants with and without ASD.

**Methods:** Participants were chronological age-matched infants between the ages of 10 and 25 months (ASD ( $n=54$ ,  $M_{age}(SD)=20.43$  (3.59) months); TD ( $n= 28$ ,  $M_{age}(SD)=19.09$  (4.18) months). Eye-tracking data was collected while infants viewed videos of actresses across three communicative contexts: (1) ID-speech, (2) ID-song-without-gestures, and (3) ID-song-with-gestures (i.e., fingerplay). (ID-song with and without gestures are both ecologically valid social interaction styles but are associated with different patterns of visual engagement (Nicholson et al., 2021); hence they are considered as separate communicative contexts here.) Visual fixation to the actresses' mouth was compared across communicative contexts in TD and ASD infants; within-group correlations tested for associations between visual fixation and concurrent *Mullen* receptive and expressive language age equivalence scores within each communicative context.

**Results:** There was a significant effect of communicative context on levels of mouth fixation ( $p<.001$ ) such that ASD and TD infants look more to mouths in ID-song-without gestures than ID-song-with gestures or ID-speech contexts, which did not differ from each other. TD infants fixated more on mouths than ASD infants overall ( $p=0.015$ ). Among TD infants, mouth-looking to ID-speech was positively associated with expressive language ( $r=0.44$ ,  $p=0.028$ ) and mouth-looking to ID-song-with-gestures was positively associated with expressive ( $r=0.48$ ,  $p=0.032$ ) and receptive language ( $r=0.77$ ,  $p<.001$ ). In ASD infants, mouth-looking to ID-speech and ID-song-with-gestures were not associated with language ability, but mouth-looking to ID-song-without-gestures was positively associated with receptive language ( $r=0.29$ ,  $p=0.041$ ).

**Conclusions:** Although ASD and TD infants' visual fixation patterns varied similarly across different communicative contexts, the adaptive value of mouth-looking to ID-speech and ID-song (with and without gestures) on language development differed by diagnosis and communicative context, potentially reflecting different underlying mechanisms. Future research will investigate the processes linking mouth looking during ID-song and ID-speech contexts with language development in ASD and TD infants. These findings have implications for early interventions aimed at improving language development in infants at risk for ASD.

## VIRTUAL POSTER SESSION — EARLY DEVELOPMENT (< 48 MONTHS)

### 523 - Early Development (< 48 months) --- (V)

**523.008** (*Virtual Poster*) An Examination of Social-Communication Behaviours in Infants and Toddlers in the General Population  
**N. C. Freeman<sup>1</sup>, E. Beattie<sup>2</sup>, B. Gallo Cordoba<sup>3</sup> and J. Barbaro<sup>2</sup>,** (1)School of Educational Psychology & Counselling, Faculty of Education, Monash University, Melbourne, VIC, Australia, (2)Olga Tennison Autism Research Centre, La Trobe University, Melbourne, VIC, Australia, (3)School of Education, Culture & Society, Faculty of Education, Monash University, Melbourne, VIC, Australia

**Background:** Children's development is marked by specific behaviours and skills that emerge in a relatively predictable sequence (i.e., developmental milestones), which are monitored through methods such as developmental surveillance, informal checklists, and validated screening tools. Most of the focus on developmental milestone research to date has been on motor skill development, with relatively fewer studies examining social-communication milestones. Further, available guidelines often do not cite the sources of data used to operationalise the milestones described. As differences in social-communication development are key predictors of a diagnosis of autism, it was of interest to examine the development of these behaviours in the general population. Examining when children typically achieve such milestones using a large, representative sample may further inform when markers of social-communication development could be considered delayed.

**Objectives:** The primary aim of the current study was to further our understanding of the chronological ages at which most infants and toddlers achieved specific social-communication and language milestones. A secondary aim was to ascertain whether there are any gender differences in these social-communication and language milestones. Lastly, we aimed to examine the subgroup of infants and toddlers who do not achieve these milestones at set ages, and examine what proportion had a diagnosis of autism, developmental and/or language delay, or were typically developing.

**Methods:** Participants included 13,507 children (7016 male, 6491 female) who were monitored by Maternal and Child Health (MCH) nurses using a developmental surveillance tool for autism: Social Attention and Communication Surveillance (SACS) during one or more free routine health checks at 12, 18, 24 and/or 42 months. The checklist used at each time point contained 12-15 social-communication items which the MCH nurse rated as 'typical' or 'atypical' based on elicitation of behaviours during the health check.

**Results:** The results suggested that for each of the behaviours (i.e., developmental milestones) monitored, there were  $\geq 90\%$  'typical' responses for all items except pointing at 12-months (85.8%). When looking at gender differences, a higher proportion of females had typical responses on all social-communication and language milestones compared with males across age groups, though not all differences were significant. It was noteworthy that for some social-communication behaviours, the majority ( $\geq 70\%$ ) of children who were rated as having an 'atypical' response were in the typically developing group: for pointing, waving/gestures, expressive and receptive language, and imitation at 12-months, for expressive and receptive language, and points to facial features at 18-months, and for expressive language and two-word utterances at 24-months.

**Conclusions:** The findings of this study can inform our understanding of the emergence of social-communication milestones, and help contextualise observed, or not observed, behaviours across early development. This, in turn, will assist professionals to interpret, and communicate to parents, when particular key early markers of autism (e.g., lack of pointing at 12 months) may be present in typically developing children. The findings have implications for MCH nurses and other primary health practitioners, as they may help normalise certain social-communication behaviours not present at expected 'milestones' with families.

**523.009** (*Virtual Poster*) Atypical Developmental Trajectories and Loss of Skills in Children at Elevated Likelihood for Autism Spectrum Disorder.  
**S. Botterberg, E. Demurie, P. Warreyn, E. Bruyneel, C. Bontinck and H. Roeyers,** Department of Experimental-Clinical and Health Psychology, Ghent University, Ghent, Belgium

**Background:** Prospective studies, in which children at elevated likelihood (EL) for ASD are followed from birth until 36 months, showed that on a group level, children with ASD demonstrated increasing trajectories of non-verbal and language skills over time. However, loss of language skills occurred in a subset of children (Landa et al., 2013). Other studies indicated a largely intact typical development between 2-6 months followed by declining trajectories and loss of early social-communicative skills in the majority of children who receive an ASD-diagnosis (Ozonoff & Iosif, 2019; Pearson et al., 2018). Since these recent findings suggest that declining trajectories could be the norm in ASD development rather than an exceptional subtype, additional research on early onset patterns is needed.

**Objectives:** The aims of this study were therefore to examine 1) initial developmental levels at 10 months in children with typical development (TD), non-typical development (non-TD) and ASD, 2) whether there are increasingly diverging or atypical trajectories over the first three years in ASD-children, and 3) levels of skill loss in TD, non-TD and ASD-children.

**Methods:** The sample included 50 children with an older sibling with ASD (EL-sibs) and 37 children with an older sibling with typical development (i.e., siblings with a typical likelihood for ASD or TL-sibs). Children were grouped based on their best-estimate outcome at 36 months: TD (n=52),

non-TD ( $n=22$ ) and ASD ( $n=13$ ). A prospective, longitudinal study was conducted in which non-verbal and language skills (MSEL) and social-communicative difficulties (ADOS-2 Social Affect) of EL-sibs and TL-sibs were measured at 10, 14, 24 and 36 months.

**Results:** Multigroup Latent Growth Curve Analysis indicated that at 10 months, the ASD-group showed significantly lower levels of non-verbal ( $M_{INTCP}=13.96, p<.001$ ) and receptive language skills ( $M_{INTCP}=10.72, p<.001$ ) compared to TD ( $M_{INTCP}=15.29, p<.001$  and  $M_{INTCP}=12.39, p<.001$ ) and non-TD ( $M_{INTCP}=14.27, p<.001$  and  $M_{INTCP}=11.68, p<.001$ ) groups. As expected, the ASD-group showed increasing patterns of non-verbal and language development, however, their average growth over time was smaller (Range  $M_{slope}=.61-.87, p<.001$ ) as compared to non-TD (Range  $M_{slope}=.73-.89, p<.001$ ) and TD (Range  $M_{slope}=.85-.96, p<.001$ ) groups. Regarding social-communicative difficulties, similar slowly increasing, almost plateauing trajectories were found over groups. Further, the ASD-group showed the most difficulties across ages starting from 14 months ( $M_{INTCP}=4.71, p<.001$ ) as compared to TD ( $M_{INTCP}=1.74, p<.001$ ) and non-TD ( $M_{INTCP}=3.09, p<.001$ ) groups. Declining raw scores on the non-verbal and language scales of the MSEL between any two visits occurred in 31% of ASD, 23% of non-TD and 11% of TD-children. Although more ASD-children showed a decline, mainly in language domains after 14 months, differences between groups were not significant ( $\chi^2(2)=3.317, p=.190$ ).

**Conclusions:** Our findings indicate atypical non-verbal and receptive language functioning for ASD already at 10 months. All outcome groups showed increasing trends over time, but ASD-children showed slower growth in non-verbal and language skills from 10-36 months (Fig.1). Although also part of normative development, skill loss, especially after 14 months and in language domains, should be followed-up in children at EL for ASD. Given limitations associated with use of ADOS-2 Calibrated Severity Scores, additional prospective research examining social-communicative skill loss is required.

### **523.010** (Virtual Poster) Biobehavioral Profiles of Social Impairments in Autism Spectrum Disorder and Fragile X Syndrome

**C. A. Wall<sup>1</sup>** and **J. Roberts<sup>2</sup>**, (1)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (2)Department of Psychology, University of South Carolina, Columbia, SC

**Background:** The heterogeneity of autism spectrum disorder (ASD) creates diagnostic challenges, pointing to a need for robust, objective markers of symptomology. Challenges are exacerbated by the phenotypic overlap between ASD and social anxiety, in addition to discreet populations with shared features, like fragile X syndrome (FXS). Biobehavioral measurement approaches integrate behavioral and biological data, and they have the potential to supplement diagnoses and shed light on the mechanisms underlying social impairments. They have particular utility for children with cognitive impairments, whose symptoms may be difficult to assess with traditional instruments. Biobehavioral measures include negative affect (NA), a biological tendency towards negative emotions; and respiratory sinus arrhythmia (RSA), the beat-to-beat variability in heart rate associated with respiration. Both are associated with impairments in FXS and non-syndromic ASD (nsASD) and predict ASD and social anxiety symptoms within these populations. However, no work has combined these measures to understand profiles of social impairments across nsASD and FXS in preschoolers with cognitive impairments.

**Objectives:** To evaluate: 1) whether baseline RSA and NA differ in nsASD, FXS, and typical controls, and 2) whether RSA regulation and NA predict ASD or social anxiety symptoms.

**Methods:** Participants included 120 preschoolers with nsASD ( $n=47, n_{males}=40, M_{age}=42.9$  months), FXS ( $n=41, n_{males}=29, M_{age}=45.4$ ), or TD ( $n=32, n_{males}=25, M_{age}=45.6$ ). Mean RSA was collected via electrocardiogram during a seated baseline condition; NA was assessed with the Childhood Behavior Questionnaire (CBQ); ASD symptom severity with the Autism Diagnostic Observation Schedule, Second Edition; social anxiety with the Spence Preschool Anxiety Scale; and developmental ability (DQ) with the Mullen Scales of Early Learning (MSEL).

**Results:** Obj1: RSA did not differ across groups ( $F(3, 116)=.253, p=.859$ ; partial  $h^2=.004$ ) controlling for DQ. Groups differed in NA ( $F(2, 117)=4.33, p=.015$ ; partial  $h^2=.063$ ). Post hoc analyses suggested the TD group had lower NA than the nsASD group ( $p=.007$ ), but not the FXS group ( $p=.120$ ); the nsASD and FXS groups did not differ ( $p=.261$ ). Obj2: RSA was related to ASD symptoms for the nsASD group only ( $B=-.461, p=.018$ ). There was a relationship of NA to social anxiety in the nsASD group ( $B=1.49, p=.018$ ) and the FXS group ( $B=3.06, p<.001$ ).

**Conclusions:** This study is the first to evaluate RSA and NA in cognitively impaired preschoolers with nsASD and contrast them with FXS. Contrary to expectations, we found no group differences in baseline RSA, potentially due to developmental effects. However, reduced RSA regulation was uniquely associated with elevated ASD symptoms in the nsASD group. This finding supports the interplay of biological competence to the expression of ASD clinical profiles and aligns with theoretical and empirical work documenting the relationship between RSA and social engagement. We also extend findings of elevated NA to preschoolers with nsASD who have cognitive impairments and report an association between elevated NA and increased social anxiety in both nsASD and FXS. This suggests that NA, which emerges early in development, may be a risk marker for the onset of later social anxiety in both nsASD and FXS.

### **523.011** (Virtual Poster) Caregiver Report of Autism and ADHD Symptoms in a Community Sample of Toddlers

**N. O. Davis<sup>1</sup>**, **K. L. Carpenter<sup>2</sup>**, **S. Compton<sup>3</sup>**, **L. Franz<sup>4</sup>**, **E. Henderson<sup>4</sup>**, **Z. Rodriguez<sup>2</sup>**, **M. Sabatos-DeVito<sup>5</sup>**, **L. Sikich<sup>2</sup>**, **M. Spanos<sup>2</sup>** and **G. Dawson<sup>2</sup>**, (1)Department of Psychiatry and Behavioral Sciences, Duke ADHD Program, Duke University Medical Center, Durham, NC, (2)Department of Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC, (3)Duke Center for Autism and Brain Development, Department of Psychiatry and Behavioral Sciences, Duke University, Durham, NC, (4)Duke University Medical Center, Durham, NC, (5)Psychiatry and Behavioral Sciences, Duke Center for Autism and Brain Development, Durham, NC

**Background:**

Co-occurrence of autism and ADHD has been well-documented in clinic-referred samples, including preschool age autistic children. In non-clinic referred samples, autism and ADHD have also been associated, suggesting that co-occurrence is not limited to clinic-referred populations. Limited work has examined associations between autism and ADHD symptoms in non-clinic-referred toddlers. During toddlerhood, autism can be diagnosed but ADHD is less often evaluated. Identifying and understanding early co-occurrence of autism and ADHD symptoms may facilitate evaluation and initiation of targeted interventions.

#### Objectives:

To examine relationships between autism and ADHD symptoms in a community sample of toddlers recruited through primary care during well-child visits. Our goals were to understand patterns of co-occurrence and explore their relationship to age and sex in toddlers.

#### Methods:

Participants were  $n=1631$  toddlers ages 14-44 months ( $M=19.5$ ,  $SD=3.5$ ) recruited through primary care clinics. Autism and ADHD symptoms were assessed by parent report on the Child Behavior Checklist (CBCL). Toddlers were classified as being "Elevated" on the autism and/or ADHD scales if their CBCL T-scores were in the Borderline or Clinical range. We employed Pearson's correlations using raw scores and general linear models to explore relationships between autism, ADHD symptoms, sex, and age. Follow-up pair-wise t-tests were corrected for multiple comparisons using the Benjamini-Hochberg correction.

#### Results:

Autism and ADHD symptoms were significantly correlated ( $n=1631$ ;  $r=.49$ ,  $p<.001$ ). Overall 5% ( $n = 82$ ) toddlers were classified as Elevated on one or both scales. Examining the scales separately, 1.5% ( $n = 24$ ) were elevated on ADHD only, 2.3% ( $n = 38$ ) were elevated on autism only, and 1.2% ( $n = 20$ ) were elevated on both autism and ADHD. Among toddlers who were elevated for autism, 34% were also elevated for ADHD. Among toddlers who were elevated for ADHD, 45% were also elevated for autism. There was no difference in the proportion of males in any Elevated group. Toddlers elevated for both autism and ADHD ( $M=24.15$ ,  $SD=6.54$ ,  $F=39.5$ ,  $p<.0001$ ) and elevated for only autism ( $M=22.84$ ,  $SD=5.32$ ,  $F=39.01$ ,  $p<.0001$ ) were older than children not elevated on either scale ( $M=19.39$ ,  $SD=3.31$ ). Toddlers elevated for ADHD did not differ in age from the other groups ( $M=20.79$ ,  $SD=4.49$ ). Children who were older ( $F=11.25$ ,  $p<.001$ ), male ( $F=18.54$ ,  $p<.0001$ ), and had higher autism scores ( $F=503.75$ ,  $p<.0001$ ) were more likely to have higher ADHD symptoms. Both age and ADHD symptoms were associated with higher autism symptoms whereby older toddlers with higher ADHD symptoms had higher autism symptoms ( $F=107.44$ ,  $p<.0001$ ). Males were more likely to have higher autism symptoms; however, this association was no longer significant when ADHD symptoms were included.

#### Conclusions:

Autism and ADHD symptoms are correlated in a community sample of toddlers. Demographic and clinical factors predicted symptom elevations, with a higher likelihood for autism in the context of older age and ADHD symptoms. Among toddlers with elevated symptoms of either disorder, over one-third had elevated symptoms of the other disorder. Toddler ADHD screening, though not routinely performed, may help with early identification of neurodevelopmental disorders. Results indicate co-occurring symptoms can be identified early which can facilitate appropriate treatment.

**523.012** (Virtual Poster) Development of Early Screening for Communication and Social Skills (ESCoMS) Instrument: Predictive Validity  
**D. Swaminathan<sup>1</sup>**, S. Nagaraj<sup>2</sup>, A. Joseph<sup>3</sup>, V. Raman<sup>3</sup>, M. Lewin<sup>4</sup>, F. Naaz Fathima<sup>5</sup>, T. Agrawal<sup>3</sup>, D. Misquith<sup>6</sup> and A. Mysore<sup>7</sup>, (1)National Institute of Mental Health and Neuro Sciences (NIMHANS), Bangalore, Bangalore, India, (2)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bangalore, India, (3)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St John's Medical College Hospital, Bengaluru, India, (4)Pediatrics, St John's Medical College Hospital, Bangalore, India, (5)Community Medicine, St John's Medical College Hospital, Bangalore, India, (6)Community Medicine, St. John's Medical College Hospital, Bangalore, India, (7)Center for Advanced Research and Excellence in Autism and Developmental Disorders (CARE-ADD), St. John's Medical College Hospital, St John's Medical College Hospital, Bangalore, India

**Background:** Early identification of autism facilitates early intervention and improves outcomes. Few tools exist to effectively screen infants for autism. We had reported the development of a 24-item screening tool, ESCoMS (Early Screening for Communication and Social skills) using a mixed methodology design (Swaminathan.D et al; INSAR 2020). We now report on the evaluation phase. This work was supported by the Indian Council for Medical Research.

**Objectives:** The objective was to evaluate the predictive validity of ESCoMS by following up a cohort of infants between 9 and 18 months after six months.

**Methods:** The 24 item ESCoMS was administered to two groups of infants between the ages of 9-18 months from various facilities within Bangalore in South India. The two groups were as follows: Normal controls - children who were born full term, without NICU admission and had been developing age appropriately and a High-Risk group - children who were born pre-mature or had history of NICU stay, seizures or developmental delays. A total of 592 normal controls and 150 high risk infant – toddlers were recruited for this phase from many centers around the city.

Six months later, 300 participants could be followed up to evaluate for possible autism diagnosis using DSM 5 and ICD 10 by a clinician blind to the respondent's performance on ESCoMS at baseline. Additionally, a variety of autism quantitative measures were used to confirm the trend of

development. The instrument's performance accuracy was calculated in terms of sensitivity, specificity, positive predictive value (PPV) and negative predictive value (NPV). For the predictive validation phase, a cut-off of 11 had been set for infants between 9-12 months and a cut-off of 9 for infants between 13-18 months, based on a ROC value obtained from phase I.

Results: Of the 300 children seen at follow up 16 children (12-High-Risk group, 4-control group) were considered highly likely to meet diagnosis based on clinical criteria (ICD 10 and DSM 5) by trained clinicians.

For the 9-12-month-old infants, at the given cut off of 11, the sensitivity was 33.3%, specificity was 89.1%, PPV of 41.9% and NPV of 94.6 %. For the 13-18-month-old infants, at the given cut off of 9, the sensitivity was 76.9% and specificity was 88.5%. PPV of 52% and NPV of 97%. To depict the predictive power of EScMS, ROC Curves were calculated separately for both age groups, considering DSM 5 as gold standard. AUC for 9-12-month-old infants was 0.647 (p-value: 0.099) and for 13-18-month-old infants was 0.846 (p-value: <0.001).

EScMS showed significant correlation with other measures (Table 1).

Sensitivity and Specificity for EScMS was calculated at different cut-off points. A cut-off of 8 showed best sensitivity of 66.7% and 84.6% and specificity 67.3% and 85.6% for the 9-12-month and 13-18 month age groups respectively.

Conclusions: This is the first screening tool for Indian children below 18 months of age. The scale is more successful at screening children above 13 months of age, which is noted across all available behavioral screening measures for this age group.

### **523.013 (Virtual Poster)** Examining the Association between Neurodevelopmental Quantitative Trait Variation in ASD Probands and Their Younger Siblings at 36 Months

A. Budavari<sup>1</sup>, L. Song<sup>2</sup>, J. B. Girault<sup>3</sup>, S. Ozonoff<sup>4</sup>, R. Landa<sup>5</sup>, L. A. Croen<sup>6</sup>, M. D. Fallin<sup>7</sup>, I. Hertz-Picciotto<sup>8</sup>, K. Lyall<sup>9</sup>, C. J. Newschaffer<sup>10</sup>, R. J. Schmidt<sup>10</sup> and H. E. Volk<sup>2</sup>, (1)Department of Mental Health, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (2)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (3)Carolina Institute for Developmental Disabilities, University of North Carolina, Chapel Hill, NC, (4)Psychiatry and Behavioral Sciences, University of California at Davis, MIND Institute, Sacramento, CA, (5)Center for Autism and Related Disorders, Kennedy Krieger Institute, Baltimore, MD, (6)Division of Research, Kaiser Permanente Division of Research, Oakland, CA, (7)University of California at Davis, Davis, CA, (8)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA, (9)College of Health and Human Development, Pennsylvania State University, University Park, PA, (10)Public Health Sciences, University of California Davis, Davis, CA

Background: Younger siblings of individuals with ASD are at increased risk for ASD, as well as other neurodevelopmental impairments. Previous studies of biological siblings and twin pairs indicate that ASD symptoms and related traits cluster within families. Few prospective studies of siblings have evaluated how proband traits may inform sibling outcomes.

Objectives: The current study examined neurodevelopmental quantitative trait variation and diagnostic status among probands with ASD and their younger siblings.

Methods: We examined the association between scores on the Social Communication Questionnaire (SCQ) in probands and scores on the Social Responsiveness Scale (SRS), Vineland Adaptive Behavior Scales (VABS), and Mullen Scales of Early Learning (MSEL) in siblings at 36 months in 180 sibling pairs from the Early Autism Risk Longitudinal Investigation (EARLI). Sibling 36-month diagnosis of ASD, non-typically developing (Non-TD), or typically developing (TD) was determined based on clinical diagnosis, ADOS score, and the MSEL early learning composite. Linear regression was used to estimate the relationship between proband trait and sibling trait. An interaction term between proband SCQ and outcome group (ASD / Non-TD vs. TD) was then added to assess if the trait relationship differed by sibling diagnosis.

Results: At 36 months, 40 siblings (22%) received an ASD diagnosis, 56 (31%) siblings were determined to be Non-TD, and 84 (47%) siblings were TD. Increasing SCQ score of the proband was found to significantly predict a decreased VABS composite score ( $\beta = -0.32$ ,  $p = .04$ ) in the sibling. Models including a proband SCQ by sibling diagnosis (ASD / Non-TD vs. TD) interaction suggested that proband SCQ score significantly predicted poorer sibling VABS composite score among those defined as ASD/Non-TD ( $\beta = -0.92$ ,  $p = .001$ ). Additional analyses indicated a relationship between proband SCQ and sibling expressive language VABS score among those defined as ASD/Non-TD ( $\beta = -1.06$ ,  $p = 0.006$ ). No other statistically significant relationships were identified between proband SCQ and sibling traits.

Conclusions:

Associations between the proband's neurodevelopmental quantitative traits and younger sibling outcomes may help in the early identification of specific neurodevelopmental impairments among high-risk (HR) siblings. Specifically, proband ASD symptomatology assessed by the SCQ may be associated with impairment level in affected younger siblings.

### **523.014 (Virtual Poster)** The Preschool Brain Imaging and Behaviour Project: A Transdiagnostic Approach to Identify Neurodevelopmental Subgroups and Trajectories in a Large European Multi-Centre Study

---

**Background:** Neurodevelopmental conditions (including autism, ADHD, developmental delay) affect approximately 10% of individuals worldwide and can significantly impact a person's quality of life (Mizuno et al., 2019; Lau-Zhu et al., 2019). Key barriers to the development of more effective support strategies are heterogeneity within single conditions, substantial overlap between conditions, and lack of, or incomplete, understanding of underlying mechanisms. The Preschool Brain Imaging and Behaviour Project (PIP) is the first European collaborative multi-site longitudinal study aimed to link individual variation in brain development and function to social, cognitive and emotional development in preschoolers with ADHD, autism, developmental delay, epilepsy, or typical development. The goal is to identify subgroups within or across established diagnostic categories to better predict developmental outcomes, and to develop more tailored support strategies. However, preschoolers, especially preschoolers with neurodevelopmental conditions (who may experience additional difficulties), pose significant challenges for reliable assessments. For any measure to have potential clinical utility as a prognostic biomarker for preschoolers, it is essential that it is feasible and accessible for this age range.

**Objectives:** To assess the feasibility of a multi-modal protocol to identify prognostic biomarkers in preschool children.

**Methods:** Across five sites in Europe (in the Netherlands, Belgium, France, Sweden and the UK), the PIP study aims to longitudinally track the development of a cohort of 480 preschool children (autism = 180, ADHD = 50, epilepsy = 20, developmental delay = 50, neurotypical = 180) between the ages of 2 ½ and 6 years old. Six dimensional transdiagnostic biobehavioural domains (executive function, emotion processing, sensory processing, reward processing, predictability and social processing) are assessed across multiple levels using behavioural, cognitive, eye-tracking, EEG and MRI measures, and a novel battery of touchscreen tasks.

**Results:** Data collection for the PIP study is ongoing. Analyses presented here are preliminary using data collected up to June 2021 (N = 84). Behavioural, cognitive, EEG, and eye-tracking measures showed high completion rates (behavioural = 95%, cognitive = 93%, EEG = 86%, eye-tracking = 83%). Furthermore, our novel touchscreen battery showed good psychometric properties (split-half reliability) with preschoolers across tasks measuring social processing (0.85), reward learning (0.71) and executive functioning (sustained attention (0.95); inhibitory control (0.87)). For MRI (conducted during children's natural sleep), completion rates for structural T1/T2 across sites was 63%, with similar rates for autistic and neurotypical children.

**Conclusions:** At the INSAR 2022 meeting, feasibility data from our multi-modal PIP protocol will be presented from a larger cohort of preschoolers, with additional data quality analyses, and in relation to child clinical profiles. It is essential to understand the factors that may contribute to data completion rates in preschoolers, to ensure that particular subgroups of children are not disproportionately excluded to accurately predict a child's development or tailor support.

### 523.015 (Virtual Poster) Validation of the Tele-RITA-T

**R. Choueiri<sup>1</sup>, W. Garrison<sup>2</sup>, V. Tokatli<sup>3</sup>, M. Ravi<sup>4</sup> and E. Prasad<sup>1</sup>,** (1)University of Massachusetts Memorial Children's Medical Center, North Worcester, MA, (2)Pediatrics, Developmental and Behavioral Pediatrics, University of Massachusetts Medical School, Worcester, MA, (3)university of Massachusetts Chan Medical School, Worcester, MA, (4)UMass Children's Hospital, Worcester, MA

---

**Background:**

The COVID-19 pandemic has emphasized the need for telehealth and remote evaluations. We have developed a modified Tele- RITA-T screening evaluation and to continue to evaluate and screen toddlers with suspected ASD during the pandemic

**Objectives:**

To validate a modified version of the RITA-T as a telehealth tool for those who are 18-36 months. Identify a cut off score to differentiate between those with ASD and non-ASD.

**Methods:**

The Tele- RITA-T includes modified activities and behavioral prompts that the parent is instructed to complete with the toddler. These prompts mirror the validated items drawn from the RITA-T. The Tele- RITA-T has a maximum score of 20 (vs. 30 for the RITA-T). After consent was obtained, a trained research assistant instructed the families on how to administer each prompt, and then scored the test. The diagnostic remote evaluation then included history, observation of play and structured prompts developed by this group: the EASI (Early Autism Screening Inventory). Diagnostic evaluation included the CARS-2 and the application of the DSM-5 criteria.

#### Results:

109 toddlers have been enrolled and evaluated using the Telehealth RITA-T. Ages varied between 18 and 34 months with a mean of 30 months. From the 109 toddlers, 29 had received the interactive RITA-T. The Tele-RITA-T correlated very well with scoring of the in-Person RITA-T. A cut off score of 10 on the Tele-RITA-T had a PPV of 90% for a diagnosis of ASD. All toddlers who previously scored in the high-risk range for ASD on the interactive RITA-T, had a score higher than 9 on the modified Tele- version.

#### Conclusions:

The Tele-RITA-T is an effective measure for the screening of toddlers for ASD risk by telehealth. Its administration with the structured observation checklist EASI improves the identification of ASD risk at a cut off score above 10.

**523.016** (Virtual Poster) Neural Coding of Exaggerated Speech in Young Children with and without Autism : Evidence from Mandarin Chinese  
**L. Ban**<sup>1,2</sup>, A. Yi<sup>3</sup>, J. Xin<sup>3</sup>, S. Li<sup>3</sup> and L. Yu<sup>1,2</sup>, (1)School of Psychology, South China Normal University, Guangzhou, China, (2)Autism Research Center, South China Normal University, Guangzhou, China, (3)Department of Child Rehabilitation, Foshan Chancheng Central Hospital, Foshan, China

---

Background: Caregivers adopt exaggerated or child-directed speech when talking to infants and young children. Exaggerated speech is typically characterized by expanded vowel formant space, increased pitch range, and prolonged voice onset time (VOT) (Cristia, 2013; Fernald & Mazzie, 1991; Kuhl, 1997). It has been shown that exaggerated speech can not only promote early phonetic and language development (Tsao et al., 2004; Zhang et al., 2011) but also facilitate second-language learning in adults (Zhang et al., 2009). Speech perception studies have demonstrated neural processing impairment of linguistic pitch information (e.g., Chinese lexical tone; Yu et al., 2015, 2021) and time-related features of consonants (Kuhl et al., 2005) as well as deficits with auditory temporal processing (Meilleur et al., 2020) in children with autism. It is therefore important to investigate whether exaggerated speech can benefit the neural coding of the specific phonetic features and the underlying mechanisms.

Objectives: Given that linguistic pitch and consonant features can be particularly challenging for speech perception of autistic children, we aimed to specifically examine whether and how exaggerated f0 and VOT affect the neural coding of lexical tone and stop consonant in young Chinese-speaking children with autism and their typically developing (TD) peers.

Methods: The present study included 20 children with autism (mean age = 43.5 months) and 24 age-matched TD children. Exaggerated and non-exaggerated lexical tone stimuli were synthesized using the syllable /i/, and consonant stimuli from the CV syllable /pi/. Acoustic parameters of the exaggerated and non-exaggerated stimuli were determined based on measurements of actual child-directed utterances and existing literature. EEG data were recorded as the participants were instructed to watch self-chosen muted cartoons and ignore any sound presented through insert earphones. Statistical analyses of the amplitude and latency of the P1 and N2 components were performed using linear mixed-effect models.

Results: For the P1 component, the autism group but not the TD group showed significantly enhanced P1 amplitude to the non-exaggerated lexical tone compared to the exaggerated tone. No other effects were found for P1. For the N2 component, the autism group responded significantly greater to the lexical tone with exaggerated f0, whereas the TD group showed no effect of f0 exaggeration. Additionally, the autism group had significantly longer N2 latency to the syllable with exaggerated VOT, and no latency difference was observed in the TD group.

Conclusions: Acoustic exaggeration affected the neural coding of lexical tone and stop consonant in young children with autism but not the TD children. One major observation was increased N2 amplitude responding to the exaggerated lexical tone in autism. Given the functional role of auditory N2 (or developmentally emerging N1) in higher-order sensory integration and phonetic perception (Čeponienė et al., 2009), the effect on N2 might reflect a facilitation effect on the neural coding of lexical features in autism. Although different elements of exaggerated speech may affect distinct aspects of speech processing, our finding suggests the utility of acoustic exaggeration targeting specific challenging phonetic properties to promote phonetic learning and speech processing of young children with autism.

**523.017** (Virtual Poster) Phenotypic Characteristics of Children with Autism Spectrum Disorder By Parental Age: Study to Explore Early Development (SEED)

**P. Powell**<sup>1</sup>, M. J. Maenner<sup>2</sup>, C. DiGuseppi<sup>3</sup>, L. A. Schieve<sup>2</sup>, G. C. Windham<sup>4</sup> and N. Dowling<sup>2</sup>, (1)Child Development & Disabilities Branch, CDC National Centers on Birth Defects and Developmental Disabilities, Atlanta, GA, (2)Centers for Disease Control and Prevention, Atlanta, GA, (3)Colorado School of Public Health, University of Colorado Anschutz Medical Campus, Aurora, CO, (4)Environmental Health Investigations Branch, California Department of Public Health, Richmond, CA

---

#### Background:

Many studies report an association between the risk of having a child with autism spectrum disorder (ASD) and greater parental age at the time of the child's birth, but few have closely examined whether specific ASD-related symptoms or behaviors are more strongly associated with parental age than others.

## Objectives:

To address this gap, we examined scores from parent-report measures and clinical assessments of ASD symptoms and behavioral problems in young children with ASD to determine if these scores varied according to parental age.

## Methods:

The Study to Explore Early Development (SEED) is a multi-site case-control study of ASD. Children ages 2–5 years completed behavioral and developmental assessments including the Mullen Scales of Early Learning (MSEL), the Autism Diagnostic Observation Schedule (ADOS), and the Autism Diagnostic Interview-Revised (ADI-R). Scores from the ADOS and ADI-R were used to identify children who met study criteria for ASD. Parents also completed standardized parent-report questionnaires including the Social Communication Questionnaire (SCQ), the Social Responsiveness Scale (SRS), and the Child Behavior Checklist (CBCL). This study included 1,417 children who met SEED criteria for ASD. The number of children with available data varied for each measure, ranging from 1,336 to 1,417 participants.

Scores from each measure were examined across three parental age categories based on the parent's age at the time of their child's birth: both parents <30 years, one parent <30 years, and both parents ≥30 years. Parental age categories were independent predictors in linear regression models. Both unadjusted and adjusted beta coefficients and 95% confidence intervals (95% CIs) were estimated for each parental age category. Adjusted beta coefficients reflected linear relationships between parental age and continuous scores from the clinical and parent-report measures after accounting for these sociodemographic variables: maternal education, maternal race/ethnicity, paternal education, age of child at clinical assessment, child's sex, SEED study site, current household income, and birth order.

## Results:

After adjusting for socio-demographics, younger parents (i.e., both under 30 years) were more likely to report greater levels of ASD-related symptoms on the SCQ ( $\beta=1.3$ ,  $p<0.01$ ) and SRS ( $\beta=6.0$ ,  $p<0.01$ ) and more problem behaviors on the CBCL ( $\beta=2.5$ ,  $p<0.01$ ) compared to older parents (**Table 1**). However, with the exception of scores from the ADI-R and ADOS repetitive behaviors and interest domain for one parent <30 ( $\beta=0.4$ ,  $p<0.05$ ; and  $\beta=-0.3$ ,  $p<0.05$ ), the more in-depth clinical measures (MSEL, ADOS, ADI-R) showed no overall differences by parental age after adjusting for socio-demographics ( $p\geq 0.05$  for all measures).

## Conclusions:

Younger parental age categories (e.g., one or both < 30 years) were more likely to report that their child had greater ASD symptom severity and behavioral problems relative to parents who were both 30 years or older. However, this pattern of results was not observed across most of the clinical assessments. While prior evidence has shown an association between the risk of ASD and parental age, research on the behavioral correlates of ASD risk factors might benefit from including multiple measures and greater consideration of how parental age might influence symptom reporting on certain instruments.

## **523.018** (Virtual Poster) Pilot Findings from the Parc Study: The Interaction between Autism Symptomatology and Adaptive Functioning over Six Months

**Background:** While adaptive functioning is known to be impaired in children with autism, individual profiles vary significantly in this regard (Alvares et al., 2019). In the context of developmental trajectories, the association between adaptive functioning and autism symptomatology remains unclear. These two domains appear to be linked for some children and appear to develop on independent trajectories for others (Sztatmari et al., 2015). Findings are inconclusive regarding the nature of the association between specific subgroups of autism symptoms with adaptive functioning (Franchini et al., 2018; Gabriels et al., 2005).

**Objectives:** To examine the way in which adaptive functioning and autism symptomatology associate and develop over a 6-month period.

**Methods:** Participants include 37 children with a recent diagnosis of autism (i.e. within the last 6 months; 3 females, mean age = 55.6 months, SD = 9.5 months). Families were recruited in the context of the pilot phase of the Pediatric Autism Research Cohort (PARC) project, an international multi-site study focused on identifying and understanding factors influencing phenotypic expression over time. Parents filled out questionnaires over a 2-year period. For this analysis, we utilized two time points that were six months apart. Questionnaires measured autism symptomatology (Autism Impact Measure; AIM; Kanne et al., 2014) and adaptive functioning (Vineland Adaptive Behavioral Scales; VABS-3; Sparrow et al., 2016). We examined one-tailed Pearson correlations between the VABS total score and the AIM total score and sub-domains, including scores indicating symptoms' frequency and impact on everyday functioning, as well as symptom sub-groups. Correlations were conducted at time 1 and at time 2.

Results: All variables except one were significantly negatively correlated at Time 1 and strengthened at time 2. VABS total scores strongly negatively correlated with AIM total scores at both time points ( $r=-.547$ ;  $r=-.716$ ). Symptoms' impact score also negatively correlated with VABS total scores at both time points ( $r=-.349$ ;  $r=-.564$ ), as well as with symptoms' frequency score ( $r=-.626$ ;  $r=-.758$ ). AIM symptom sub-groups negatively correlated with VABS total scores at both time points: communication ( $r=-.528$ ;  $r=-.774$ ), peer interaction ( $r=-.509$ ;  $r=-.609$ ), social responsiveness ( $r=-.354$ ;  $r=-.704$ ), and repetitive behavior ( $r=-.398$ ;  $r=-.439$ ). Atypical behavior did not significantly correlate with the VABS total score at time 1 ( $r=-.275$ ,  $p=.055$ ), but did at time 2 ( $r=-.457$ ,  $p<.01$ ).

Conclusions: These findings suggest that adaptive functioning associates with parent-report autism symptomatology concurrently and longitudinally. Furthermore, this association appears to strengthen over time. At Time 2, the association between adaptive functioning and symptoms belonging to the DSM-5's criteria A become more prominent than the link between adaptive functioning and symptoms associated with criteria B. The frequency of symptoms more strongly associated with adaptive functioning than the reported impact of symptoms, both concurrently and over time. This may indicate that, beyond parents perceived impact of symptoms, the role of symptom frequency in the development of adaptive skills is worthy of specific exploration. While preliminary and all parent-report, these pilot findings deepen our understanding of longitudinal associations between adaptive functioning and symptomatology and highlight the need for further study of this area.

#### **523.019 (Virtual Poster) Skill Attainment and Loss in Phelan-Mcdermid Syndrome**

**I. Giserman-Kiss<sup>1</sup>, E. Mohanty<sup>2</sup>, C. Farmer<sup>3</sup>, A. Thurm<sup>4</sup>, J. A. Bernstein<sup>5</sup>, J. D. Buxbaum<sup>6</sup>, E. Berry-Kravis<sup>7</sup>, C. M. Powell<sup>8</sup>, M. Sahin<sup>9</sup>, L. V. Soorya<sup>10</sup> and A. Kolevzon<sup>11</sup>,** (1)Neurodevelopmental and Behavioral Phenotyping Service, National Institutes of Mental Health, Bethesda, MD, (2)University of Wisconsin, Milwaukee, WI, (3)National Institute of Mental Health, Bethesda, MD, (4)Office of the Clinical Director, National Institute of Mental Health, Bethesda, MD, (5)Pediatrics, Stanford University, Stanford, CA, (6)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (7)Pediatrics, Neurological Sciences, & Biochemistry, Rush University Medical Center, Chicago, IL, (8)Neurobiology, UAB School of Medicine, Birmingham, AL, (9)Boston Children's Hospital, Boston, MA, (10)Department of Psychiatry, Rush University Medical Center, Chicago, IL, (11)Seaver Autism Center for Research and Treatment, Department of Psychiatry, Icahn School of Medicine at Mount Sinai Hospital, New York, NY

Background: Phelan-McDermid Syndrome (PMS), a genetic condition involving SHANK3, is associated with profound intellectual and multiple disabilities, including severe motor impairments, absence of speech, and neurologic diagnoses such as epilepsy. Major milestones are commonly delayed or not met and considerable loss of developmental skills (i.e., regression) after attainment is often reported.

Objectives: We describe skill attainment and loss among individuals with PMS, focusing on key developmental characteristics that may be tracked by pediatric providers in developmental monitoring. We seek to understand if there are early profiles that may be noteworthy for this condition.

Methods: Parent-reported information about the timing of milestone attainment was drawn from a prospective natural history study of children and adolescents with confirmed genetic diagnoses of PMS. Participants ( $N = 100$ ) were between 3 and 20 years old (mean age 8.8 years; 54% male; 9% Asian, 2% Black, 85% White, 3% unknown race).

Results: Nearly all participants (97%) were able to walk independently, but the age at which this skill was attained was delayed for half of the sample (median [IQR]: 18 [15, 26] months). Non-attainment of language milestones was common: 34% did not attain single words and 61% never attained phrase speech. Of those who did attain at least single words, the age of onset was delayed (median [IQR]: 30 [24, 46] months). Language skills were also commonly reported as lost (24%). Of the entire sample, 39% reported probable or definite loss of other skills, most commonly babbling (35%) and responding to name (14%).

Conclusions: This study contributes to the literature by using semi-structured interviews to obtain information about milestone attainment and loss in a well-described sample of children and adolescents with PMS. The results support the conclusion that individuals with PMS are likely to experience pervasive and widespread delays, and even non-acquisition, of important skills during development. Further, even when acquisition occurs, individuals with PMS appear to be at risk of skill loss. Findings from this study will contribute to the dearth of information regarding the early development of individuals with PMS, informing healthcare providers, families, and other stakeholders of common developmental patterns seen amongst this population.

#### **523.020 (Virtual Poster) The Co-Development of the Pupillary Light Reflex and Sensory Reactivity over Infancy and Their Relationship to the Emergence of Autism: A Multi-Group Cross-Lagged Panel Analysis**

**L. Fish<sup>1</sup>, P. Nyström<sup>2</sup>, J. Begum Ali<sup>3</sup>, L. Mason<sup>4</sup>, G. Pasco<sup>5</sup>, R. Arthur<sup>6</sup>, T. Charman<sup>7</sup>, M. Johnson<sup>8</sup>, T. Falck-Ytter<sup>9</sup> and E. J. Jones<sup>4</sup>,** (1)King's College London, London, United Kingdom, (2)Uppsala University, Uppsala, Sweden, (3)Centre for Brain and Cognitive Development, Birkbeck, University of London, London, United Kingdom, (4)Centre for Brain and Cognitive Development, Birkbeck University of London, London, United Kingdom, (5)Institute of Psychiatry, Psychology and Neuroscience, King's College London, London, United Kingdom, (6)Department of Psychology, University of Cambridge, Cambridge, United Kingdom, (7)Center of Neurodevelopmental Disorders (KIND), Centre for Psychiatry Research; Department of Women's and Children's Health, Karolinska Institutet, Stockholm, Sweden

**Background:** Though the route/s through the aetiology of autism manifest into recognisable symptoms at 2-3 years remains unclear, insights are being provided by longitudinal prospective studies with infants with a family history of autism (who have a 10-20% likelihood of developing autism and a further 20% likelihood of other developmental difficulties). Prospective longitudinal studies have uncovered multiple putative early neurocognitive markers of autism in infancy, with some of the earliest being sensory in nature. Investigating how the development of Sensory Sensitivity (e.g., the Pupillary Light Reflex; PLR) and behavioural Sensory Reactivity interrelated over infancy to influence emerging autism traits may illuminate mechanistic pathways through which symptoms manifest.

**Objectives:** We aimed to explore: a) how pupil Sensory Sensitivity (PLR Constriction Amplitude/Latency) and behavioural Sensory Reactivity longitudinally interrelate over the first two years of life, b) how any earlier Sensory Sensitivity and Sensory Reactivity relate to later dimensional autism-associated social difficulties and repetitive behaviours at 3 years of age, and c) whether familial likelihood for autism influences these relationships.

**Methods:** The sample consisted of 299 infants; 217 had a family history of autism (Elevated Likelihood). The PLR (Latency [onset; ms]) and behavioural Sensory Reactivity longitudinally at 9, 14 and 24 months and autism traits at 3-years. The PLR was induced using stimuli consisting of a bright contrasting change in light; pupil diameter was measured using eye-tracking technology. Sensory Reactivity was operationalised using an adapted measurement invariant metric based on the Perceptual Sensitivity subscale of the Infant/ Early Childhood Behaviour Questionnaire (I/ECBQ; Gartstein & Rothbart, 2003; Putnam, Gartstein, & Rothbart, 2006). The Social Responsiveness Scale (SRS; Constantino & Gruber, 2005) was used to measure autism social and repetitive behaviours trait levels. Multi-group cross-lagged panel analysis we assessed the influence of autism familial likelihood on the infant developmental interrelationship between PLR and Sensory Reactivity and their association with later autism traits. Structural invariance tests were used to determine if relationships between variables within the model significantly differed across familial likelihood for autism (Elevated Likelihood or Typical Likelihood).

**Results:** Across the sample, 9-month Sensory Reactivity positively predicted later autism traits at 3-years. No relationship was found between 9- to 14-month Sensory Sensitivity or Sensory Reactivity in either familial likelihood group. In those with an Elevated Likelihood of autism, 14-month PLR Latency positively predicted 24-month Sensory Reactivity; no association was found in the Typical Likelihood group. In the Typical Likelihood group, 14-month Sensory Reactivity negatively predicted 24-month Latency; no association was found in the Elevated Likelihood group.

**Conclusions:** Findings may represent altered early top-down modulation of low-level sensory processing in emerging autism symptoms. Future investigations should explore additional measures to provide insight into the neural underpinnings of these associations.

### **523.021 (Virtual Poster)** Viability of Virtual Gaze Data in Preschoolers with and without Autism Spectrum Disorder

**T. S. Boyd<sup>1</sup>, A. Steele<sup>2</sup>, T. Buonocore<sup>2</sup>, R. J. Luyster<sup>2</sup> and S. Arunachalam<sup>1</sup>,** (1)Communicative Sciences and Disorders, New York University, New York, NY, (2)Communication Sciences and Disorders, Emerson College, Boston, MA

**Background:** The COVID-19 pandemic prompted many researchers to shift from lab-based to online research. Eye-tracking is a common method used to study language development in children with Autistic Spectrum Disorder (ASD). One approach to using eye-tracking methods in online studies is recording children's faces as they view the screen and manually coding their gaze. Substantial numbers of children with ASD are often excluded in lab studies for contributing insufficient gaze data (e.g., Venker, 2019; Venker et al., 2020) compared to non-spectrum children (e.g., Venker, 2019; Valteau et al., 2018). Distractions in the home environment may pose even more challenges for viability of online data.

**Objectives:** We sought to determine the feasibility of online at-home eye gaze data collection for preschoolers with and without ASD by quantifying data loss and by evaluating the relation between home events and viability of gaze data.

**Methods:** Thirty children with ASD (18 males, 12 females) aged 36 to 71 months ( $M = 47.27$ ,  $SD = 8.91$ ) and 30 non-spectrum children (18 males, 12 females) aged 24 to 35 months ( $M = 27.57$ ,  $SD = 3.04$ ) participated. Samples were matched at the group level by sex and language. Participants and their caregivers logged into a zoom meeting on their home computer or tablet. Participants completed two trials of a word-learning task in which they heard novel words paired with novel objects. Children then viewed three novel objects on the screen (Figure 1) and were tested on their learning. To evaluate data viability, research assistants manually coded frame by frame for whether children looked at the screen; trials for which children were looking at the screen for at least 50% of the trial were counted as viable. Research assistants also coded for events (e.g., caregiver interruptions) and participant behaviors (e.g., body and head movements).

**Results:** All participants contributed viable gaze data on at least one test trial. Three children with ASD (10%) and one non-spectrum child (3%) only contributed viable data on one of two trials; the groups did not differ ( $p = .62$ , two tailed Fisher's exact test). Participant behaviors were related to trial viability. In particular, the frequency of children's body and head movements during each trial was significantly related to the percentage of track loss ( $r(120) = .37$ ,  $p = .02$ ).

**Conclusions:** Compared to previous studies in which 22% (Venker, 2019) or 27% (Venker et al., 2020) of children with ASD did not provide viable gaze data, the rate of 10% in the present sample is promising. The exclusion rate of 3% for the present non-spectrum sample is also lower than some past research (e.g. 11% in Valteau et al., 2018). Results suggest online studies in a home environment can yield higher rates of viable gaze data than lab studies, despite the presence of distractions. These findings can alleviate concerns of lower data quality for online studies and encourage further research on data viability in the home setting.

### **523.022 (Virtual Poster)** Towards Feeling, Understanding, and Caring: The Development of Empathy in Young Autistic Children

**B. LI<sup>1</sup>, L. Stockmann<sup>1</sup>, E. M. Blijd-Hoogewys<sup>2</sup>, I. Vergari<sup>1</sup> and C. Rieffe<sup>1,3,4</sup>,** (1)Institute of Psychology, Leiden University, Leiden, Netherlands, (2)INTER-PSY, Groningen, Netherlands, (3)Faculty of Electrical Engineering, Mathematics and Computer Science, University of Twente, Enschede, Netherlands, (4)Institute of Education, University College London, London, United Kingdom

**Background:**

Empathy is crucial for maintaining social relationships and for motivating moral and compassionate behaviors (Eisenberg et al., 2010). Autistic people are often portrayed as lacking empathy. Recent research, examining empathy as a multicomponent construct, advocates that, while autistic individuals may have difficulties in understanding others' emotions and thereby might be hindered from responding prosocially, they are not indifferent to others' feelings (Fletcher-Watson & Bird, 2020). This multicomponent approach not only helps removing the negative portrait of autism (Santesteban et al., 2020), but it can also facilitate identifying the unique challenges that autistic people face in empathy development.

#### Objectives:

Aiming to advance our understanding of empathy development in young autistic children, this four-wave longitudinal study examined the development of affective empathy (emotion contagion), cognitive empathy, and prosocial empathy (intent to comfort), in 1-to-6-year-old children with and without autism.

#### Methods:

Children with ( $N = 61$ ;  $M_{age} = 55.49$  months) and without autism ( $N = 145$ ;  $M_{age} = 52.16$  months) and their parents participated in the research, once a year, for four consecutive years. Children were visited either at school or at an intervention center for autism (for the autistic group only), where the experimenter acted out three emotional episodes (happy, angry, and in pain) and evaluated children's empathic reactions. Parents filled out two questionnaires to evaluate their children's empathy abilities.

#### Results:

Consistent with literature, both the experimenter and parents reported lower levels of cognitive empathy and prosocial empathy in autistic children than in non-autistic children. As for affective empathy, whereas the experimenter reported a lower level in autistic children, parents reported no group difference. Consistent with literature, affective empathy remained stable and prosocial actions increased with age in both groups. Yet this increase was stronger in autistic children. While cognitive empathy also increased with age in autistic children, it remained stable in non-autistic children. Possibly, compared to autistic children, non-autistic children reached the more advanced levels earlier, and thus there was less room for increases.

#### Conclusions:

While autistic children encountered difficulties in both cognitive and prosocial empathy, our study showed that they did not lack the capacity to feel for others, and they had potential for developing empathic abilities. Though their struggles in cognitive and prosocial empathy should be interpreted carefully. First, as the "double empathy problem" (Milton, 2012) states, difficulties in understanding others' minds occur not only in autistic individuals, but also in non-autistic individuals, who often struggle to understand the mental states of autistic people. This might explain our discrepancy between experimenter- and parent-rated affective empathy. Second, the prosocial empathy evaluated by our questionnaire described typical empathic reactions of non-autistic people, such as comforting and helping. However, autistic children might display prosocial actions differently, e.g., focusing on problem-solving (Rieffe et al., 2021). Future research should investigate the unique styles of empathy expression and reaction in autistic people, without setting the non-autistic styles as the norm. Besides, it can be informative to examine empathy as a bidirectional interaction, instead of focusing only on how autistic people react to non-autistic people.

## Epidemiology

### ORAL SESSION - 7B — EPIDEMIOLOGY

#### 319 - Epidemiology

**319.001** (Oral) Maternal Inflammatory Conditions during Pregnancy and Risk of Autism Spectrum and Other Neurodevelopmental Disorders  
**L. A. Croen<sup>1</sup>**, Y. Qian<sup>2</sup>, J. L. Ames<sup>2</sup>, S. Alexeeff<sup>3</sup>, P. Ashwood<sup>3</sup>, E. P. Gunderson<sup>2</sup>, Y. W. Wu<sup>4</sup>, L. Weiss<sup>5</sup>, R. Yolken<sup>6</sup> and J. Van de Water<sup>7</sup>, (1)Division of Research, Kaiser Permanente Division of Research, Oakland, CA, (2)Division of Research, Kaiser Permanente Northern California, Oakland, CA, (3)MIND Institute, University of California, Davis, Sacramento, CA, (4)UCSF, San Francisco, CA, (5)Department of Psychiatry and Institute for Human Genetics, University of California San Francisco, San Francisco, CA, (6)Johns Hopkins University, Baltimore, MD, (7)MIND Institute, University of California, Davis, Davis, CA

**Background:** Maternal inflammation can result from immune dysregulation as well as metabolic perturbations during pregnancy, including maternal type-2 diabetes, gestational diabetes, and pre-pregnancy obesity. Common immune-mediated and cardiometabolic conditions have been shown to be associated with risk of autism and other neurodevelopmental disorders. Much of the supporting data for the association between these maternal conditions and neurodevelopmental outcomes have come from animal models or retrospective epidemiological studies. There remain gaps in our understanding of the role of maternal gestational immune dysregulation and cardiometabolic disorders as potential risk factors for altered neurodevelopment in humans.

**Objectives:** To investigate common maternal immune-mediated and cardiometabolic conditions associated with inflammation during pregnancy and risk of autism spectrum disorders and other neurodevelopmental outcomes in a large and diverse population receiving medical care in the same integrated healthcare delivery system.

**Methods:** This case-control study was nested in the population of children born at Kaiser Permanente Northern California from January 2011 – January 2016 who survived to age two and for whom mothers received healthcare and prenatal care in the 2 years prior to delivery. Three groups of children were included: autism spectrum disorder (ASD, N=311), children with other neurodevelopmental disorders (intellectual disability, learning disability, language delay or developmental delay, cerebral palsy) (DD, N=1291), and a random sample of children from the general population with no ASD or DD diagnoses (GP, N=967). Maternal immune-mediated (infection, asthma, allergy, autoimmune disease) and cardiometabolic conditions (gestational diabetes, diabetes, hypertension (chronic, gestational), preeclampsia, and obesity) diagnosed and recorded during pregnancy were retrieved from the KPNC maternal electronic health records. Covariates included several sociodemographic factors shown in previous studies to be significantly associated with risk of neurodevelopmental disorders and the maternal conditions under study. These included maternal age at delivery, maternal race, maternal education, and child sex. We fit crude and adjusted logistic regression models to estimate the association between maternal conditions during pregnancy and childhood neurodevelopmental outcomes.

**Results:** We found that women diagnosed with asthma were significantly more likely to deliver infants who were later diagnosed with ASD (OR=1.62, 95% CI: [1.15 - 2.29]) or DD (OR=1.30, 95% CI: [1.02 - 1.64]). The risk profile associated with maternal asthma differed significantly between male and female offspring, with increased risks observed only among females for ASD (OR=2.93, 95% CI: [1.63-5.25]; interaction p-value=0.0173) and DD (OR=1.68, 95% CI: [1.18-2.38]; interaction p-value=0.0468). Furthermore, the risk of ASD, but not DD, was significantly associated with obesity (OR=1.51, 95% CI: [1.07 - 2.13]) and increased substantially among women with extreme obesity (OR=2.27, 95% CI: [1.21 - 4.24]), especially in combination with asthma (OR=16.9, 95% CI: [5.13 - 55.71]).

**Conclusions:** Common inflammatory conditions during pregnancy pose a risk for neurodevelopmental disorders in children. Women who experience both asthma and obesity may be especially vulnerable to adverse outcomes and may benefit from early screening and intervention to reduce risks of autism spectrum disorders in their offspring.

**319.002 (Oral) Significant Regional Differences in Autism and Intellectual Disability Risk Associated with Cesarean Section Reflect Background Variation in Cesarean Section Rates**

**D. A. Bilder<sup>1</sup>, D. Chen<sup>2</sup>, M. J. Maenner<sup>3</sup>, M. M. Hughes<sup>4</sup>, S. Dalton<sup>5</sup>, J. A. Hall-Lande<sup>5</sup> and A. V. Bakian<sup>1</sup>,** (1)Psychiatry, University of Utah, Salt Lake City, UT, (2)Study Design and Biostatistics Center, University of Utah, Salt Lake City, UT, (3)Centers for Disease Control and Prevention, Atlanta, GA, (4)Obstetrics and Gynecology, University of Utah, Salt Lake City, UT, (5)UCEDD, University of MN, Minneapolis, MN

**Background:** Prior epidemiological studies investigating the association between repeat cesarean section (C/S) and autism spectrum disorder (ASD) and intellectual disability (ID) have reported mixed results and are limited by lack of diversity inclusion (i.e., racial, ethnic, and geographic) and disability classification method. While primary C/S is frequently precipitated by non-reassuring fetal surveillance, repeat C/S is performed for most subsequent births to avert uncommon--though severe--complications of vaginal birth after C/S (VBAC, e.g., uterine rupture and birth asphyxia).

**Objectives:** Through a case-cohort design, this study evaluates the relationships between ASD and/or ID risk (ASD/ID) and delivery method for children ascertained with ASD/ID across sites participating in the Centers for Disease Control and Prevention's Autism and Developmental Disabilities Monitoring Network (ADDM) through review of evaluations contained in health and education records.

**Methods:** In even-numbered years 2000-2016, 8-year-old children were ascertained with ASD without ID, ASD+ID, and ID without ASD (N=8738, N=3524, N=5527, respectively) across ADDM sites in the mid-Atlantic, Southeastern, and Western US, and linked to birth certificate records. The comparison cohort (N=1,582,307) was composed of all births ascertained through the National Center for Health Statistics corresponding to birth year and ascertainment areas. Delivery method (vaginal delivery, VBAC, primary C/S, repeat C/S) and covariates (i.e., sex, birth year, gestational age, birthweight, parity, maternal age, maternal education, maternal race/ethnicity, maternal fever, premature rupture of membranes, abruptio placentae, placenta previa, breech, fetal distress, and 5-minute Apgar score) were obtained from birth records. Multivariable binomial logistic regression adjusted for covariates were performed to measure ASD/ID risk associated with delivery method in the entire sample and stratified by geographic region.

**Results:** In regard to ASD/ID risk, primary C/S was associated with all case groups, vaginal deliveries were protective against case status, and VBAC had no significant association with any case status (Table 1). Overall, repeat C/S was associated with increased risk for ASD without ID (OR: 1.19; 95%CI: 1.11-1.28), ASD+ID (OR: 1.21, 95%CI: 1.08-1.36), and ID without ASD (OR: 1.27, 95%CI: 1.16-1.39). C/S rates were highest in the mid-Atlantic (28.4%) and lowest in the West (19.7%). Regional variation existed in the relationship between repeat C/S and ASD/ID risk (Figure 1). Regarding repeat C/S and ASD/ID risk, the West demonstrated no significant association (ASD without ID [OR:1.08; 95%CI: 0.93-1.27], ASD+ID [OR: 1.00, 95%CI: 0.77-1.31], and ID without ASD [OR: 1.01, 95%CI: 0.83-1.23]), the Southeast maintained significant relationships in all case groups, and the mid-Atlantic had mixed results.

**Conclusions:** Significant regional differences in ASD/ID risk associated with C/S reflected background variations in C/S rates. Repeat C/S in Western states occurred least frequently and was not significantly associated with ASD or ID. Less clearly delineated was the relationship between C/S rates and associated ASD/ID risk in the mid-Atlantic and Southeast. Understanding how regional differences in C/S indications may influence their association with ASD/ID could provide insight into underlying mechanisms that link these phenomena. In particular, further investigation is merited into maternal indications for primary C/S that recur in subsequent pregnancies and health care practices that vary regionally.

**319.003 (Oral) Maternal Autoantibodies and Autism-Risk Prediction in the EMA Study**

**A. Ramirez-Celis<sup>1</sup>, J. Van de Water<sup>2</sup>, L. A. Croen<sup>3</sup>, C. K. Yoshida<sup>4</sup> and J. Schauer<sup>2</sup>,** (1)UC Davis, Davis, CA, (2)MIND Institute, University of California, Davis, CA, (3)Division of Research, Kaiser Permanente Division of Research, Oakland, CA, (4)Division of Research, Kaiser Permanente, Oakland, CA

**Background:** Autism spectrum disorder (ASD) affects ~2% of the US population and the incidence is on the rise; however, we still lack biomarkers that predict autism risk to facilitate early intervention services. We previously reported maternal IgG cross-reactivity to eight brain proteins (CRMP1, CRMP2, GDA, LDHA, LDHB, NSE, STIP1, and YBOX) and found that reactivity to a combination of two or more specific antigens (MAR ASD+ patterns) was highly accurate to predict autism risk in up to 20% of the ASD study population.

**Objectives:** This project aimed to expand upon our previous studies and test the accuracy of our MAR ASD+ patterns: CRMP1+GDA, CRMP1+CRMP2, NSE+STIP1, CRMP2+STIP1, LDHA+YBOX, LDHB+YBOX, GDA+YBOX, STIP1+YBOX, and CRMP1+STIP1 to predict ASD-risk in a new cohort, using samples from the prospective EMA study.

**Methods:** This prospective case-control study used plasma samples obtained from mothers whose children were enrolled in the EMA (Early Markers of Autism) study. This project included three study groups: ASD (N= 540), developmental delay (DD, N=184), and general population controls (GP, N=420). Maternal IgG reactivity against the eight protein antigens was determined by Enzyme-Linked Immunosorbent Assay (ELISA) using commercially available proteins. To evaluate the association for each pattern with child outcomes, we used Fisher Exact Test ( $p < 0.05$ ) and calculated the odds ratios (ORs) with 95% confidence intervals.

**Results:** We tested the MAR ASD+ patterns from our previous study and found that 10% of the ASD samples had significant IgG reactivity to any pattern combo vs 1% of controls ( $p < 0.001$ , OR 7.81, 95% CI from 3.32 to 22.43) which means that having maternal antibody reactivity to any pattern increases almost 8 times the ASD-risk relative to the controls, and almost 3 times compared to the developmentally delayed group ( $p=0.01$ , OR 2.77, 95% CI from 1.19 to 7.47). Of interest, 4% of the DD group reacted to some of the patterns but did not reach statistical significance ( $p=0.07$ , OR 2.72, 95% CI from 0.77 to 9.96), suggesting that reactivity to any MAR ASD+ pattern is not significant in the GP or DD groups, but is highly specific to the ASD group.

**Conclusions:** This is the first report that uses the MAR ASD patterns of reactivity to predict autism risk in a prospective study demonstrating the presence of maternal autoantibodies during gestation. The MAR ASD patterns covered up to 10% of the ASD population in the EMA study and were significantly correlated to ASD outcomes.

### **319.004 (Oral) Maternal Diagnoses in Pregnancy and Risk of Autism Spectrum Disorder**

**V. Khachadourian<sup>1</sup>, E. Arildskov<sup>2</sup>, A. Schlessinger<sup>3</sup>, P. F. O'Reilly<sup>4</sup>, J. Grove<sup>5</sup>, A. Kodesh<sup>6</sup>, S. Z. Levine<sup>7</sup>, J. D. Buxbaum<sup>8</sup>, D. Schendel<sup>9</sup>, L. A. Croen<sup>8</sup>, S. Hansen<sup>2</sup>, S. Sandin<sup>9</sup>, A. Reichenberg<sup>9</sup> and M. Janecka<sup>10</sup>,** (1)Icahn School of Medicine at Mount Siani, New York, NY, (2)Aarhus University, Aarhus, Denmark, (3)Department of Pharmacological Sciences, Icahn School of Medicine at Mount Sinai, New York, NY, (4)Icahn School of Medicine at Mount Sinai, New York, NY, (5)Department of Community Mental Health, University of Haifa, Haifa, Israel, (6)University of Haifa, Haifa, Israel, (7)Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (8)Division of Research, Kaiser Permanente Division of Research, Oakland, CA, (9)Seaver Autism Center, Department of Psychiatry, Icahn School of Medicine at Mount Sinai, New York, NY, (10)Seaver Autism Center for Research and Treatment Icahn school of Medicine at Mount Sinai, New York, NY

**Background:** The potential etiological role of maternal health during pregnancy in autism spectrum disorder (ASD) has received growing attention. Nevertheless, studies have often focused on a narrow range of diagnoses and failed to account for the potential effects of co-occurring conditions.

**Objectives:** This study sought to systematically investigate the association between maternal diagnoses in pregnancy and the risk of offspring ASD, accounting for correlations between diagnoses. Furthermore, we leveraged timing of diagnoses and a sibling study design to examine impacts of familial confounding on estimated associations between maternal non-chronic diagnoses and ASD.

**Methods:** This exploratory study used a population-based sample from Denmark to assess associations between maternal diagnoses before and during pregnancy and risk of ASD. The study included children born in 1998-2007 and their mothers. Maternal diagnoses were based on ICD-10 codes and classified as chronic and non-chronic diagnoses using the Chronic Condition Indicator developed by the Agency for Healthcare Research and Quality. Cox proportional hazard regression models were fit to quantify the risk of ASD associated with maternal diagnoses around pregnancy. All models were adjusted for the child's year of birth, maternal age at childbirth, and the total number of maternal diagnoses around pregnancy. To assess potential familial confounding, we first compared the associations between ASD and maternal non-chronic diagnoses recorded during the period from 24 to 48 months before the child's birth with those recorded during the 24-months period before the child's birth. Under the assumption that the non-chronic diagnoses recorded 24 to 48 months before the child's birth do not have an impact on the risk of offspring ASD, non-null effects could be suggestive of a potential bias in the estimated associations. Second, we conducted sibling analysis to indirectly adjust for familial confounding.

**Results:** The analytic sample included 653,580 children (7,866 ASD; 645,714 controls) born to 425,399 mothers. We tested 90 chronic and 241 non-chronic maternal diagnoses (ICD-10 codes) for an association with ASD. After controlling for multiple testing, 10 chronic and 22 non-chronic diagnoses were statistically significantly associated with ASD (Table 1). In a multivariable model concurrently including these 32 diagnoses, five chronic and 15 non-chronic diagnoses were significantly associated with ASD (Table 1). Pregnancy complications and injuries accounted for a major portion of the non-chronic maternal diagnoses associated with risk of ASD (e.g., diabetes mellitus in pregnancy: HR=1.28, 95%CI: 1.08-1.51; skull and facial bones fractures: HR=1.61, 95%CI: 1.09-2.37), and maternal psychiatric diagnoses were most strongly associated with ASD among the chronic ones (e.g., major depressive disorder: HR=1.89, 95%CI: 1.39-2.56). Results from the timing of diagnosis and sibling analyses provided limited evidence for the role of familial confounding in the observed associations.

**Conclusions:** Testing the wide range of maternal diagnoses and accounting for their co-occurrence, we observed both novel and established maternal conditions around pregnancy associated with ASD. The study findings highlight the importance of maternal health around pregnancy in the risk of offspring ASD. Our findings can inform studies exploring mechanisms of ASD etiology and help with identifying high-risk pregnancies.

**410.060** (Poster) A Mixtures Approach to Assessing the Association of Prenatal Diet and Autism-Related Outcomes in the EARLI Study  
**J. Rando<sup>1</sup>, R. Vecchione<sup>2</sup>, G. B. Hamra<sup>3</sup>, H. E. Volk<sup>4</sup>, M. D. Fallin<sup>4</sup>, L. A. Croen<sup>5</sup>, I. Hertz-Picciotto<sup>6</sup>, C. J. Newschaffer<sup>7</sup>, R. J. Schmidt<sup>8</sup> and K. Lyall<sup>9</sup>,**  
 (1)AJ Drexel Autism Institute, Philadelphia, PA, (2)Drexel University, Philadelphia, PA, (3)Epidemiology, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (4)Wendy Klag Center for Autism and Developmental Disabilities, Johns Hopkins Bloomberg School of Public Health, Baltimore, MD, (5)Division of Research, Kaiser Permanente Division of Research, Oakland, CA, (6)University of California at Davis, Davis, CA, (7)College of Health and Human Development, Pennsylvania State University, University Park, PA, (8)Public Health Sciences, University of California Davis, Davis, CA, (9)A.J. Drexel Autism Institute, Drexel University, Philadelphia, PA

**Background:**

Maternal diet plays a key role in fetal brain development, and a growing body of evidence indicates an association between specific nutrients, such as folic acid and vitamin D, and Autism Spectrum Disorder (ASD) diagnoses. However, studies have not investigated the combined effects of dietary components captured as food groups on ASD and ASD-related traits. Operationalizing maternal diet as component food groups, rather than component nutrients, not only captures combined intake of nutrients, but also more readily aligns with the way individuals conceptualize diet to facilitate clearer dietary recommendations.

**Objectives:**

We sought to use Bayesian mixture modeling to estimate the combined and interactive effects of prenatal intake of multiple food groups on ASD-related traits.

**Methods:**

Study participants were drawn from the Early Autism Risk Longitudinal Investigation (EARLI), a high autism probability cohort that followed mothers who had a child with ASD through a subsequent pregnancy until that child was three years old. Autism-related traits were measured in the child at 36 months using the Social Responsiveness Scale (SRS), which measures social traits related to autism. Maternal diet data was captured mid-pregnancy using a validated Food Frequency Questionnaire. Diet data was converted into servings per day of seventeen *a priori* food groups, selected based on their established relationship with health outcomes and potential role in neurodevelopment, including fruit, alcohol, red meat, processed meat, dairy, whole grains, nuts, legumes, and subcategories of vegetables and fish. The combined effect of standardized servings per day of these food groups on raw SRS scores was assessed using Bayesian Kernel Machine Regression (BKMR). Posterior Inclusion Probabilities were assessed to determine the ten food groups that had the greatest association with SRS scores, and models were rerun after variable selection.

**Results:**

BKMR results did not indicate a significant mixture effect of the food groups on child SRS scores. However, two food groups demonstrated associations with SRS scores when servings per day of other food groups were fixed at their 50<sup>th</sup> percentile (Figure 1). Increased red meat intake was associated with an increase in child SRS scores (indicative of a stronger autism phenotype) (association comparing the 75<sup>th</sup> to 25<sup>th</sup> percentile = 4.45, SD = 2.6), while increased leafy green vegetable intake was associated with a decrease in child SRS scores (association comparing the 75<sup>th</sup> to 25<sup>th</sup> percentile = -5.65, SD = 3.5), though confidence bands were wide (Figure 2). Adjustment for several factors, including maternal body mass index and demographics, yielded similar results.

**Conclusions:**
